GENERAL PREFACE TO THE *TREATISE*

This volume is part of a comprehensive *Treatise on Basic Philosophy*. The treatise encompasses what the author takes to be the nucleus of contemporary philosophy, namely semantics (theories of meaning and truth), epistemology (theories of knowledge), metaphysics (general theories of the world), and ethics (theories of value and of right action).

Social philosophy, political philosophy, legal philosophy, the philosophy of education, aesthetics, the philosophy of religion and other branches of philosophy have been excluded from the above *quadrivium* either because they have been absorbed by the sciences of man or because they may be regarded as applications of both fundamental philosophy and logic. Nor has logic been included in the *Treatise* although it is as much a part of philosophy as it is of mathematics. The reason for this exclusion is that logic has become a subject so technical that only mathematicians can hope to make original contributions to it. We have just borrowed whatever logic we use.

The philosophy expounded in the *Treatise* is systematic and, to some extent, also exact and scientific. That is, the philosophical theories formulated in these volumes are (*a*) formulated in certain exact (mathematical) languages and (*b*) hoped to be consistent with contemporary science.

Now a word of apology for attempting to build a system of basic philosophy. As we are supposed to live in the age of analysis, it may well be wondered whether there is any room left, except in the cemeteries of ideas, for philosophical syntheses. The author's opinion is that analysis, though necessary, is insufficient – except of course for destruction. The ultimate goal of theoretical research, be it in philosophy, science, or mathematics, is the construction of systems, i.e. theories. Moreover these theories should be articulated into systems rather than being disjoint, let alone mutually at odds.

Once we have got a system we may proceed to taking it apart. First the tree, then the sawdust. And having attained the sawdust stage we should move on to the next, namely the building of further systems. And this for three reasons: because the world itself is systemic, because no idea can become fully clear unless it is embedded in some system or other, and because sawdust philosophy is rather boring.

The author dedicates this work to his philosophy teacher

Kanenas T. Pota

in gratitude for his advice: "Do your own thing. Your reward will be doing it, your punishment having done it".

PREFACE TO *SEMANTICS I*

This is a study of the concepts of reference, representation, sense, truth, and their kin. These semantic concepts are prominent in the following sample statements: ⌜The field tensor *refers* to the field⌝, ⌜A field theory *represents* the field it refers to⌝, ⌜The *sense* of the field tensor is sketched by the field equations⌝, and ⌜Experiment indicates that the field theory is *approximately true*⌝.

Ours is, then, a work in philosophical semantics and moreover one centered on the semantics of factual (natural or social) science rather than on the semantics of either pure mathematics or of the natural languages. The semantics of science is, in a nutshell, the study of the symbol-construct-fact triangle whenever the construct of interest belongs to science. Thus conceived our discipline is closer to epistemology than to mathematics, linguistics, or the philosophy of language.

The central aim of this work is to constitute a semantics of science – not any theory but one capable of bringing some clarity to certain burning issues in contemporary science, that can be settled neither by computation nor by measurement. To illustrate: What are the genuine referents of quantum mechanics or of the theory of evolution?, and Which is the best way to endow a mathematical formalism with a precise factual sense and a definite factual reference – quite apart from questions of truth?

A consequence of the restriction of our field of inquiry is that entire topics, such as the theory of quotation marks, the semantics of proper names, the paradoxes of self-reference, the norms of linguistic felicity, and even modal logic have been discarded as irrelevant to our concern. Likewise most model theoretic concepts, notably those of satisfaction, formal truth, and consequence, have been treated cursorily for not being directly relevant to factual science and for being in good hands anyway. We have focused our attention upon the semantic notions that are usually neglected or ill treated, mainly those of factual meaning and factual truth, and have tried to keep close to live science.

The treatment of the various subjects is systematic or nearly so: every basic concept has been the object of a theory, and the various theories have been articulated into a single framework. Some use has been made of certain elementary mathematical ideas, such as those of set, function, lattice, Boolean algebra, ideal, filter, topological space, and metric space. However, these tools are handled in a rather informal way and have been made to serve philosophical research instead of replacing it. (Beware of hollow exactness, for it is the same as exact emptiness.) Moreover the technical slices of the book have been sandwiched between examples and spiced with comments. This layout should make for leisurely reading.

The reader will undoubtedly apply his readermanship to skim and skip as he sees fit. However, unless he wishes to skid he will be well advised to keep in mind the general plan of the book as exhibited by the Table of Contents. In particular he should not become impatient if truth and extension show up late and if analyticity and definite description are found in the periphery. Reasons will be given for such departures from tradition.

This work has been conceived both for independent study and as a textbook for courses and seminars in semantics. It should also be helpful as collateral reading in courses on the foundations, methodology and philosophy of science.

This study is an outcome of seminars taught at the Universidad de Buenos Aires (1958), University of Pennsylvania (1960–61), Universidad Nacional de México (1968), McGill University (1968–69 and 1970–71), and ETH Zürich (1973). The program of the investigation and a preview of some of its results were given at the first conference of the Society for Exact Philosophy (see Bunge, 1972a) and at the XVth World Congress of Philosophy (see Bunge, 1973d).

ACKNOWLEDGEMENTS

It is a pleasure to thank all those who made useful comments and criticisms, whether constructive or destructive, in the classroom or in writing. I thank, in particular, my former students Professors Roger Angel and Charles Castonguay, as well as Messrs Glenn Kessler and Sonmez Soran, and my former research associates Professors Peter Kirschenmann, Hiroshi Kurosaki, Carlos Alberto Lungarzo, Franz Oppacher, and Raimo Tuomela, and my former research assistants Drs David Probst and David Salt. I have also benefited from remarks by Professors Harry Beatty, John Corcoran, Walter Felscher, Joachim Lambek, Scott A. Kleiner, Stelios Negrepontis, Juan A. Nuño, Roberto Torretti, Ilmar Tammelo, and Paul Weingartner. But, since my critics saw only fragments of early drafts, they should not be accused of complicity.

I am also happy to record my deep gratitude to the Canada Council for the Killam grant it awarded this research project and to the John Simon Guggenheim Memorial Foundation for a fellowship during the tenure of which this work was given its final shape. Finally I am grateful to the Aarhus Universitet and the ETH Zürich for their generous hospitality during my sabbatical year 1972–73.

T	Theory (hypothetico-deductive system)
$\mathcal{V}$	Truth value function

INTRODUCTION

In this Introduction we shall sketch a profile of our field of inquiry. This is necessary because semantics is too often mistaken for lexicography and therefore dismissed as trivial, while at other times it is disparaged for being concerned with reputedly shady characters such as meaning and allegedly defunct ones like truth. Moreover our special concern, the semantics of science, is a newcomer – at least as a systematic body – and therefore in need of an introduction.

1. Goal

Semantics is the field of inquiry centrally concerned with meaning and truth. It can be empirical or nonempirical. When brought to bear on concrete objects, such as a community of speakers, semantics seeks to answer problems concerning certain linguistic facts – such as disclosing the interpretation code inherent in the language or explaning the speakers' ability or inability to utter and understand new sentences of the language. This kind of semantics will then be both theoretical and experimental: it will be a branch of what used to be called 'behavioral science'. Taking a cue from Chomsky and Miller (1963) we may say that, rather than being a closely knit and autonomous discipline, this kind of semantics is the union of two fields: a chapter of linguistics and one of psychology:

Empirical Semantics
- *Linguistic semantics:* the semantics of natural languages
- *Psycholinguistic semantics:* the psychology of speech acts and contents, or the study of language users

If, on the other hand, semantics concerns itself with conceptual objects, such as mathematical structures or scientific hypotheses, then it remains nonempirical in the sense that it makes no direct use of observation and measurement to test its conjectures and models – nor does it need to, because this kind of semantics does not describe and predict facts. In other words, nonempirical semantics is concerned not only with linguistic items but also, and primarily, with the constructs which some such items stand for as well as with their eventual relation to the real world. (More on constructs in Ch. 1, Sec. 1.2.) This branch of semantics is then closer to the theory of knowledge than the theory of language. (We shall take a look at this point in Ch. 10, Sec. 3.) Moreover, under penalty of being useless, nonempirical semantics should account for our experience with conceptual objects – thus being vicariously empirical. In particular, it should be concerned with our experience in interpreting conceptual symbols, elucidating the sense of constructs, uncovering their referents, and estimating truth values. Furthermore, the way it performs this task should constitute the supreme test of this branch of semantics: there is no justification for a semantic theory that fits neither mathematics nor science nor ordinary knowledge. Conceived in this way, nonempirical semantics may be split up as follows:

- *Nonempirical Semantics*
  - *Basic* or general
  - *Applied* or special
    - S. of mathematics (model theory)
    - S. of science
    - S. of ordinary knowledge

This book is concerned with but a fragment of nonempirical semantics and not at all with empirical semantics. The philosopher as such is not competent to tackle problems in empirical semantics: the best he can do is to study it with the hope of ferreting out the methodology and philosophy of scientific linguistics and psycholinguistics. Of course he may occasionally ask penetrating questions and, with less frequency, propose valuable insights in this field or any other. But, *qua* philosopher, he is not competent to expand such insights into theories proper (i.e. theories in mathematical linguistics), nor is he equipped to design experiments to put such theories to the test. The philosopher, as such, is as much of an amateur in linguistics and psychology as in physics and biology. But he can be a professional philosophical semanticist.

We shall deal exclusively with nonempirical semantics, i.e. with the semantic problems that cannot be investigated by empirical means because they are not concerned with any factual items but, at most, with certain features of our knowledge of such objects. In particular we shall not study the bewildering variety of concepts designated by the ambiguous term 'meaning' (see Schaff, 1962; Cohen, 1966; Hill, 1971). We shall instead restrict ourselves to the semantic concept of meaning, i.e. the sense and reference of predicates, propositions, and theories. In particular we shall not investigate the process by which an organism assigns a significance to a sign: we regard the pragmatic concept of meaning as a business of psycholinguistics (see e.g. Osgood *et al.*, 1957; Luria, 1969), anthropologists, and historians. Likewise we are interested in the semantic concept(s) of truth rather than in the psychological concepts of personal truth, strength of belief, credibility, and so on. Our choice does not imply a rejection of either empirical semantics or pragmatics: it only involves a deliberate restriction of the field of our inquiry – *ergo* a choice of method.

A further restriction on the scope of our investigation will be this. We shall pay special attention to the *semantics of factual science*, one of the three branches of applied or special semantics we recognized a while ago. That is, our inquiry shall focus on the notions of factual reference, factual sense, and factual truth that are relevant to scientific knowledge. The ultimate goal of our research is to accomplish for these notions what model theory has done for the concepts of satisfaction, formal truth, consequence, and extension – without however hoping to attain the neatness characterizing model theory. (For the semantics of logic see van Fraassen (1971), for the semantics of mathematics consult Robinson (1963) or Bell and Slomson (1969).)

In the pursuit of our goal we shall attempt to be both systematic and relevant to real science. To put it in nasty terms: We shall do our best to avoid the two chief blemishes of most of the available views and theories in basic semantics. These shortcomings are the lack of comprehensive systems in which *all* of the semantic concepts hang together and thus illumine one another, and the *irrelevance* to the semantic problems that pop up in live science. We shall try to give a fairly exact treatment but, if we have to choose between a fruitful insight on the one hand, and a rigorous but useless formalism on the other hand, we shall prefer the former. For, as cuckoos and physicists well know, given a fertilized egg there exists a bird willing to hatch it.

Because our semantic system is frankly unorthodox, its measure of success should not be gauged by its agreement with any of the extant views. It should be estimated, rather, by its ability to (*a*) clarify and codify hitherto obscure or stray notions, (*b*) perform suitable semantic analyses of fragments of current factual science, and (*c*) help in the systematic (axiomatic) reconstruction of existing theories in factual science.

2. METHOD

Because our primary concern will be with the semantics of scientific theories, our investigation will rank largely as metatheoretical. Now, every metatheory is couched in a metalanguage allowing us to express certain statements about items occurring in the (object) language used to express the propositions of the object theory. Throughout our quest we shall use as strong a metalanguage as required, for our aim is rather to get a few things done than to economize. We shall employ whatever tool may seem promising to attain precision, unity and clarity: in particular we shall use elementary set theory, a few algebraic theories, and a sprinkling of topology. (For a superb précis of the mathematics needed by the exact philosopher see Hartnett (1963, 1970).) In this sense our semantics will be in line with the semantics of Tarski and Carnap. It differs from theirs (*a*) in its *object*, which is factual science instead of mathematics, (*b*) in its *philosophical underpinnings*, which are realist rather than either nominalist, empiricist, of Fregean, and (*c*) in its *degree of formalization*, which is lower. While the first two differences are clear, the third deserves a short explanation.

Our exposé, though quite formal and systematic, will not be formalized in the metamathematical sense of the word. In particular we shall not specify our metalanguage in advance. We shall not do it partly because any such specification places a restriction, often unsuspected, upon the concepts and propositions that can be expressed in that language. And we do not care for such limitations, particularly when it is not clear which they are. For example, we want to be able to speak of infinite conjunctions and disjunctions, such as law statements, and even of nondenumerable sets of propositions, such as the formulas representing the successive positions of a particle in the course of time. To write off such constructs just because they overflow finitary logic would be unwise, and to try and find out in each case which logical theory justifies them would be going beyond the scope of this work. We take it for granted that, given a useful mathematical or scientific concept, there exists a branch of logic on which it can roost.

As stated above, we assume that logic and mathematics are sufficient to uncover the form and structure of every construct. We assume also that they are necessary to build theories aiming at elucidating and systematizing the semantic concepts of factual reference, factual sense, and factual truth. But, of course, we do not claim that logic, mathematics and the semantical theories contrived with their help will suffice to reveal the syntax and the semantics of every particular scientific construct – any more than geometry suffices to triangulate the universe. However, a combination of logic, mathematics, semantics and substantive knowledge can do the trick of uncovering the formalism and the semantics of a scientific theory. At any rate nothing else has done it, so it is worth trying.

The preceding assumptions concerning the role of logic and mathematics in constructing philosophical theories, such as semantics, characterize what may be called *exact philosophy* (see Bunge, ed., 1973a). They are likely to be challenged by philosophers of a traditional cast of mind. But they may also be doubted by progressives. A case in point is the notion of sense (or intension or connotation or content) – a favorite with conservatives as well as a *bête noire* of progressives for being allegedly impregnable to mathematization. We shall meet the challenge by proposing a mathematical theory of sense – or rather three such theories, one for each component of the sense of a construct (Chs. 4 and 5). Should these particular theories fail, others could take their place: approaches and programs die only if nobody works on them. After all, simpler ideas, like that of many, or class, were regarded as typically nonmathematical, hence unclear, until about one century ago. In any event, a bill of difficulties and failures does not constitute a philosophy.

Ordinary language philosophers and hermeneutic philosophers will complain that our method is misplaced, because logic and mathematics are incapable of discerning the structural subtleties of ordinary language (which one pray?). And if smart they will score a point of two, either because the locution in question has not yet been tamed or because the mathematicians have failed to pay proper attention to it. Given chance and motivation, mathematicians will tackle any problem of form: after all this is their province.

What holds for the analysis of form is also true of the analysis of meaning. Thus at first sight it would seem that 'or' and 'and' are not commutative in ordinary language: that their place makes a difference to meaning. If this were true then logic would be guilty of a gross oversimplification that would render it incompetent to analyze ordinary language. Example:

⌜You should study as well as play.⌝ (1)

does not mean the same as

⌜You should play as well as study.⌝ (2)

These statements are obviously different. Yet their ostensive structure, namely $s \,\&\, p$, and $p \,\&\, s$, is the same. Now, 'ostensive' signifies "superficial". There are hidden assumptions (presuppositions) that must be unearthed. In the case of (1) the presupposition is that the interlocutor, who is supposed to study, is neglecting his studies, whereas in the case of (2) the presupposition is that he is studying and neglecting his playing. More suitable formalizations would therefore be

$$\begin{aligned}(1) &= \neg s \,\&\, p \,\&\, Obl\,(s \,\&\, p)\\ (2) &= s \,\&\, \neg p \,\&\, Obl\,(s \,\&\, p) \neq (1),\end{aligned}$$

where '*Obl*' stands for the deontic operator "ought", taken care of by deontic logic.

Conclusion: As with structure analysis so with meaning analysis: no genuine shade of meaning need remain uncovered if our analysis is pushed far enough. The resulting depth of our analysis will depend on the power of the analytic tools we have employed. What holds for logical form and for meaning holds for philosophical problems in general: if genuine they can be and ought to be tackled in an exact manner. Even though some exact philosophers may lack the *esprit de finesse* characterizing some inexact philosophers, the problems the latter discover can only be solved with a pinch of *esprit de géométrie*.

A final remark on method. We shall be concerned throughout with theories and their components, i.e. statements, or the designata of declarative sentences. Hence we need not investigate nonalethic constructs such as problems (expressed by questions or by commands) and norms (expressed by imperatives). In principle these and other nondeclarative phrases may be treated by either of two methods: the direct and the indirect. The *direct* procedure consists in taking the bull by the horns and building theories (e.g. systems of deontic logic and of erotetic logic) legalizing, codifying and so cleansing some of our naive ideas on the subject. The *indirect* method consists in transforming the problem by translating the given nondeclarative sentence into a declarative one – i.e. in shedding the pragmatic trimmings of the original phrase. For example, 'Run!' may be transformed into 'The subject is ordered to run', and 'Where is x?' into 'The question is to locate x'. The problem whether every nondeclarative sentence has a "declarative prototype" (Marhenke, 1950) or a "propositional content" (Searle, 1969) seems open but does not affect our enterprise. We need not commit ourselves on this matter and we need not espouse either method for, as pointed out a while ago, scientific theories – our chief analysanda – contain just statements: only the research process leading to and from theories involves questions, norms, promises, threats, etc. However, our results concerning reference, sense, and truth, can be applied to nonalethic constructs provided the latter can be translated or distilled into their alethic counterparts. In this way we can speak of the meaning of problems and norms, or of the significance of questions and commands. In other words, we shall adopt the following principle: *If a construct has an alethic counterpart then the semantics of the former (though not its pragmatics) equals the semantics of the latter.*

Having delineated the goal and method of our endeavor, we proceed to take off.

CHAPTER 1

DESIGNATION

The goal of this chapter is to characterize the most basic of all semantic concepts: that of designation. This concept occurs in statements such as ⌜Sign x designates concept (or proposition) y⌝. Since a significant sign is a member of some language or other, we must start by defining the notion of a language and, in particular, that of a conceptual language, i.e. one capable of expressing propositions. But this will necessitate a clarification of the very nature and status of concepts and propositions. Which will in turn lead us to discussing some of the philosophical underpinnings and ramifications of our enterprise – for philosophical semantics, though a distinct discipline, is not an isolated one.

1. SYMBOL AND IDEA

1.1. *Language*

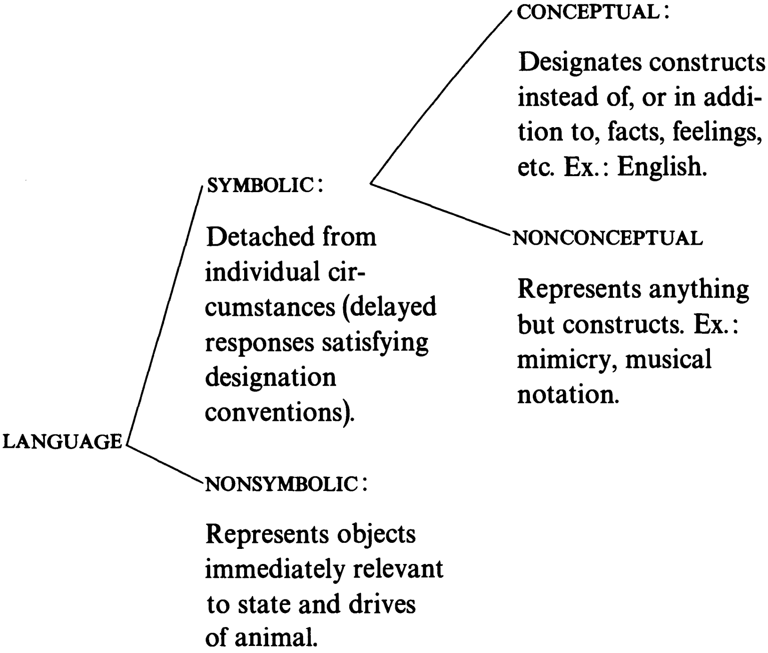
An artificial sign, whether written, uttered, or in any other guise, is a physical object – a thing or a process that a thing undergoes. But of course it is a very special object, namely one that

(i) *represents* some other object (physical or conceptual) or is part of some much proxy,

(ii) belongs to some *sign system* (= language), within which it can concatenate with other signs to produce further signs, and such that the whole system is used for

(iii) the *communication* or transmission of information concerning states of affairs, ideas, etc.

For something to be called a sign it need not be spoken or written: the signs used by bees and apes satisfy all the preceding conditions. Consequently a language need not be symbolic (i.e. involving conventions), let alone conceptual. Any *system of coded signals used for communication purposes* qualifies as a language. Moreover, the coding and decoding need not be accompanied by understanding: they can be automatic – as is often the case within humans. In any event we have the following possible partition of languages.



LANGUAGE
- SYMBOLIC: Detached from individual circumstances (delayed responses satisfying designation conventions).
  - CONCEPTUAL: Designates constructs instead of, or in addition to, facts, feelings, etc. Ex.: English.
  - NONCONCEPTUAL Represents anything but constructs. Ex.: mimicry, musical notation.
- NONSYMBOLIC: Represents objects immediately relevant to state and drives of animal.

We are interested only in symbolic languages: the study of our various systems of growls, snarls, shrieks, and gestures belongs to psychology. (Moreover we are not interested in individual symbols but rather in equivalence classes of such: linguistics is concerned with the tee shape rather than with any concrete instance of the sound or letter tee.) Essentially, a symbolic language is a set of basic symbols (the alphabet) that can concatenate forming strings. A formation device picks the subset of expressions or well formed formulas, which in turn designate certain objects. And a transformation device converts certain expressions into others. More precisely, we shall adopt the following characterization of the overall structure of a finitary symbolic language (whether or not conceptual):

DEFINITION 1.1 A septuple $\mathscr{L}_K=\langle\Sigma, \Box, \circ, \phi, \tau, \Omega, \Delta\rangle$, where K, Σ and Ω are sets, $\Box$ is a distinguished element of Σ, $\circ$ is an operation on Σ, ϕ and τ are families of mappings, and Δ is a function, is called a (finitary) *symbolic language* for communicating systems of kind K iff

(i) Σ, the *alphabet* of $\mathscr{L}_K$, is denumerable and every element of Σ is a symbol that any member of the class K of things can produce or receive;

(ii) the structure $\langle\Sigma^*, \Box, \circ\rangle$, where Σ^* is the set of finite concatenations (*strings*) of elements of Σ, is the free monoid generated by Σ, with identity (neutral) element $\Box$ (the *blank*);

(iii) ϕ, the *formation* device, is a collection of maps from the n-tuples of strings in $(\Sigma^*)^n$ to a subset Σ^{**} of Σ^* (the *expressions*, or *complete utterances*, or *wff*'s of $\mathscr{L}_K$);

(iv) τ, the *transformation* device, is a collection of maps from the n-tuples of wff's in $(\Sigma^{**})^n$ into Σ^{**};

(v) every element of the set Ω of *objects* is associated with (or it evokes) a definite state in an arbitrary member of the set K of users of $\mathscr{L}_K$ (but not conversely: some states of all users correspond to no members of Ω);

(vi) Δ, the *coding* function (or *interpretation* map) of $\mathscr{L}_K$, is a many-one function from the expressions in Σ^{**} to the family $\mathscr{P}(\Omega)$ of all the subsets of Ω (i.e. Δ assigns every complete utterance, e.g., a phrase, a certain class of objects).

More explicitly, the membership of Σ is the totality of basic (atomic) signals or letters, including the nonsignal $\Box$. These signals concatenate associatively to form the set of strings (both well formed and ill formed) Σ^*. For example, if a and b are in Σ, then $a\circ(b\circ\Box)=a\circ b$, which may not be the same as $b\circ a$, is a member of Σ^* though not necessarily of Σ^{**}. The maps in ϕ pick those strings (finite concatenations) that count as correct expressions (or well formed formulas) of $\mathscr{L}_K$, i.e. the elements of Σ^{**}. For example, one of the functions in ϕ will be that which carries the couple $\langle(x), Px\rangle$, belonging to $(\Sigma^*)^2$, into the expression $(x)\,Px$, that belongs to Σ^{**}. (Because Σ^* is denumerable, though infinite, so is Σ^{**}. In other words, the language we are describing contains only a countable infinity of sentences. This is a serious limitation but it need not concern us here, as it will have no consequences for our future work.) So far the basic ideas of the *syntax* of a language. (For mathematical linguistics see e.g. Chomsky and Miller (1963), Chomsky (1963), Ginsburg (1966), Marcus (1967), Arbib (1968), or Harris (1968), each with a different standpoint.) These basic ideas allow one to define a number of useful derivative notions, among others the following two.

DEFINITION 1.2 Let Σ^* be the set of strings of a language $\mathscr{L}_K$. If x and y are in Σ^*, then x is a *part* of y iff there are two strings w and z in Σ^* such that $w \circ x \circ z = y$.

This part-whole relation is reflexive, antisymmetric, and transitive as it should be. Should x be an initial (or final) segment of y, then we should take w (or z) to be the blank $\square$. We shall need this concept in Sec. 2.1.

DEFINITION 1.3 Let Σ^* be the set of strings of a symbolic language $\mathscr{L}_K$. The *length* of a member x of Σ^* is the number of basic signs (counting repetitions) that are a part of x.

(Note the difference between the length of an expression and the complexity of the corresponding construct if any. Any given construct may be expressed by a number of strings of varying length. More on the difference between constructs and their linguistic wrappings in Sec. 1.2.)

So much, or rather little, for the syntax of $\mathscr{L}_K$. Its *semantics* is given by adding to its syntax a set Ω of objects and a coding function Δ. This function associates every expression in Σ^{**} with a collection of objects (perhaps just a singleton) called the *denotatum* of the corresponding expression. For example, in arithmetic we have, *inter alia*, Δ: Numerals$\to$ Numbers. The function Δ is many-one: any collection of objects may be called by different names. The objects in question may be physical (occasionally other signs) or conceptual. A particular language is specified by determining not only its syntax (essentially its vocabulary Σ and its grammar $\gamma = \langle \phi, \tau \rangle$) but also its semantics – essentially its denotata Ω and its coding function Δ. While the former decrees what strings are well formed, the latter decides which are well informed.

Caution: the *semantics of a language* is sometimes mistaken for a semantic *theory* (e.g. by Katz and Fodor, 1963). The former is an integral part of a language: it consists roughly of its dictionary, i.e. of the coding function $\Delta : \Sigma^{**} \to \mathscr{P}(\Omega)$. On the other hand a semantic *theory* is a hypothetico-deductive system couched in some language and concerned with explicating semantic concepts. In other words, while the semantics of a language boils down to its dictionary, a semantic theory may include a theory about dictionaries but is not supposed to include any particular dictionary. Likewise a theory of chemical binding does not contain a list of chemical compounds but enables one to explain and predict their formation. (For further criticisms of the Katz-Fodor view see Bar-Hillel (1970).) Enough of this because there are no viable semantic theories of natural languages anyway.

It has become fashionable to include, in the semantics of a language, the conditions under which certain expressions of the language (its sentences) are true, i.e., their *truth conditions*. We shall not adopt this policy for the following reasons. First, because we shall assign truth values to (some) propositions rather than to their linguistic expressions (sentences). Second and more important, because the proposing and discussing of truth conditions or criteria is a task for the special sciences not for a general theory of language. A language should be rich and neutral enough to allow one to express in it any number of mutually incompatible truth conditions. What semantics can do is to study the general concept of a truth condition – provided it does it in the light of the experience gained in the sciences instead of legislating a priori. (More on this in Ch. 8, Sec. 2.4.) So much for the semantics of a language.

A more complete specification of any language $\mathscr{L}_K$ should include its *pragmatics*. The pragmatics of $\mathscr{L}_K$ may be construed as a map Π_K of the set Σ^* of expressions (both sound and lame) into a set of behavior items of the members of K, the users of $\mathscr{L}_K$. But since the effective determination of such a function Π_K is a matter for empirical investigation we shall not be concerned with pragmatics here. (True, there have been attempts to build a priori systems of pragmatics, by abstracting from concrete linguistic circumstances – in particular from the psychical and social make-up of the language users. But such attempts are methodologically as misguided as any other aprioristic approach to empirical matters.) Another reason for leaving pragmatics aside is that, *pace* Putnam (1970), pragmatics presupposes semantics in the sense that before attempting to investigate what person x means by expression y, or how person z uses the truth concept, one should be reasonably clear about the semantic concepts of meaning and truth – just as the physicist makes sure he understands the concept of atomic weight before proceeding to measuring atomic weights. More on this in Ch. 10, Sec. 3.4.

We conclude here our hasty characterization of the concept of a language. We take language for granted and leave it in competent hands – those of linguists, psycholinguists, sociolinguists and historical linguists. Our concern is with what can be said with languages of a special kind, namely the conceptual ones. That is, we are interested in following the Δ arrow.

1.2. *Construct*

From now on we shall restrict our attention to *conceptual languages*, which are the ones employed in mathematics, science, and philosophy. In anticipation of the formal definition to be given in Sec. 2.2 we may say that what characterizes a conceptual language is that some of its expressions symbolize ideas. If we abstract from ideation, which is a concrete brain process, as well as from communication, which is a concrete physical process, we get *constructs*: concepts (in particular predicates), propositions, and bodies of such – for example, theories. Unlike cognitive psychology, psycholinguistics, and pragmatics, all of which are concerned with real people engaged in thinking and communicating, philosophical semantics abstracts from people, and hence does not handle communication. (Nor does mathematical linguistics for that matter.) Philosophical semantics handles constructs *as if* they were autonomous – i.e., Platonic Ideas – without however assuming that there *are* such.

The existence of constructs may be regarded as a pretense on a par with the infinite plane wave and the self sufficient steppenwolf: all three are fictions. (See Vaihinger, 1920; Henkin, 1953.) In each case the real thing is far more complex but, if we want to theorize, we must start by building more or less sketchy models: once the modeling is under way we may contemplate complication and articulation. In any event we shall agree that a conceptual language is a language suitable for expressing constructs of some kind, e.g., biological theories. Moreover we assume that the chief linguistic categories *correspond* to (but are not identical with) the conceptual categories: (some) terms correspond to concepts, (some) sentences to propositions, certain fragments of languages to theories. (Cf. Kneale, 1972.) See Table 1.1., which summarizes the preceding informal characterization of the sign-construct relations.

(Note that we make no use of the notion of a semantic category [*Bedeutungskategorie*] introduced by E. Husserl and worked out by S.

Leśniewski and K. Ajdukiewicz. It does not improve things for us because a semantic category, such as a name or a sentence, is supposed to be "defined by its meaning" (Ajdukiewicz, 1935), and none of those authors had a theory of meaning to offer. In any case their semantic categories are actually syntactic categories, and the elucidation of this concept is a problem for theoretical linguistics not for philosophical semantics. Here we take languages and linguistics for granted.)

TABLE 1.1

Linguistic categories and conceptual categories

Linguistic category		Conceptual category	
		Variable	Constant
Term	Individual name	Unspecified individual x. Paradigm: arbitrary member of a set.	Specific individual c, or individual concept. Paradigm: "3"
	Class name	Unspecified set X. Paradigm: abstract set.	Specific ("concrete") set. Ex.: the set of electrons.
	Predicate letter	Unspecified predicate X. Paradigm: arbitrary predicate.	Specific predicate P. Ex.: a concept of pressure.
Expression	Phrase	Definite description schema. Ex.: "The cube of n".	Definite description. Ex.: "The cube of 2".
	Sentence	Statement schema (propositional function). Paradigms: Px, Xa, Xy.	Specific statement. Ex.: "Wolves do not wage wars".
	Language	Abstract theory. Paradigm: Boolean algebra.	Specific theory (= theory of a model). Paradigm: arithmetic.

The unit construct is the *concept*. The concept of a concept cannot be defined without circularity but it may be characterized in various ways. From a logical point of view concepts are the building blocks of statements. (Or the other way around: propositions are certain compounds of concepts.) *Example 1* All three components of the statement $\ulcorner 3>2 \urcorner$ are concepts. *Example 2* Every one of the components (coordinates) of the relational structure "$\langle N, +, 0\rangle$", where 'N' designates the set of natural numbers, is a concept and so is the structure as a whole. *Example 3* Every symbol in Newton's formula for the gravitational force designates a concept, and the formula as a whole designates a proposition (which in turn represents an objective stable pattern).

We may distinguish two kinds of concept: individual, such as "Mars", and collective, such as "planet". The latter, i.e. class concepts, are usually called *predicates.* Predicates can be unary like "long", binary like "longer than", ternary like that occurring in "a is b times longer than c", and so on. Let us for a moment focus our attention upon predicates.

1.3. *Predicate*

We shall analyze the concept of a predicate with the help of the mathematical concept of a function. A *function* f is a correspondence between two sets A and B such that, to every member x of A, there is a single element y of B. The correspondence is written '$f:A \rightarrow B$', where A is called the *domain* and B the *range* of f. The value f takes at $x \in A$ is designated by $f(x)$, in turn an element y of B. That is, $f(x) = y$. This is the gist of the general concept of a function.

We are interested in a particular kind of functions, namely propositional functions. A *propositional function* P is a function whose values are propositions. That is, a propositional function, or *predicate*, is a function from individuals to statements. Thus "lives" ("is alive") may be regarded as a certain mapping L from a set D of objects such that, for an individual c in D, $L(c)$ is the proposition "c is alive". Briefly, $L:D \rightarrow S$, where the domain D is in this case the set of organisms and S a certain set of statements, namely the class of propositions in which the concept L occurs. Likewise "dissolves" may be analyzed as a function from the set of ordered pairs ⟨solvent, solute⟩ to a set of statements. In general, a predicate (or propositional function) of *rank* (or *order*) n, where n is some integer greater than zero, will be analyzed as a function

$$P: A_1 \times A_2 \times \cdots \times A_n \rightarrow S$$

where each A_i, for $1 \leqslant i \leqslant n$, is a set of objects, S is a class of statements (propositions), and the cross represents the cartesian product of the sets of objects concerned. In simpler terms: a predicate of rank n is that which combines n objects, say $x_1, x_2, \ldots, x_n$, not necessarily real nor necessarily distinct from one another, to produce something else, namely $Px_1x_2 \ldots x_n$, called a *statement* or *proposition*, and constituting the value of P at the point $\langle x_1, x_2, \ldots, x_n\rangle$. Moreover, given an arbitrary function $f: A \to B$ the corresponding predicate will be taken to be the propositional function

$$P: A \times B \to S \quad \text{such that} \quad Pxy = (f(x) = y) \quad \text{for} \quad x \in A, y \in B.$$

The previous analysis of a predicate as a function applies to atomic, i.e. logically simple predicates, such as "between". Because we have construed atomic predicates as functions we must build complex (molecular) predicates by respecting the formation rules of complex functions out of simpler functions. Thus just as the sum and the product of two functions are definable only on their common domain, so *the disjunction and the conjunction of two predicates must be defined on their overlap* – provided the latter is not void. Otherwise the predicate letter will fail to stand for a genuine predicate: it will be a nonsense sign. In short, we stipulate that, if P and Q are predicates with a common domain $D = A_1 \times A_2 \times \cdots \times A_n$, then

$$\begin{aligned} \neg P: D \to S \quad &\text{such that} \quad (\neg P)\, x_1 x_2 \ldots x_n = \neg (P x_1 x_2 \ldots x_n) \\ P \circ Q: D \to S \quad &\text{such that} \quad (P \circ Q)\, x_1 x_2 \ldots x_n = \\ &\qquad = P x_1 x_2 \ldots x_n \circ Q x_1 x_2 \ldots x_n \end{aligned}$$

where $x_i \in A_i$ for $1 \leqslant i \leqslant n$ and $\circ$ is an arbitrary binary connective, such as "&" or "⇔". The advantages of this construal are multiple. First, it holds for all predicates. Second, it exhibits the referents of a statement. Third, it does not require the concept of truth – whence it is independent of any particular theory of truth. Fourth, it writes off without further ado, as ill formed, compounds such as 'black thought' and 'cleverly melting at 100 °K' because their components, though *bona fide* predicates, are defined on disjoint domains. Such pseudopredicates can be assigned neither sense nor reference.

Note that our construal of a predicate differs from Frege's analysis as a function from individuals to truth values. (Recall Frege (1891), in Angelelli (1967) p. 133: "*ein Begriff ist eine Funktion, deren Wert immer ein Wahrheitswert ist*".) To put it in contemporary mathematical jargon, Frege identifies a predicate F with the characteristic function χ_D of the domain D of F. In short he sets $F = \chi_D: D \to \{0, 1\}$. But then he is unable to distinguish among the various predicates with the same domain, because there is only one characteristic function for each set. Frege's construal of a predicate is therefore unacceptable. Besides, it is inconsistent with his own (wavering) anti-extensionalism and it involves an unanalyzed concept of truth. (More in Ch. 8, Sec. 3.6.)

On the other hand we accept Frege's conception of a proposition (which he often called *Gedanke*, i.e. thought), namely as the designatum of a declarative sentence independent of its particular wording. (This is a rough characterization not a definition.) That was also the manner Bolzano (1837), the Russell of *PM*, and Church thought of propositions as distinct from their linguistic containers (see, e.g. Church, 1956). We shall not define the concept of a proposition (or statement) but rather the whole structure of a metric Boolean algebra of propositions – not until Ch. 8, Sec. 3.2, though. For the time being we shall clarify what we do *not* mean by a predicate and its values (propositions).

The vain attempt to frame quick definitions of "concept" and "proposition" has produced a number of more or less interesting mistakes. *First:* "A concept is the designatum of a grammatical predicate or predicate letter". Counterexamples: the artificial predicate signs 'crittle' and 'analytic or hot' stand for no concepts. Only the converse is true if qualified: every genuine concept can be either named or described by at least one string in some language. *Second:* "A concept is anything that has a sense (*Begriffsinhalt*)". Or, which is nearly equivalent: "anything which is capable of being the sense of a name *x* is called a *concept of x*" (Church, 1951, p. 11). Unnecessary: there are unnamed (though describable) concepts – witness the silent majority of real numbers and functions. And insufficient: propositions and theories too have a sense. *Third*: "A concept is anything that can be assigned a referent (*Begriffsgegenstand*)". Not necessarily so: sets are concepts and yet they do not refer to anything. *Fourth*: "A proposition is the designatum of a sentence". Close but not quite: the nonsense sentences in nursery rhymes and in some philosophical writings express no propositions. *Fifth*: "A proposition is whatever is either true or false". Not quite: an untested factual statement has no truth value (see Ch. 8). To say that it has got one, only we ignore which, is sheer Platonizing and it does not advance us: the truth of the matter of factual truth is that truth values are contingent upon tests. (More in Ch. 8.) *Sixth*: "A proposition is anything that satisfies the propositional calculus". Necessary but not sufficient: other objects besides propositions obey the same algebra. *Seventh*: "A proposition is a collection of synonymous sentences in a language (i.e., an equivalence class of sentences under the relation of synonymy in a language)". Tempting but hollow, for it does not seem possible to give a purely linguistic account of synonymy. In fact we recognize two sentences as having the same significance, over and above their linguistic disparities, just in case they happen to stand for the same proposition. Example: the different sentences 'p & q' and 'q & p' designate the same proposition. In other words equisignificance, a linguistic property, ir reducible to a semantic property, namely the identity of the underlying constructs. (More precisely, as will be argued in Ch. 7, two constructs are identical just in case they have the same meaning, which happens if and only if they have the same sense and point to the same referents.)

So much for a preliminary clarification of "concept" and "proposition". We turn next to theory in relation to language

1.4. *Theory and Language*

The third category of construct is the theory, or hypothetico-deductive system. The formulas of a theory may be specific statements or they may contain unbound variables of some kind. In either case the formulas are formulated in, or expressed by, sentences in some language – the *language of the theory*. One and the same language may be used to formulate any number of alternative theories: when formulating a theory we pick a subset of all the possible expressions of a language and organize this collection (or rather the corresponding set of statements) in a deductive manner. The language itself must be neutral with respect to both the selection and the organization of the material (recall Sec. 1.1). Thus while the language may contain the sentences 'a is a P' and 'a is not a P', the theory will pick either or none of them.

The following example should bear out our thesis that theory and language must be kept as distinct as gift and wrapping. Let $\mathscr{L}$ be the following language:

Logical alphabet of $\mathscr{L} = \{\neg, \vee, \exists\}$

Extralogical alphabet of $\mathscr{L} = \{a, b, x; P\}$ with a and b individual constants, x and individual variable, and P a unary predicate letter

Atomic sentences of $\mathscr{L} = \{Pa, Pb\}$

Sentences of $\mathscr{L} = \{Pa, Pb, \neg Pa, \neg Pb, Pa \vee Pb, \neg Pa \vee Pb, Pa \vee \neg Pb,$
$\neg Pa \vee \neg Pb, (\exists x)Px, \neg(\exists x)Px, (\exists x)\neg Px,$
$\neg(\exists x)\neg Px, \ldots\}$

Theory 1		*Theory* 2
Language of T_1	$=\mathscr{L}=$	Language of T_2
Logic of T_1 =	First order predicate calculus	= Logic of T_2
Axiom 1 $\neg Pa \vee Pb$.		Axiom $\neg(Pa \vee Pb)$
Axiom 2 Pa		Theorem 1 $\neg Pa \wedge \neg Pb$.
Theorem 1 Pb		Theorem 2 $\neg Pa$
Theorem 2 $(\exists x)\, Px$		Theorem 3 $\neg Pb$
		Theorem 4 $(\exists x) \neg Px$.

Although the set of sentences of each theory is a subset of the collection of sentences of their common language, the two subsets do not coincide and moreover they do not stand in their own right but "say" something even if this something is abstract for lack of interpretation of the various symbols involved. Whether a system of signs constitutes a *language* (and is consequently neutral) or *expresses* a theory (and is consequently committed) can be decided only by finding out whether it makes a choice among all the possible sentences – i.e. whether it excludes some of the formulas of the given language.

Nevertheless the language/theory division, though genuine, is relative. Indeed every universal theory, whether in logic or in pure mathematics, can be *used as a language* by another, more specific theory. Thus logic is used as a language or vehicle of communication by every mathematical theory, and mathematics is a language of theoretical science. There are two ways in which a theory can be utilized as a language by another theory. One is to borrow only some of the *concepts* of the universal theory and their corresponding symbols without using any of the axioms and theorems of that theory. This is how most mathematicians use logic. It is also the way molecular biologists use information theory: although they talk of the information carried by a DNA molecule they never compute or measure that quantity of information. Another, fuller, utilization of a theory by a second theory occurs when the latter employs some of the *statements* (hence also some of the concepts) of the former. This is how physicists use functional analysis and sociologists graph theory: these theories enter into the very building of the specific factual theories. In sum, the distinction between language and theory, though neat, is as relative as the one between means and goals.

However a relative difference *is* a difference. Hence it is mistaken to define a theory as a certain set of *sentences* from some language, and a model as a structure in which such strings, conceived as *inscriptions*, are satisfied. Such an elimination of constructs in favor of their linguistic embodiments is no mere carelessness but deliberate: it is a necessary component of nominalism. This philosophy, espoused by eminent logicians such as Hilbert and Tarski, and at one time Quine, has its advantages: it simplifies, it avoids the pitfalls of both Platonism and psychologism and last, but not least, any computer can be talked into adopting it.

However, nominalism does not supply an adequate semantic theory. For one thing it overrates the importance of notation and wording and therefore cannot account for the fact that any given proposition can be formulated in a number of different languages. For another, if one refuses to accept anything beyond signs *qua* physical objects and their eventual physical denotata, then he cannot explain why symbols enter into non-physical (e.g. logical) relations – not to speak of their form and content, which are likewise non-physical. (Consider: whereas twice 3 is 6, twice '3' is '33'.) Thirdly, for the same reason the Ockhamist is likely to multiply the number of entities without necessity, as he may take seriously Eddington's parable of the two tables: the layman's (concept of a) smooth table and the scientist's (concept of a) mostly hollow one, both denoted by a single word. The nominalist may thus end up by positing a plurality of realities, thus committing philosophical suicide – as Chwistek (1949) did. Fourthly, if the nominalist assigns to some of his marks, e.g. sentences, certain non-physical properties such as truth or falsity (as Tarski does), then he slips into hylemorphism – the very Platonic devil he wishes to exorcise. Fifthly, the nominalist must repudiate any theory which, like non-standard analysis, teems with nameless constructs (Robinson, 1966). (For further criticisms see Frege (1893) in Geach and Black, Eds. (1952), and Putnam (1971).)

We shall consequently stress the traditional distinction between term and concept, predicate letter and predicate, sentence and proposition, and language and theory. We shall say that the first member of each pair stands for, expresses, or designates the second member. But this relation of designation deserves a separate section.

2. DESIGNATION

2.1. *Name*

Names are those terms in a language that designate objects of some kind. Thus the numerals '3' and 'III' name the number three. In a conceptual language all names designate constructs. But the converse is false: notwithstanding nominalism, most constructs go unnamed. Thus, only a few irrational numbers and a few functions have got standard names. Still, just as anonymous persons can be identified by their features and actions, so constructs can be identified by their properties even if they are assigned no individual names. For example, the function "two fifths of the cube plus seven" has got no special name but it is unambiguously characterized by the preceding description, which amounts to saying what the function does – namely sending x into $\frac{2}{5}x^3+7$, where x is a real number. In short, there are unnamed constructs but not ineffable ones.

There are names of (some) individuals, names of (some) classes (or common names), of (some) relations, and so on. In either case names may designate a fixed or an arbitrary member of a collection, i.e. an unspecified individual. Thus we may agree to call 'x' an arbitrary real number. (Note that a variable is not quite the same as a blank. While all blanks or voids are the same, namely nothing, variables can differ from one another and can be manipulated. Thus '$x+y=z$' is not the same as ' $+$ $=$ '. Nor is a variable something that varies.)

Names are symbols and as such they act as proxies for their nominata. We should not forget what they stand for – unless we happen to be computers. For example, strictly speaking we should not say 'Let R *be* the real line' but rather 'Let R *name* (*designate*) the real line'. However, as long as we are alert to the distinction between signs and their designata we can afford to confuse them in our speech and writing for the sake of brevity. In short, we can indulge in self-designation provided we keep in mind that symbols are just that – conventional signs proxying for something else.

The refusal to distinguish symbols from what they symbolize can be made into a philosophy. It is, indeed, the core of the nominalist or vulgar materialist philosophy of mathematics. This philosophy appeals to the haters of intangibles and the lovers of simplicity: instead of having symbols on the one hand and constructs on the other it offers a single bag of tangible entities, some natural and others (the signs) artificial. Thus a member of this persuasion will claim, for example, that "The expression or string consisting of '(x) ('followed by 'P' followed by '$x\Rightarrow$' followed by 'P' followed by 'x)' is an analytic sentence of the language L'. And he will be happy with the nursery school identification of the number one with a vertical stroke. A simple creed indeed – hence one inadequate to tackle the complex facts of life. For example the creed makes no room for the principle that symbols, in particular names, are replaceable because conventional: that "the real thing" is the designatum not its name: that no particular sign is indispensable. (For a vigorous defense of this thesis see Frege (1895). Even Bourbaki (1970, Ch. I), despite its nominalist flare-ups, warns against confusing symbol with designatum.)

The preceding semantic principle, that although names may be necessary (or convenient) none of them is indispensable, has been credited to Shakespeare. In fact, in *Romeo and Juliet* he held that the scent of a rose is name-invariant. This principle, sometimes called the "principle of reference" (Linsky, 1967), can be given a more exact though far less poetic formulation, such as the following. Let x be part of an expression $e(x)$ in a language $\mathcal{L}$ and let $e(y)$ be the expression resulting from trading x for y in $e(x)$, where y is yet another sign in $\mathcal{L}$. If x and y have the same designatum, then so have $e(x)$ and $e(y)$. Consequently the two can be mutually substituted *salva significatione et salva veritate*. One may adopt this necessary triviality as part of the definition of the designation relation.

Thus we accept Shakespeare's thesis that nothing is in a name: that what really matters is the nominatum. If the latter happens to be a construct, not a physical object, then we may say, following Frege and Church, that the name points to the sense *or* to the referent of the construct. But we may as well substitute 'and' for 'or', as the concept of ambiguity has a pragmatic ring about it. In our theory of meaning a sign that stands for a concept performs both functions: it signifies the sense as well as the referent of the construct it designates. (See Ch. 7, Sec. 1.) Thus the class name *Homo sapiens* symbolizes the technical concept of man. The sense of this concept is given by some of the hypotheses occurring in the sciences of man, while its reference class is of course the set of humans. Whether or not this latter set is empty (as some of us are beginning to suspect) is no business of the semanticist: the determination of the actual extension of concepts is a task of scientists not of philosophers. But this matter will be taken up in detail in Ch. 2 and in Ch. 9, Sec. 1.

Names are conventional but they need not be arbitrary. While some are formed spontaneously others are contrived according to rule. About the most sophisticated of all rule-directed naming procedures is Gödel's, which assigns to every basic symbol in the linguistic wrapping of a theory a unique natural number in such a way that, given any natural number, the corresponding symbol can be effectively retrieved. We shall need no such powerful method: the most modest of all naming procedures will suffice us – namely the *quotation marks* technique. We shall employ three kinds of quotes:

> 'single' quotes to mention symbols,
> "double" quotes to designate constructs, and
> ⌜corners⌝ to name propositions (a kind of construct).

2.2. *The Designation Function*

According to Definition 1.1 (Sec. 1.1), a language is a certain septuple $\mathscr{L}_K = \langle \Sigma, \square, \circ, \phi, \tau, \Omega, \Delta \rangle$, where Δ is a correspondence between the signs of $\mathscr{L}_K$ (formed from items in Σ with the help of the operation $\circ$) and the objects in Ω. The role of Δ is then to inject some significance into a bunch of dumb marks, which would otherwise symbolize nothing. In the case of conceptual languages, which are the ones we are interested in, the set Ω shrinks to a subset C, a collection of constructs, and Δ becomes the designation function, briefly $\mathscr{D}$. More precisely, we have

DEFINITION 1.4 Let L be a system of predicate logic. Then the septuple $\mathscr{L}_{KL} = \langle \Sigma, \square, \circ, \phi, \tau, C, \mathscr{D} \rangle$ is a *conceptual language* iff

(i) $\mathscr{L}_{KL}$ is a language;

(ii) Σ contains at least the signs required to designate the basic concepts of the logical system L;

(iii) C is a nonempty set of constructs containing at least all those in L;

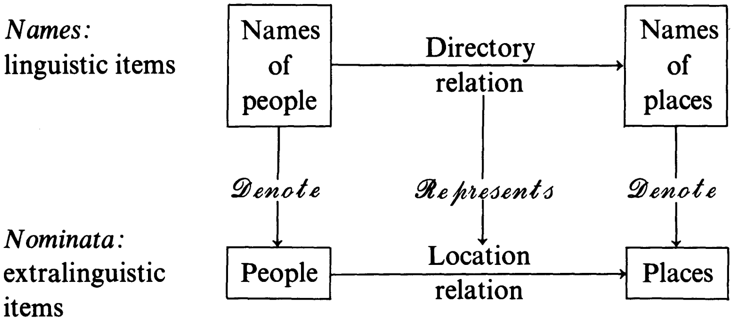
(iv) $\mathscr{D}$ is a many-one function from the set Σ^{**} of expressions (wff's) of $\mathscr{L}_{KL}$ into (but not onto) the collection $\mathscr{P}(C)$ of subsets of C;

(v) Any two signs in Σ^{**} with the same designatum (i.e. for which $\mathscr{D}$ takes the same value) can be mutually exchanged wherever they occur in Σ^{**}.

Note the following points. First, since $\mathscr{L}_{KL}$ is a conceptual language, not gibberish, every wff in it stands for (proxies) some construct. On the other hand $\mathscr{D}$ is not onto: there may be in C nameless constructs, such as the nonstandard objects in nonstandard analysis. Second, condition (v), sometimes called 'Leibniz' principle of the substitutivity of identicals', does not warrant any such substitutivety but rather the one of *different* expressions provided they happen to designate the same constructs. Third, this principle has nothing to do with reference. Hence it is not illustrated by ⌜The morning star = The evening star⌝. This last statement is, strictly speaking, false. What is true is that the two descriptions have the same referent – namely Venus. More on this in the next chapter. Fourth, the principle (v) has been challenged because it fails for the so-called "intensional contexts", i.e. in connection with "propositional attitudes" expressed by verbs like 'to know' and 'to believe'. For example, although '3' and 'III' designate the same number, the statement ⌜Everybody knows that 3 = III⌝ is plainly false (see, e.g., Linsky, 1967). We shall not take up this question since it belongs in pragmatics or in psychology (see Ch. 8, Sec. 4.3).

Fifth, the principle (v) is essential to all symbolic thinking. Its explicit statement should contribute to clarifying the way symbols perform their function, which is not to live their own life but to stand for, or deputize for, something else. Thus an equation such as ⌜$a = b$⌝ informs us that the letters 'a' and 'b', though different, name the same object. This trivial remark should help the beginning student of mathematics, who is often baffled by the apparent inconsistency of ⌜$a = b$⌝. And the remark should embarrass the nominalist, for in the formula '$a = b$' the two sides are not the same name. If mathematics were concerned with signs and languages rather than their designata, we should write: 'a' = 'b', which is false. In fact, as Frege (1879) noted long ago, we are here concerned with a single concept, now called 'a', now 'b'. (This does not endorse Frege's view that the theory of identity concerns only names or terms. The theory of identity is supposed to be universal, in the sense that it holds for objects of all kinds.)

Sixth and last, note that we have not defined the designation function $\mathscr{D}$: we have not specified the way it maps expressions into constructs. Any precise characterization of $\mathscr{D}$ involves the exact specification of such a correspondence, therefore of its domain Σ^{**} and range $\mathscr{P}(C)$ – hence a loss of generality. As soon as the designation function is specified, the conceptual language $\mathscr{L}_{KL}$ becomes a particular *semantic system.* A customary way of specifying ("defining") a semantic system is to lay down *designation rules* such as "Let 'M' designate the Newtonian mass function" (Carnap, 1942). But of course a formula such as this is a rule from a pragmatic point of view only, as it expresses a decision or convention. From a semantic point of view it is not a rule but a statement, namely an instance of "$\mathscr{D}(\sigma)=c$", where $\sigma\in\Sigma^{**}$ is a sign and c the construct σ designates. Besides, designation "rules", though necessary, are not sufficient for the purpose of formulating a body of factual knowledge, however modest it may be. Even an address book involves an additional semantic notion, namely that of *denotation*, a relation which goes from signs to factual items, either directly or via constructs. (More on denotation in Ch. 2, Sec. 2.4.) This relation includes the directory relation that matches names of people to names of places (addresses) and *represents* the physical relation between people and their dwellings:



In the case of scientific theories we have the composition of two relations: designation $\mathscr{D}$, from signs to constructs, and reference $\mathscr{R}$, from constructs to factual items. That is, in addition to the ordinary assumptions (construct-construct links) and the designation "rules", scientific theories also contain construct-fact correspondences. The latter tell us what the theories are about: which of its constructs refer to what and which represent what. In other words, the semantic systems of factual science, unlike those of pure mathematics, include semantic hypotheses or assumptions, often misnamed 'correspondence rules' (Chs. 2, 3, and 6). For this reason, and because a language should be a neutral instrument for expressing ideas, our Definition 1.4 of a conceptual language should not be mistaken for a definition of a factual theory. In other words, Definition 1.4 characterizes only a class of languages suitable for expressing a body of factual knowledge.

3. METAPHYSICAL CONCOMITANTS

3.1. *Basic Ontology*

Our definition of a language in Sec. 1.1 involved not only signs but also their denotata, i.e. the values of the coding function Δ. The denotata may be, but mostly are not, linguistic items. In fact the denotata of a sign system may be anything whatever: individuals, sets, relations, concrete or abstract, possible or impossible. They are *objects* in the general philosophical sense of the word, not in the sense of concrete tangible things.

We shall take this general notion of an object as primitive or undefined, for it is far too basic and important to be definable. And we may let ontology take care of its characterization even though we reject the very notion of a general theory of objects of any kind. In any case we shall assume the following partitions:

(i) Every *object* is either a factual item (e.g. an event) or a construct (e.g. a set) and none is both.

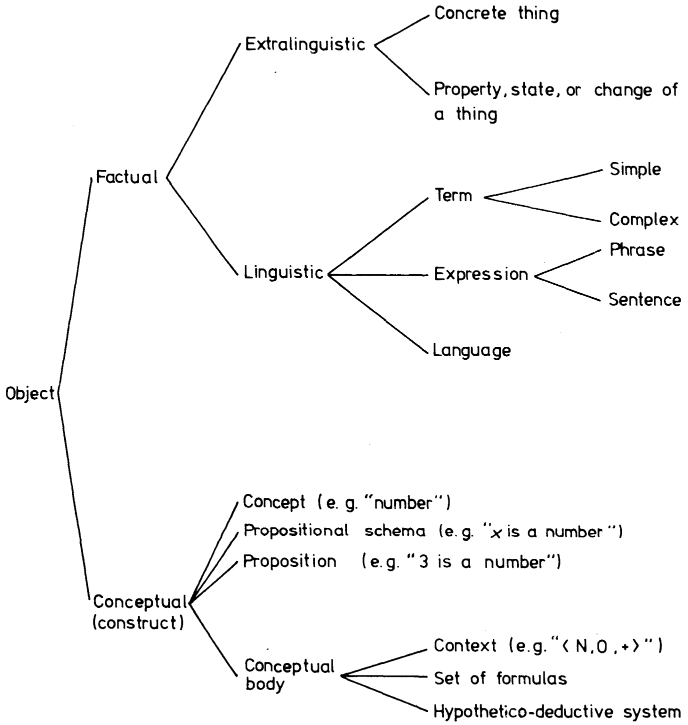
(ii) Every *factual object* is either linguistic or extralinguistic and none is both.

(iii) Every *linguistic object* is either a term (a member of some Σ or of some Σ^*) or an expression (an element of some Σ^{**}) or a whole language.

(iv) Every *construct* is either a predicate or a propositional function or a proposition or a set of either (with or without a structure).

In other words, the basic ontology accompanying our semantics admits the kinds of object shown overleaf.

That there is such a diversity of kinds of object is suggested by the fact that they satisfy radically different sets of laws: for example, the concepts of physics do not obey the same laws as their referents. Whether or not all objects in our ontology are attributed an *autonomous* existence is another matter – one for metaphysics not for semantics. However, the author hastens to declare that in his own metaphysics neither constructs nor even linguistic items are self-existing: the two are artifacts, hence dependent upon man – they were and are being created by mankind and will follow the fate of mankind. Surely signs, e.g. inscriptions, are physical objects: but they depend upon man for their coming into being as well as for their functioning as signs (proxies) for whatever they stand for. As to constructs, they are total fictions: what is real is the brain process that consists in thinking of some object. Let us elaborate on this point.



Object
Factual
Extralinguistic
Concrete thing
Property, state, or change of a thing
Linguistic
Term
Simple
Complex
Expression
Phrase
Sentence
Language
Conceptual (construct)
Concept (e. g. "number")
Propositional schema (e. g. "x is a number")
Proposition (e. g. "3 is a number")
Conceptual body
Context (e.g. "⟨ N, 0 , + ⟩ ")
Set of formulas
Hypothetico-deductive system

3.2. *Beyond Platonism and Nominalism*

Consider an external event such as a lightning bolt and a linguistic fact such as someone's uttering the sentence 'That was lightning'. Between these two physical processes we have an intermediate brain process – a thought. Change the speaker or the language and the sentence may change. However, we may surmise that, if the speakers' genetic make-ups and their funds of experience are similar, so will be their thought processes, whence their various utterances, though possibly different, will stand for the same statement or proposition. (See Fig. 1.1.)

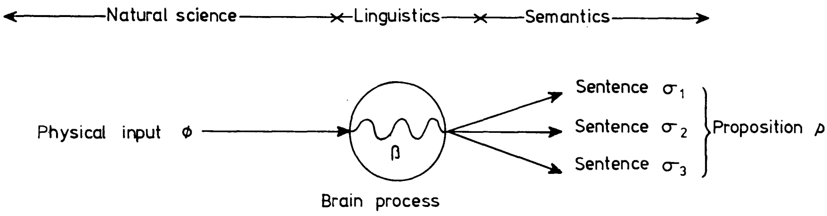


Fig. 1.1. A physical stimulus ϕ, the brain process β (thinking) it elicits, and its linguistic outputs σ_i, sentences expressing the proposition p.

Propositions are not physical objects: they have no reality aside from brain processes – just as there is no motion independent of moving things. It is a fiction, albeit an indispensable not an idle one, to assume that, in addition to the factual items and independently of them, there is such a thing as a proposition. For Platonists like Bolzano there are propositions *in themselves*, that need not have been thought by anyone, hence that may never be "discovered" (Bolzano, 1837). We make no such metaphysical assumption: we make instead the *methodological pretense*, or useful fiction, that things happen *as though* there were autonomously existing propositions (statements) as the designata of some sentences. (Cf. Sec. 1.2.) The concept of existence involved herein is that of conceptual existence not physical existence (Ch. 10, Sec. 4.1). We can turn the Platonist and the fictionalist loose in the field of constructs precisely because these *are* fictions. It is only where real (concrete, material) entities are concerned that the restrain advocated by the nominalist is in place.

Let us take another look at the situation depicted by Figure 1.1. The real events are the lightning, its perception, the thought process triggered in the subject by that perception, and his linguistic utterances. Each of these real events can be studied by some factual science. In particular, linguistics may take care of the sentences – and literary criticism may decree which sentences are "felicitous". Philosophical semantics starts thereafter, where linguistics leaves off. The former is not concerned with speech acts or even with linguistic items for their own sake or as constituents of human behavior but only insofar as they represent constructs.

So much so that philosophical semantics is hardly interested in nonconceptual signs such as 'ouch!' and 'liquid dream' or even in inscriptions, such as hieroglyphs. In other words, semantics is concerned with whatever grows at the tip of a conceptual sign. In this sense semantics is not a part of semiotics conceived as the science of signs (Morris, 1938). Philosophical semantics is a science of constructs and therefore may be regarded as a separate philosophical discipline or else as part of epistemology (see Ch. 10, Sec. 3).

Our view, though not Platonist, contrasts with the nominalist approach to semantics. Whether medieval or contemporary, materialist or empiricist, nominalism trusts the tangible (things and words) as much as it mistrusts the intangible – thoughts and constructs. Language is allegedly ostensible and controllable, whereas thought is hidden and can be wild, and constructs are admittedly fictions. The nominalist deals in terms and sentences not in concepts and propositions (see e.g. Zinov'ev, 1973). The motivations of nominalism are quite sound: to avoid obscurity, wildness, ghostliness, and Platonic hypostatizations. But the surgery it counsels, in particular the excision of constructs, eliminates the semantic problem instead of solving it. The "final solution", consisting in construing everything conceptual as a matter of signs, is in the same vein as the behaviorist proposal of regarding thinking as imperceptible laryngeal movements or as a disposition to talk: the former beheads semantics just as the latter decerebrates psychology. Whatever we may think of nominalist metaphysics, we cannot subscribe to nominalist semantics if we want to understand (*a*) that constructs are not entities on a par with things, (*b*) the very idea of a conceptual symbol as distinct from a nonconceptual one, (*c*) the dispensable character of every single symbol (but of course not of symbolization), (*d*) the fact that conceptual symbols must be adapted to the laws (logical, mathematical or philosophical) of constructs rather than the other way around, and (*e*) that these laws are not factual and are not subject to empirical tests.

The fruitful stand with respect to intangibles is not writing them off but to investigate whether they are lawful and whether positing them explains anything. Thus instead of outlawing the concept of a proposition, logicians have built propositional calculi. Likewise instead of ostracizing the concept of meaning for being intangible, we should clarify it by constructing a theory of meaning, just as scientists have been taming their own intangibles – fields, hydrogen bonds, gene pools, learning abilities, social structures, and the rest. Even linguists go beyond facts in order to understand them: in fact their mathematical models of language discard speakers and speech acts and they contain high brow constructs. Thus the set Σ^* of strings of a language (Sec. 1.1) is infinite; a phoneme is not a particular sound but an equivalence class of sounds – such as the m's uttered by different speakers; and the deep structure of a phrase is not perceptible either. A mathematical model of a language is not an empirical item but a more or less coarse representation of actual facts, to be tested by confrontation with empirical items. In the case of linguistics the empirical items are the finite samples of a language, such as those produced by Shakespeare, Johnny, and so on. Were the linguist to confine himself to such samples he would find hardly any stable and deep regularities: patterns, whether linguistic or chemical, must be hypothesized. Samples suggest and test a model but do not constitute it. Likewise if the semanticist were to limit himself to words and dictionaries he would never come up with theories of meaning and truth. His business is not to observe and describe speech acts but to analyze and systematize the semantic properties of concepts, propositions, and theories. By so doing he need not hypostatize constructs and meanings: conceptualists need not, nay they should not be Platonists. The conceptualist shares the nominalist's conviction that there are no universals in actual discourse – which is a string of concrete events (Goodman, 1951, p. 288). Only, he cannot see how universals could be dispensed with in *theorizing* about "word events", "illocutionary acts", or any other items.

We conclude with Table 1.2, which lists the main philosophies of the sign-construct relation to be discussed in this book.

TABLE 1.2

Sign and construct: main views

View	Sign	Concept, Proposition	Theory
Platonism	A physical object – the shadow of an idea.	A constituent of the Realm of Ideas, which is self-existent.	A body of ideas. Objects of a mathematical theory = Concepts.
Psychologism	A physical object acting as a proxy for some thought.	A thought of some kind.	A set of thoughts, actual or possible.
Nominalism (materialist or empiricist)	A physical (or alternatively experiential) item that stands in its own right or represents some other item of the same kind.	There is none.	A set of expressions: a part of a language. Objects of a mathematical theory = Signs (marks).
Conceptualist materialism	A physical object that stands for another object (or set of objects) – physical, mental, or abstract.	No constructs aside from mental objects, in turn brain processes. Construct = Equivalence class of brain processes – i.e. neither a concrete individual nor a Platonic Idea. For the sake of expediency pretend constructs exist by themselves.	A set of statements with deductive structure. Objects of mathematical theories = Constructs. Scientific theories have an external reference.

CHAPTER 2

REFERENCE

We propose to study now the semantical concept of reference – the *suppositio* of medieval logicians. This concept occurs in statements such as ⌜She was *referring* to witches⌝, ⌜Ecology *concerns* the organism-environment relationships⌝, ⌜Economics *deals with* the production and circulation of merchandises⌝, and ⌜Political science is *about* political institutions⌝. This semantic concept of reference should be distinguished from the psychological or pragmatic notion of reference involved in ⌜That theory suggests (or makes one think of) x⌝, ⌜This theory is meant to apply to x⌝, and ⌜The intended referent of x is y⌝. This other notion of reference is involved in learning how people actually create, learn, or use ideas, whereas the semantic concept of reference comes up when asking what a statement is about quite apart from the way it is conceived, applied, misapplied, or tested.

It might seem that an investigation of the semantic concept of reference should be trivial and therefore useless: don't we normally know what we are talking about? Unfortunately not: there is often endless argument as to what certain scientific theories are about. Hence we should welcome any semantic doctrine that could be of some help in spotting the genuine referents of a scientific theory. Since no such semantic doctrine seems to be available, we shall have to build one. But before proceeding to this task let a few examples vindicate our claim that the referents of a statement, or of a set of statements, are not always in evidence and that there are no obvious tools for bringing them to light.

1. MOTIVATION

Consider the following cases gleaned from the literature.

Case 1 Several philosophers have maintained that ⌜p is true⌝ is identical to ⌜p⌝, i.e. that the truth concept is redundant. On the other hand Bolzano held that the subject (referent) of ⌜p is true⌝ is p itself, which is not the case with the latter statement, whence the two are different. He even suggested the possibility of iterating this procedure, thus coming up with an infinite ladder of statements, every one of which has the previous one as its subject or referent (Bolzano, 1851, p. 85).

Case 2 The same philosopher had held previously that ⌜Some people are literate⌝ concerns only literate persons while ⌜Some people are not literate⌝ is about illiterates only (Bolzano, 1837, III, Sec. 305). True or false? And how about their equivalents ⌜Not everyone is illiterate⌝ and ⌜Not everyone is literate⌝ respectively?

Case 3 Aristotle taught that "A single science is one whose domain is a single genus" (*Post. Anal.*, Bk. I, Ch. 28). Right or wrong? How about ecology?

Case 4 Evolutionary biologists are divided on the question of the referents ("units") of population genetics and of the theory of evolution (see Williams, 1966, Ch. 4). Is it individual organisms, species, or populations? And does the theory state that selection acts on genotypes (individuals) or rather on phenotypes (populations)?

Case 5 Some proponents of the so-called identity theory argue that, although neurophysiology and psychology employ concepts with different senses, they have exactly the same referent, namely the person, whence those sciences constitute different ways of viewing the same facts, namely mental (= neurophysiological) events. This particular defense of the identity theory rests then on the semantic hypothesis that Referent = Fact. How about the ethology and the physiology of birds, which share their referents?

Case 6 Eminent physicists have claimed that the special theory of relativity is about the behavior of clocks and yardsticks. Others have held that it concerns observers in relative motion. Still others, that the referents of the theory are point masses inhabited by competent and well equipped experimenters communicating with one another through light signals. Finally, there are those who contend the theory to be about any systems connectible by electromagnetic signals. Take your pick.

Case 7 Most physicists act on the assumption that the quantum theory refers to autonomously existing microsystems such as neutrons and photons. But when it comes to "philosophizing" many claim that the theory is about sealed (unanalyzable) blocks constituted, in arbitrary proportions, by microsystems, measuring instruments, and observers.

Still others hold that the theory is concerned with the knowledge of nature rather than the latter (Heisenberg, 1958, p. 100).

Case 8 Consider the formula ⌜For all integers x: $x+1=1+x$⌝. Is it just about integers or rather about the whole system $\langle Z, 1, +\rangle$ (Rosenbloom, 1950, p. 110)? In any case, by which criterion is it either?

Case 9 The theory of control systems has been developed by engineers but has applications in biology and other fields of inquiry concerned with things, whether inanimate or alive, that have control devices built into them. Does the theory have a definite reference class at all?

Case 10 What is the reference class of elementary logic? Combinations of letters? Sentences? Propositions? Argumentative people? The world?

There should remain little doubt that identifying the referents of a statement or of a theory can be a thorny problem and that we need a semantic theory capable of helping us to perform that task. We shall presently expound one such theory. More precisely, we shall first study the rather unruly relation of reference and shall later on introduce a couple of law-abiding reference functions – one for predicates, the other for statements. The outcome may be regarded as a calculus of reference allowing one to compute the reference class of any composite statement as a function of the reference classes of its constituents. This calculus should help us to solve problems of referential ambiguity. By the same token it should free us from the recourse to authority as the "method" for ascertaining what scientific theories are about. On the other hand our calculus will not presume to tell us when a given predicate is applicable, i.e. what its correct reference or field of validity is: this is a business of science. In other words, we distinguish reference from extension – a subject to be studied in Ch. 9, Secs. 1 and 2.

2. THE REFERENCE RELATION

2.1. *An Unruly Relation*

We stipulate that the reference relation $\mathscr{R}$ holds between constructs (concepts, statements, or theories) on the one hand, and objects of any kind on the other. In other words, we adopt the following

CONVENTION The graph (or extension) of the reference relation $\mathscr{R}$ is a set of ordered pairs construct-object, i.e.,

$$\mathscr{E}(\mathscr{R}) \subseteq C \times \Omega, \quad \text{with} \quad C \subset \Omega,$$

where 'C' stands for the class of constructs and 'Ω' for the class of objects.

$\mathscr{R}$ has no simple formal properties. In particular $\mathscr{R}$ is not reflexive throughout its graph. For example, the concept of a star concerns stars rather than itself. On the other hand the number 7 refers to nothing. Nor is $\mathscr{R}$ either symmetric or antisymmetric. Finally $\mathscr{R}$ is not transitive either, as shown by the following counterexample:

$$r = \ulcorner\text{The statement below is false}\urcorner \tag{1}$$

$$s \tag{2}$$

where s refers to a third statement t. Clearly, although $\mathscr{R}rs$ and $\mathscr{R}st$, it is not the case that $\mathscr{R}rt$.

This last result has an important application in the foundations and philosophy of science, namely in relation to the semantic status of metanomological statements, or laws of laws (Bunge, 1961a; Angel, 1970). Consider the following propositions:

> A fundamental physical statement (e.g. equation) should involve no constants other than universal constants. (3)
>
> Newton's laws of motion are invariant under Galilei transformations. (4)
>
> Every quantum-mechanical formula should correspond to some classical formula. (5)
>
> If a local field theory is relativistically invariant, then it is also invariant under the combined conceptual inversion of charge, time, and parity. (6)

These statements and many others – some descriptive, some prescriptive – are often treated on a par with the object statements of a theory. However, it is apparent that they are *metastatements*, i.e. that they concern further statements. (Caution: not every metastatement belongs to some metatheory. None of the above does. Moreover some metastatements belong to object theories – as is the case with (4) and (6) above. For a typical confusion of 'metastatement' and 'metatheoretical statement' see Freudenthal (1971).) Further, since the reference relation is not transitive, the above propositions fail to refer to the same object their referents are about. Thus statement (4) is not a law of motion and (6) is not a field law – hence neither can be tested by observations on physical objects. Which suggests that, in spite of operationism, semantics should precede methodology: before we pose the problem of testing a statement we should know what it refers to. Enough of this for the moment.

In conclusion, $\mathscr{R}$ is neither reflexive nor symmetrical nor transitive – nor, indeed, seems to have any other definite formal trait. It is a wishy-washy relation and as such not amenable to theory. All our remarks in this section will therefore be intuitive. To obtain regularity we shall have to introduce a reference function. This will be done in Sec. 3; but before that we must take a closer look at $\mathscr{R}$.

2.2. *Immediate and Mediate Reference*

Consider a specific theory, or theoretical model t, of some concrete system s. Any such specific theory "defines" a model object m, or conceptual image of s, that is hoped to capture some of the traits of the latter. We may say that, while the *immediate referent* of t is the model object m, the ultimate or *mediate referent* of t is the real thing s (Bunge, 1967a). Table 2.1 exemplifies the idea.

TABLE 2.1

Examples of immediate and mediate reference

Theoretical model t or specific theory	Model object m = immediate referent of t.	Real system s = immediate referent of m. = mediate referent of t.
Enterprise theory	Directed graph	Enterprise
Contagion theory	Diffusion equation	Epidemics
Volterra's predation equations	Predator-prey system in constant environment	Rabbit-fox system or the like in wild life
Eye dioptrics theory	System of lenses	Mammalian eye
Magnetostatics of magnetic dipoles	Magnetic dipole	Terrestrial magnetic field

In every such case (*a*) the formulas of the theoretical model (specific theory) concern directly the model object itself, and mediately the thing modeled: for example, a theorem in enterprise theory may be about the degree of a vertex in the hierarchical tree of the enterprise; (b) the formulas are true of the model object (e.g. the unperturbed rabbit-fox economy) but only approximately true of the real thing – e.g. the rabbit-fox system in a variable environment subject to droughts, viruses, etc.; (*c*) the reference relation holds between every pair: $\mathscr{R}tm \,\&\, \mathscr{R}ms \,\&\, \mathscr{R}ts$ even though it is not transitive.

2.3. *Reference Class*

The set of referents of a given construct *c* is called its reference class. More explicitly, we introduce

DEFINITION 2.1 If *c* is a construct, then the *reference class* of *c* is the set of objects referred to by *c* (or the collection of items to which *c* bears $\mathscr{R}$), i.e. the relation class $[c]$ of *c* relative to $\mathscr{R}$:

If c is in C, then $[c] =_{\mathrm{df}} \{x \in \Omega \mid \mathscr{R}cx\} = \overleftarrow{\mathscr{R}}\text{‘}c$.

DEFINITION 2.2 A construct *c* *refers partially* to a class $A \subset \Omega$ iff A is included in the reference class of *c*, i.e., if $A \subseteq [c] = \overleftarrow{\mathscr{R}}\text{‘}c$.

Some constructs concern a single natural kind while others are about heterogeneous classes. (We do not apologize for employing the concept of a natural kind, essential to science, but we leave its elucidation to ontology.) For example, the reference class of "viscous" is the set of fluids, while that of "writing" is composed of the set of people and the set of written symbols. This difference is consecrated in the following

DEFINITION 2.3 A reference class is said to be *homogeneous* iff it is composed of elements of a single natural kind.

DEFINITION 2.4 A nonempty reference class is called *inhomogeneous* iff it is not homogeneous.

Every statement in factual science has a reference class assumed to be nonempty even though, on closer investigation, that class may prove void. For this reason it is often advisable to speak of *hypothetical* (or assumed) reference classes. A hypothetical reference class is often called an *intended* reference. It is not convenient to employ this second term in semantics, as it suggests the psychological concept of intention. (Whether or not somebody intends to entertain the hypothesis that a given construct has a certain reference class is a matter for psychology.) The class of objects for which a statement or a theory holds true may be called its *actual reference class*.

Since a scientific theory is a set of factual statements (with a deductive structure) every such theory has a reference class. This class is known or assumed to be nonempty. If the assumption has not yet been substantiated, then the theory itself may point the way to its referents. For example, a theory concerning a hypothetical extinct biological species will be instrumental in the search for fossil evidence relevant to the hypothesis. Should the hypothesis turn out to be false, the actual reference class of the theory would shrink to nought, but the assumed reference class would remain nonempty though indeterminate and idle, at least until further notice.

The reference class of a theory, whether it be the assumed or the actual one, is sometimes called the *ontology* of the theory. This is a misnomer, for an ontology is not a set of things but a philosophical theory concerning the basic traits of the world. Strictly speaking, the *ontology of a scientific theory* is the set of ontological (metaphysical, cosmological) hypotheses presupposed or countenanced by the theory. (See Bunge, 1973b.) For example, the reference class of classical electrodynamics is constituted by the set of bodies and the set of electromagnetic fields. On the other hand the ontology of the same theory is composed of wide ranging generalizations such as "Every thing is either body or field or a compositum of body and field", "The world is a plenum not a collection of atoms in void", "Except at boundaries all properties are continuous", "All properties are lawfully interrelated", and so on. Alternative systems of electrodynamics may or may not have different reference classes. If a change in scientific theory involves a modified reference class then the associated ontology may or may not change. (For example, action at a distance electrodynamics do not involve the field concept and consequently their ontology is closer to Greek atomism than to Aristotle's or Descartes' plenistic cosmologies. On the other hand the exact number of kinds of elementary particle and their precise properties are irrelevant to metaphysics.) One and the same scientific theory is consistent with a multitude of ontologies – all of a feather, though. Although science determines its own metaphysics, it does so only in outline: there is considerable leeway.

The preceding considerations on the relation between the reference class of a theory and its ontologies does not apply to formal science. The reference classes occurring in logic and mathematics are constituted by conceptual objects. For example, the reference class of the propositional calculus is the set of all propositions; number theory is concerned with numbers; topology is about topological spaces – and so on. In general: in formal science $\mathscr{R}$ never points to anything outside formal science. In other words, within formal science $\mathscr{R}$ pairs off constructs to constructs, i.e. $\mathscr{E}(\mathscr{R}) \subseteq C \times C$. To put it another way, we adopt

THESIS 2.1 *If c is a construct in formal science (logic or mathematics), then* $[c] = \overleftarrow{\mathscr{R}}`c \subseteq C$.

This is the postulate of the formal (nonfactual and a fortiori nonempirical) character of logic and mathematics. (Cf. Kraft, 1970.) If the thesis of the autonomy of formal science is accepted then it becomes clear (*a*) why the semantics of logic and mathematics, i.e. model theory (including Tarski's theory of truth), is hardly relevant to the semantics of factual science; (*b*) why logical and mathematical theories are not tested in the laboratory, and (*c*) why logic and mathematics have no associated ontologies – since ontologies are, by definition, theories about *entia* or existents. (If one insists on speaking of the 'ontology of formal objects' then one ought to identify it with formal science not with a branch of philosophy.) However, all this is controversial and will be taken up again, particularly in Ch. 10, Sec. 4.

2.4. *Factual Reference and Object Variable*

Factual items, such as things and events, are conveniently characterized as nonconceptual. To be more precise, we introduce

DEFINITION 2.5 The totality F of *factual objects* is the subset of Ω formed by nonconceptual elements and such that F is disjoint from C:

$$F =_{df} \{x \in \Omega \mid \neg(x \in C)\}.$$

If a concept, statement, or theory refers to one or more factual objects, it will be said to be *factual*. The subrelation $\mathscr{R}_F$ of factual reference pairs constructs off to factual objects, i.e. its extension is contained in the set of construct-fact pairs:

$$\mathscr{E}(\mathscr{R}_F) \subseteq C \times F.$$

This particular concept of reference comes with a particular concept of reference class as characterized by

DEFINITION 2.6 If c is a construct, then the *factual reference class* of c is the set of factual objects referred to by c:

$$c \in C \Rightarrow [c]_F = \overleftarrow{\mathcal{R}}_F{}^{\backprime} c =_{df} \{x \in F \mid \mathcal{R}cx\} \subseteq F.$$

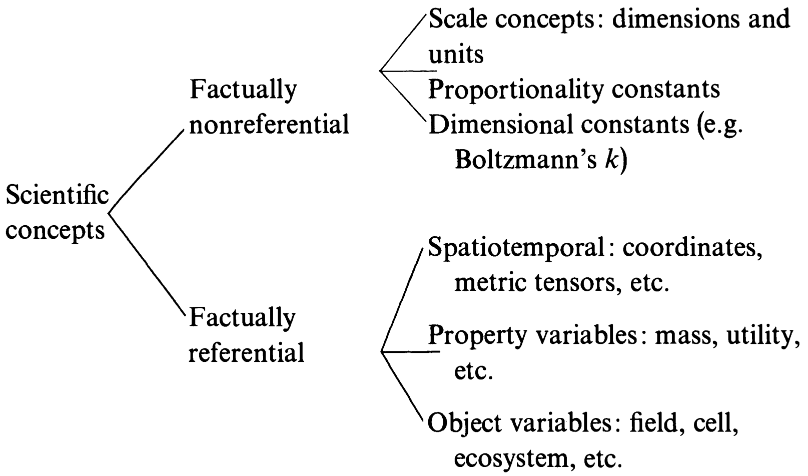
Factual science contains both factually referential concepts, like the one of attention, and concepts with an empty factual reference, such as "2". The same holds for metaphysics or ontology. Having a nonempty factual reference class suffices for a construct to belong either in science or in metaphysics. More explicitly, we state

THESIS 2.2 If $c \in C$ and $\emptyset \subset [c]_F \subseteq F$, *then* c *belongs in factual science or in metaphysics.*

Having a precise mathematical form is no indication of ontological status: a factual concept, i.e. one with factual referents, may have a precise mathematical form while a nonfactual concept may fail to have one. Until one century ago some of the concepts of the infinitesimal calculus were in the latter condition.

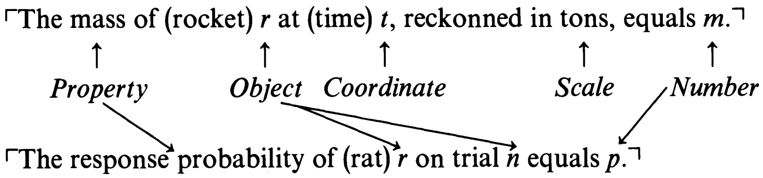
Scientific concepts are often partitioned into constants and variables. Many of them, whether of the first kind or of the second, are quantitative concepts, and most of these are assigned dimensions and units. Thus the dimension value of a speed is LT^{-1}, and a standard speed unit is $cm\ sec^{-1}$. But dimensions and units give no precise indication of semantic status: any ratio of magnitudes with the same dimension value is dimensionless, hence unit free, even though it may concern some concrete object or other. And dimensional constants, like the gravitational constant γ, are not the value of a property of some physical system, so that they are devoid of factual reference even though they occur in law statements (Bunge, 1967b). A suitable semantic partition of the specific or technical concepts of factual science is rather the one shown overleaf.

What we have somewhat improperly called *scale concepts*, such as L and *cm*, have no factual reference. They are ingredients of some other concepts which do have a factual reference. Thus speeds, with dimension value LT^{-1} and reckoned on a suitable unit, are always speeds of something. This something, usually hinted at in the context, is of course the referent of "speed" – car, light wave, or what have you. In contrast, proportionality constants and dimensional constants, whether or not universal (independent of any particular material), are factually nonreferential: they concern nothing in particular. Thus unlike the velocity *of* light or the electric charge *of* the electron, Boltzmann's constant k is not the value of some property of a physical system.



Scientific concepts
Factually nonreferential
Scale concepts: dimensions and units
Proportionality constants
Dimensional constants (e.g. Boltzmann's k)
Factually referential
Spatiotemporal: coordinates, metric tensors, etc.
Property variables: mass, utility, etc.
Object variables: field, cell, ecosystem, etc.

The variables that are factually referential can in turn be classed into: (*a*) *object variables*, referring to things such as photons or persons; (*b*) *property variables*, representing properties of concrete things and relations among them, and (*c*) *spatiotemporal variables*, concerning the basic world framework. Variables of all three kinds are likely to occur in one and the same statement. Examples:



⌜The mass of (rocket) r at (time) t, reckonned in tons, equals m.⌝

⌜The response probability of (rat) r on trial n equals p.⌝
Property
Object
Coordinate
Scale
Number

The object variable (or constant, as the case may be) is not usually indicated in an explicit manner, except when a number of individuals (atoms, rats, nations) are involved, in which case each thing is assigned a numeral, a letter, or some other symbol – as is the case with ⌜P_i is the population of the *i*th country⌝. However, of all the variables the object variables are the most important. Without them the property variables would be baseless and the spatiotemporal variables would be purely mathematical constructs. Indeed, a property other than a purely formal (mathematical) property is a property of some concrete individual or other, whether actual or conjectural. And the spatiotemporal variables occurring in factual science have a similar though less apparent concrete support. Thus in physics every distance value is a distance between two points in some concrete system. And a time interval is the time separation between two events, one of which may be taken as the start of a process. No things, neither properties nor events – nor space or time. However, in the case of spatiotemporal variables it is usually possible and convenient to feign that the spatiotemporal framework is given prior to, and independent of, things and events. This pretense (the hypothesis of absolute space and time), if taken literally, ensues in an illusion of thinglessness, hence of absence of factual reference. The illusion is dispelled by a foundational analysis of spatiotemporal concepts and by the associated metaphysical construction of a relational theory of spacetime, i.e. one according to which space and time are defined on the class of facts. Without such a metaphysical groundwork the semantic analysis of statements containing spatiotemporal variables would be incomplete and misleading. Thus semantics and metaphysics, far from being mutually exclusive, are complementary. (More in Ch. 10, Sec. 4.)

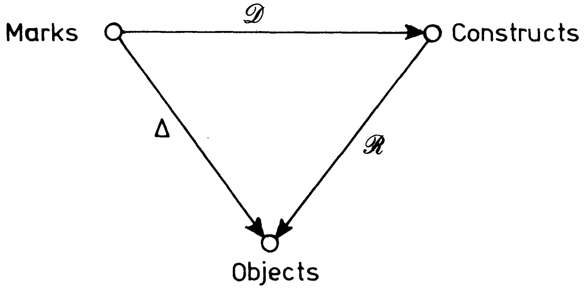
2.5. *Denotation*

Consider the following table.

Linguistic object—$\mathscr{D}$→	*Construct*—$\mathscr{R}$→	*Object*
Proper name	Individual concept	Individual
Predicate letter	Predicate	Property
Declarative sentence	Proposition	Set of facts

The relations $\mathscr{D}$ of designation and $\mathscr{R}$ of reference can be coupled to produce a relation that pairs off signs to objects. This relation, to be designated by Δ, will be construed as the (relational) product of $\mathscr{D}$ and $\mathscr{R}$. That is, we adopt

DEFINITION 2.7 Let Σ^{**} be the set of expressions of a conceptual language. The relation Δ, with domain Σ^{**} and codomain the set $\mathcal{P}(\Omega)$ of classes of objects, and such that $\Delta = \mathcal{D} \cap \mathcal{R}$, is called the *denotation* relation.



When the denotatum of a sign happens to be conceptual, Δ coincides with $\mathcal{D}$. Thus

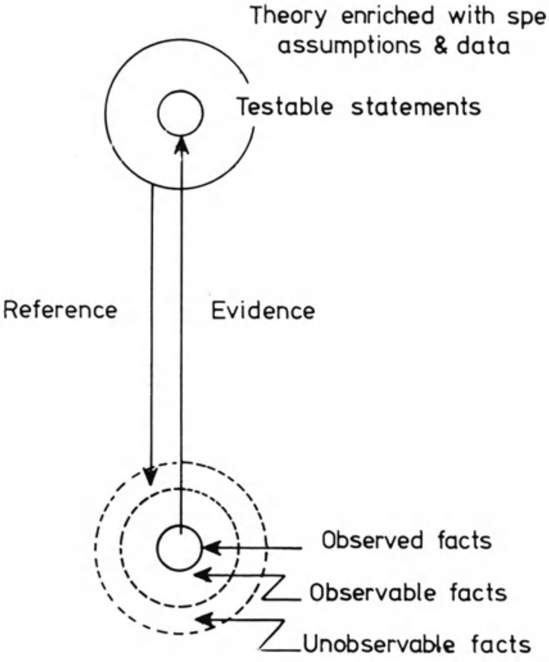
'3' designates "3" = '3' denotes "3".

In other words, within formal science there is no difference between designation and denotation. But as soon as a construct refers to some extraconceptual object the difference becomes patent, and with it the impotence of the semantics of formal science to account for factual science. This concept of denotation has the advantage that it could not possibly be mistaken for the notions of reference and extension, as it so often happens with the presystematic notion of denotation (Geach, 1962). We can now use it although we shall not need it often.

2.6. *Reference and Evidence*

Reference classes should be kept distinct from bodies of evidence or evidence classes. Thus a hypothesis concerning the last glaciation period does not refer to the scars left by glaciers on rocks or to the distribution of certain plant species in our day. Likewise a theory about schizophrenia is not to be mistaken for a theory of the behavioral manifestations of it. This sounds obvious and has been pointed out before (Feigl, 1950), yet it has been controverted and is still being denied by die-hard operationists.

In general, the reference class of a scientific theory does not coincide with the body of evidence relevant to it – which may be nil. The two relations involved herein are radically different: whereas the relation of factual reference pairs off constructs to facts or things, the relation of evidence has the ***subset*** of observable facts as its domain and a subset of the totality of constructs as its codomain. (See Figure 2.1.) In other words, only some facts – namely those accessible to observation – count as evidence for or against a statement that refers to any given class of facts.



Theory enriched with specific assumptions & data
Testable statements
Reference
Evidence
Observed facts
Observable facts
Unobservable facts

Fig. 2.1. Reference is at best the converse of evidence.

And only some of the statements in a theory, even when adjoined specific assumptions and data, are susceptible to empirical test: all others must remain content with vicarious evidence, if any. (For details see Bunge, 1967a, Ch. 5 Sec. 5.6; Ch. 8 Sec. 8.4; Ch. 12; 1973a, Ch. 2; and 1973b, Ch. 10.) In sum *Reference ≠ Evidence*. Consequently *Reference class ≠ ≠ Evidence class*.

The differences between reference and evidence are best understood in relation to any theory concerning entities that are not accessible to direct observation, such as microphysical theories and economic theories. In this case the testability of the theory depends not so much on the size and kind of its reference class as on the existence of auxiliary theories capable of bridging the gap between the hypothetical referents and their observable concomitants, as well as on the experimental techniques capable of switching on and recording such unobservable-observable couplings.

The size of the reference class of a theory is irrelevant to the testability of the theory. Thus a theory explaining a unique process, such as the formation of our Moon, or the crumbling down of the American Empire, can have a sizable body of evidence. On the other hand a theory about an extremely large number of individuals, such as the neutrinos, is bound to have a comparatively poor evidence class due to the weakness of the interactions among neutrinos and other things. In short, the size of the reference class of a scientific theory furnishes no indication whatever about its testability. Conversely, the size of the evidence class of a theory is of little help in determining the reference class.

Consequently it is unnecessary, nay impossible, to elaborate on the testability-reference relation. All we can do is to issue warning notices and to enunciate the following

THESIS 2.3 If a theory is empirically testable then it has a nonempty hypothetical reference class.

The converse is false: hypothesized reference does not ensure testability. (Thus we can imagine, and theorize on, things that are in principle inscrutable, like the soul of plants.) Nonempty reference is then necessary for empirical testability. But it is insufficient. Consequently before we inquire into the possibility of testing a theory we must find out what it refers to. (Imagine trying to design an experiment for testing a hypothesis with no definite reference, such as a conjecture about a possible world.) Consequence for philosophy: *The semantics of science should precede the methodology of science.* This conclusion contradicts the so-called verifiability doctrine of meaning, according to which the meaning (and in particular the reference) of a statement consists in the way it is verified or, more generally, put to the test. This doctrine has constituted a stumbling block in the development of semantics, for it has mixed up questions of semantics, such as those of sense and reference, with problems of methodology, such as that of empirical testability. (Worse: it has left the latter unanalyzed.) Positivist semantics has had its chance and has failed. Give now realist semantics a chance.

2.7. *Misleading Cues in the Search for Referents*

Before taking the trouble to build a theory of reference we should check whether any of the existing views on the matter might help us to spot the referents of any given scientific formula. Let us therefore make a quick – hence necessarily somewhat unfair – review of the most popular opinions on the subject.

(i) *Grammaticalism:* "The denotatum of a sentence is always denoted by the grammatical subject". This view is false if grammatical predicates are regarded as unary, partially true if their actual complexity is taken into account. Thus traditional grammar would tell us that the referent of ⌜Woman is sweeter than man⌝ is the fair sex, while in point of fact the statement refers to both sexes. A suitable enlargement of the notions of grammatical predicate and subject might help us out in the case of ordinary language expressions. But it would be insufficient for spotting the referents of a statement clad in mathematical language: grammar cannot and does not want to attain the fine structure accessible to mathematics. It would be pointless to ask the grammarian to find the reference class of, say, a Gaussian distribution or a differential equation. Only an analysis of the whole theory in which the formula occurs could produce the desired result. And such an analysis, which lies within the scope of the semantics of science, is beyond the scope of grammar – even of the Chomsky type.

(ii) *Psychologism:* "Search for the intentional object, i.e. for the object of consciousness associated with the given construct". This recipe of Brentano's is definitely misleading: one and the same formula can be "read" in different ways by different persons. In other words, the intended referent of a construct depends not only on the construct but also on the person who thinks of it and the circumstances under which he or she is thinking. This is of interest to psychology not to semantics: the latter is concerned with the hypothetical though possibly real referents of constructs.

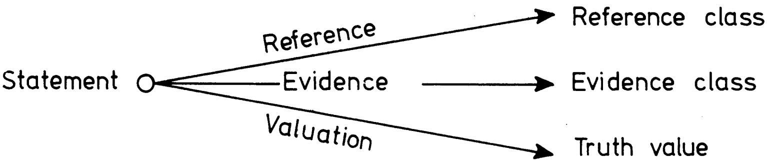
(iii) *Linguistic pragmatism:* "No expression refers by itself: it is only some user who, under definite circumstances, can attach a referent to an expression. Hence the act of referring, not reference, should be the object of semantic analysis". While it is true that expressions have no reference unless someone uses them, there is nothing wrong with abstracting from users and circumstances to speak of the reference class of a construct as a fixed set. Surely scientific theories would not exist unless there existed beings capable of making and using them. But the objectivity of such theories depends on their being assigned reference classes assumed (rightly or wrongly) to consist of real entities. (The concept of semantic objectivity is involved herein. That of methodological objectivity will concern us in Ch. 10, Sec. 1.2.) Paradoxically enough, there is no objectivity without abstraction from users and circumstances. If someone claims that a certain theory concerns *A*'s rather than *B*'s, he is expected to substantiate this claim by analyzing the initial assumptions of the theory rather than his own speech acts. Reference hypotheses must be impersonal and open to public inspection.

(iv) *Classical operationism:* "The meaning (=denotation) of a piece of science is to be sought in the operations aimed at testing it: a formula is meaningless unless the procedures for verifying it are specified." This thesis boils down to the conflation of reference and evidence, criticized in Sec. 2.6. Besides, the operationist criterion does not help us in spotting the hypothetical referents of a predicate, for predicates are not testable. And it is misleading in relation to statements, for it diverts our attention from reference to evidence: from the real thing (e.g. loving) to its observable manifestations (e.g. blushings), from facts to documents about them. Empirical tests must be preceded by reference analyses: without knowing or assuming what a given statement is about we would not know how to put it to the test.

(v) *Frege:* "Statements denote (*bedeuten*) truth values". While names and definite descriptions can denote objects, the denotation (*Bedeutung*) of a statement is either truth or falsity. Thus whereas the description "2^2" denotes the number four, the statement $\ulcorner 2^2=4 \urcorner$ denotes truth, and so does $\ulcorner 2>1 \urcorner$. Consequently

$$(2^2=4)=(2>1)$$

"is a correct equation" (Frege (1891) in Angelelli, p. 132). The ambiguous use of the term 'denotation' and the absurdity it leads to would deserve no mention were it not that this slip has been blown up into a doctrine that has misled many a contemporary semanticist. Moral: Keep reference and truth value separate. (Another: Honor the great man's hits not his misses.) A statement *has* a reference class, may be *supported* (or undermined) by an evidence class, and it may be *assigned* a truth value.



(vi) *Phenomenology:* "Referents are a nuisance: just bracket them out". According to Husserl, to get a direct spiritual vision of an essence (*Wesensschau*) we must discard (*ausklammern*) the external world and drop all previous knowledge of the object. No comment.

Conclusion: The popular views on reference, in particular operationism and Wittgenstein's, do not help us to identify the referents of a construct. Moreover they are misleading. Worse: neither do any of the elaborate and articulate systems of semantics help us out, particularly in relation to scientific constructs. Thus Carnap (1942, 1947), whose work was no doubt exact, elaborate and systematic, did not propose a theory of reference and was hardly interested in our subject. This may have been due to the mistaken impression that reference presents no real problem. Which may be true in the cases of ordinary knowledge and mathematics. But scientific constructs, which dwell between those two covers, do pose a challenge, as we saw in Sec. 1. Let us accept this challenge.

3. THE REFERENCE FUNCTIONS

3.1. *Desiderata*

Consider the table on the next page.

A first point to note is that we are tacitly distinguishing reference from extension. Thus in the 2nd row we state that "Clairvoyance" concerns mind readers and the like without claiming that there are any such

	Construct	Referent(s)
1	Human	Mankind
2	Clairvoyance	Mind readers, soothsayers, etc.
3	Conducting	Bodies
4	The moon is round	Moon
5	The moon is round or the cat is fat.	Moon and cat
6	The moon is round and the cat is fat.	Moon and cat
7	All quarks are charged.	Quarks
8	Nobody has so far observed any quark.	Quarks and people
9	Some people loathe animals.	People and animals
10	Nobody loathes animals.	People and animals

individuals. Moreover, if pressed we might grant that the extension of that predicate is nought, while insisting that its assumed reference class is composed of the individuals who claim to have that ability. Likewise in the 7th row we talk about the hypothetical entities called quarks, which at the time of writing have not been identified in the laboratory: the extension of "Quark" is not known. In short, as a rule $\mathscr{R}(c) \neq \mathscr{E}(c)$, where $\mathscr{R}$ and $\mathscr{E}$ designate the reference and the extension functions respectively. In this we follow Buridan (cf. Geach, 1962).

Secondly, it can be observed that reference is rather insensitive to the propositional connectives, i.e. to the gross propositional structure of a statement. Look at lines 5 and 6: the disjunction and the conjunction of two given statements are assigned the same referents. And lines 9 and 10 suggest that a statement and its negate should be assigned the same referents – which is reasonable since they are about the same things. Finally, lines 7 and 8 suggest that a theoretical statement should not be mistaken for a pragmatic one: while the former is supposed to have an objective reference, the latter is bound to concern, at least partly, the cognitive subject.

The above example and others suggest that a theory of reference should satisfy the following desiderata.

*D*1 The theory should define at least one reference function, not just a relation, if it is to enable one to compute the reference class of a complex predicate or formula out of the assumed reference classes of its components.

*D*2 The range of the reference function(s) should be a set of sets rather than the collection Ω of objects, since a single construct may concern a whole class of things.

*D*3 The reference class of a statement and of its negate should be the same.

*D*4 The reference class of an arbitrary propositional compound should equal the union of the reference classes of the components.

*D*5 The reference class of a relation should equal the field of the latter.

The functions to be introduced in the next subsection will prove to satisfy the preceding desiderata.

3.2. *Principles and Definitions*

We need two reference functions, one for predicates, the other for statements. These two types of construct are related in the following way (cf. Ch. 1, Sec. 2.2). An n-ary predicate P is a function

$$P: A_1 \times A_2 \times \cdots \times A_n \to S$$

from n-tuples of objects (individuals) to statements, such that the value of P at $\langle a_1, a_2, \ldots, a_n \rangle$ in $A_1 \times A_2 \times \cdots \times A_n$ is the atomic statement $Pa_1 a_2 \ldots a_n$ in S. The reference function for predicates will be defined on a set of predicates, and the one for statements will be defined on the set of statements formed with those predicates. The former is introduced by

DEFINITION 2.8 The *reference class of a predicate* is the collection of its arguments. More precisely, let $\mathbb{P}$ be a family of n-ary predicates with domain $A_1 \times A_2 \times \cdots \times A_n$. The function

$$\mathcal{R}_p : \mathbb{P} \to \mathcal{P}\Big(\bigcup_{1 \leqslant i \leqslant n} A_i \Big)$$

from predicates to the power set of the union of the cartesian factors of the domains of the former is called the *predicate reference function* iff it is defined for every P in $\mathbb{P}$ and

$$\mathcal{R}_p(P) = \bigcup_{1 \leqslant i \leqslant n} A_i .$$

Example 1 $\mathcal{R}$(Mutating) = Organisms. *Example 2.* Define a binary relation $<$ on some set A. Then the reference class of $<$ is A. *Example 3*. Let $F: A \rightarrow B$ be a function. Since F is a particular case of a relation on $A \times B$, $\mathscr{R}_p(F) = A \cup B$.

DEFINITION 2.9 Let $\mathbb{P}$ be a family of n-ary predicates with domain $A_1 \times A_2 \times \cdots \times A_n$ and let S be the totality of statements formed with them. The function

$$\mathscr{R}_s : S \rightarrow \mathscr{P}\Big(\bigcup_{1 \leqslant i \leqslant n} A_i \Big)$$

is called the *statement reference function* iff it is defined for every s in S and satisfies the following conditions:

(i) The referents of an *atomic statement* are the arguments of the predicate concerned. More precisely, for every atomic formula $Pa_1 a_2 \ldots a_n$ in S

$$\mathscr{R}_s(Pa_1 a_2 \ldots a_n) = \{a_1, a_2, \ldots, a_n\}.$$

(ii) The reference class of an arbitrary *propositional compound* equals the union of the reference classes of its components. More exactly, if $s_1, s_2, \ldots, s_m$ are statements in S and if ω is an m-ary propositional operation,

$$\mathscr{R}_s(\omega(s_1, s_2, \ldots, s_m)) = \bigcup_{1 \leqslant j \leqslant m} \mathscr{R}_s(s_j).$$

(iii) The reference class of a *quantified formula* equals the reference class of the predicate occurring in the formula. More explicitly, if P is an n-ary predicate in $\mathbb{P}$, and the Q_i, for $1 \leqslant i \leqslant n$, are arbitrary quantifiers, then

$$\mathscr{R}_s((Q_1 x_1)(Q_2 x_2) \ldots (Q_n x_n) Px_1 x_2 \ldots x_n) = \mathscr{R}_p(P).$$

Example 1. $\mathscr{R}_s$(Venus is larger than Mars) = {Venus, Mars}.

Example 2. $\mathscr{R}_s(p \,\&\, q) = \mathscr{R}_s(p \vee q) = \mathscr{R}_s(p) \cup \mathscr{R}_s(q)$.

Example 3. $\mathscr{R}_s$(All humans are mammals) = Animal Kingdom.
More on this in the next subsection and in Sec. 5.2.

The relations among the various sets and functions involved in the preceding definitions are summarized in the diagram on the next page.

$$\begin{tikzcd}
\text{Predicate } P \arrow[r, "\mathcal{R}_p"] & \bigcup\limits_{1\leqslant i\leqslant n} A_i \\
\text{Domain } A_1\times A_2\times\cdots\times A_n \arrow[r] & \text{Statement family } S \arrow[u, "\mathcal{R}_s"']
\end{tikzcd}$$

Remark 1 Constructs other than predicates and statements, such as the individual x and the set y occurring in the statement $\ulcorner x\in y\urcorner$, are assigned no referents in our theory. The reason is that individuals and collections thereof are to function as referents themselves. *Remark 2* According to Definition 9i, $\ulcorner Pa\urcorner$ is taken to concern the object named a, not the name 'a'. One might be tempted to introduce a new symbol, say 'a', for the nominatum of a. But this would start an infinite regress. *Remark 3* Our analysis of reference is applicable in all contexts, whether or not "extensional" (truth functional). For example,

$$\mathcal{R}(\text{Smith knows that } p)=\{\text{Smith}, p\}.$$

A binary epistemic predicate E, such as "knowing", "believing", or "doubting", will be analyzed as a function

$$E\colon \text{People}\times\text{Statements}\rightarrow\text{Statements},$$

whence

$$\mathcal{R}(E)=\text{People}\cup\text{Statements}.$$

There is nothing opaque about "oblique" reference if analyzed as multiple rather than single. More on "intensional" contexts in Ch. 4, Sec. 1.3. *Remark 4* Our definitions of the reference functions are necessary but not sufficient for a correct identification of the referents of a construct. A precise identification requires some fund of knowledge and it depends upon one's metaphysics. Consider, indeed, the statement that the weather is fine. The *ostensive* (or manifest or superficial) referent of this statement is the weather. But the weather is not a thing: it is a state of a thing. The *deep* (or hidden or genuine) referents of the given statement are the terrestrial atmosphere and mankind. In fact the given proposition may be construed as short for ⌜The atmosphere is in a state that suits humans⌝. The metaphysical principle behind this analysis of the given proposition is that the referents of factual constructs are concrete systems (things). For a radically different view concerning the relations of semantics to metaphysics, see Shwayder (1961).

3.3. *Some Consequences*

We proceed to drawing a few consequences from our Definitions 8 and 9 of the reference functions for predicates and for statements.

COROLLARY 2.1a The reference class of the equality (inequality) relation equals the set A on which $=$ is defined:

$$\mathcal{R}_p(=)=\mathcal{R}_p(\neq)=A.$$

COROLLARY 2.1b The reference class of a statement of inequality (equality) is constituted by the individuals concerned. That is, if $a, b \in A$, then

$$\mathcal{R}_s(a\neq b)=\{a, b\}, \qquad \mathcal{R}_s(a=b)=\{a\}.$$

COROLLARY 2.2a The reference class of the membership relation $\in$ equals the universe U of sets on which it is defined:

$$\mathcal{R}_p(\in)=U.$$

COROLLARY 2.2b The reference class of a statement of class membership is constituted by the relata concerned:

$$R_s(a\in A)=\{a, A\}$$

Remark. This last corollary gives rise to an apparent paradox. A membership statement is equivalent to a predicative statement:

$$Pa \quad \text{iff} \quad a\in\mathcal{E}(P), \quad \text{where} \quad \mathcal{E}(P)=\{x \mid Px\}$$

is the extension of the predicate. But $\mathcal{R}_s(Pa)=\{a\}\neq\mathcal{R}_s\,(a\in A)$. That is, *equivalents may have different reference classes*. And why should they unless equivalence be mistaken for identity or reference class for extension? ⌜Pa⌝ is equivalent to but not identical with ⌜$a\in\mathcal{E}(P)$⌝, if only because the predicates involved in each statement are not only of different rank and different type: while P applies to individuals, $\in$ relates individuals to sets and thus mixes objects of different types. Moral: The reference class we assign to a statement depends on the way we analyze the latter.

COROLLARY 2.3a The reference class of a set relation equals the union of the sets involved: If ρ is a binary relation between the sets A and B, then

$$\mathcal{R}_p(\rho)=A\cup B.$$

COROLLARY 2.3b The reference class of a statement of class relation consists of the classes involved:

$$\mathcal{R}_s(\rho AB)=\{A,B\}.$$

In particular

$$\mathcal{R}_s(A\subseteq B)=\{A, B\}$$

COROLLARY 2.4a The reference class of the conditional predicate $P\Rightarrow Q=\neg P\vee Q$ equals the domain shared by P and Q. More explicitly: if $P{:}A\rightarrow S$ and $Q{:}B\rightarrow S$ are unary predicates in $\mathbb{P}$, then because $P\Rightarrow Q{:}A\cap B\rightarrow S$,

$$\mathcal{R}_p(P\Rightarrow Q)=\mathcal{R}_p(P)\cap\mathcal{R}_p(Q)=A\cap B.$$

COROLLARY 2.4b The reference class of a universal conditional equals the intersection of the reference classes of the predicates involved:

$$\mathcal{R}_s((x)\,(Px\Rightarrow Qx)=\mathcal{R}_p(P)\cap\mathcal{R}_p(Q)).$$

Example The reference class of ⌜All ravens are black⌝, as well as of its negate, is the class of birds not that of black things nor any other one. Indeed, the predicate "$R\Rightarrow B$" is defined on the intersection of the domains of R and B, i.e. on $\mathcal{R}_p(R)$, because the domain of R is Birds and that of B is Things. More in Sec. 5.2.

COROLLARY 2.5a The reference class of a tautological predicate equals the union of the reference classes of the component predicates, whence it is not generally empty. In particular

(i) $\mathcal{R}_p(P\vee\neg P)=\mathcal{R}_p(P)$,
(ii) $\mathcal{R}_s((P)_{P\in\mathbb{P}}(P\vee\neg P))=\bigcup_{P\in\mathbb{P}}\mathcal{R}_p(P)$.

COROLLARY 2.5b The reference class of a tautological statement equals the union of the reference classes of the predicates involved, whence it is not generally empty. In particular

(i) $\mathcal{R}_s((x)(Px \vee \neg Px)) = \mathcal{R}_p(P)$,
(ii) $\mathcal{R}_s((P)_{P \in \mathbb{P}}\,(x)(Px \vee \neg Px) = \bigcup_{P \in \mathbb{P}} \mathcal{R}_p(P)$.

Remark 1 The tautology in (i) is *valid in the domain* of P, while the one in (ii) is valid in the total domain of the predicate family $\mathbb{P}$, i.e. *valid* without further ado. *Remark 2* Reference class and extension coincide only in the case of tautological predicates, or of tautologies, involving unary predicates. This coincidence seems to be an important source of the common confusion between reference class and extension.

COROLLARY 2.6a The reference class of a predicate and its negate are the same: If P is in $\mathbb{P}$, then

$$\mathcal{R}_p(P) = \mathcal{R}_p(\neg P).$$

COROLLARY 2.6b The reference class of a statement and of its denial are the same: if p is in S, then

$$\mathcal{R}_s(p) = \mathcal{R}_s(\neg p).$$

Example $\mathcal{R}_s$ (Some people are cruel) $= \mathcal{R}_s$ (Nobody is cruel) = People.

COROLLARY 2.7 The reference class of a singular tautological statement, or of its negate (the corresponding contradiction), equals the union of the reference classes of its component. In particular

$$\mathcal{R}_s(p \vee \neg p) = \mathcal{R}_s(p \mathbin{\&} \neg p) = \mathcal{R}_s(p) = \mathcal{R}_s(\neg p).$$

Remark 1 It is often claimed that analytic statements do not inform about the world because they are not about it. While the claim is right the reason given in support of it is dubious. ⌜Antarctica is cold or it is not cold⌝ concerns Antarctica, both for common sense and on our semantics, even though it "says" nothing, i.e. its factual content is nil. It is for the latter reason, not because of its alleged lack of reference, that the tautology is not affected by the recent finding that Antarctica was not cold during the Triassic. The same holds for analytically false statements: if singular they refer even if they do not inform. *Remark 2* Likewise for tautological predicates: since they hold for anything they refer to everything. *Remark 3* The preceding consideration would seem to contradict the thesis of the autonomy of logic espoused in Sec. 2.3. It does not, for what is peculiar to tautological singular statements is their *validity irrespective of their reference*, hence the impossibility of checking them against experimental evidence. *Remark 4* Since any given tautology is equivalent to every other tautology, it would seem that Corollary 7 leads to contradiction. It does not because we have refrained from requiring that equivalents be coreferential. Recall the comment to Corollary 2b. *Remark 5* The preceding remarks show the need for a concept of strong equivalence, or equivalence both syntactical and semantical. A possible definition is this: Two statements are said to be *strongly equivalent* iff they are equivalent and have the same referents. However, we shall not pursue this matter here. *Remark 6* Our reference functions refer to (are defined on) predicates and statements not on signs such as predicate letters and sentences. While on Definitions 8 and 9 every predicate or statement is referential (even if it concerns the null individual), not every expression denotes. A nonsense sign such as '&(%+' presumably occurs in no conceptual language, hence it designates nothing, whence it denotes nothing. (But of course it may suggest something – e.g. that the linotype ran amok – and may thus have a pragmatic meaning.) Even sophisticated signs composed of individually significant marks in a way that looks well formed may fail to designate constructs. (Two famous frauds are '1/0' and '$\{x \mid \neg(x \in x)\}$'. These are not, as is sometimes held, irreferential concepts: they are just nonconceptual signs.) *Remark 7* Even logical predicates refer – namely to constructs. For example, the reference class of the conjunction is the set of all the statements on which it is defined. This follows from Definition 8 applied to & construed as a certain function $\&: S \times S \rightarrow S$.

What follows will not depend critically on the precise formulation of our definitions of $\mathscr{R}_p$ and $\mathscr{R}_s$: in most cases it will suffice to assume that these functions are somehow well defined. Moreover, in the sequel we shall hardly distinguish between these two functions, for we shall be concerned with constructs in general.

3.4. *Context and Coreference*

The concepts of reference functions and reference class allow us to elucidate a number of other concepts. For example the following notions.

DEFINITION 2.10 The ordered triple $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$ is called a (conceptual) *context* (or *frame*) iff S is a set of statements in which only the predicate constants in the predicate family $\mathbb{P}$ occur, and the reference class of every P in $\mathbb{P}$ is included in the universe or domain $D \subseteq \Omega$.

DEFINITION 2.11 c is called an *individual construct* in the context of frame $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$ iff (i) c is either in $\mathbb{P}$ or in S, and (ii) the reference class of c is a unit set or singleton.

DEFINITION 2.12 c is called a *universal construct* in the context or frame $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$ iff c is in $\mathbb{P}$ or in S but is not an individual construct.

Remark The preceding definitions of individual and universal relativize these concepts to a definite conceptual context or frame. This is as it should be, for one and the same object may be regarded as an individual in a given context and as a set in another. And a property may concern every individual in a class but not all individuals. This gives some precision to the classical distinction formulated by the Philosopher: "By the term 'universal' I mean that which is of such a nature as to be predicated of many subjects, by 'individual' that which is not thus predicated. Thus 'man' is a universal, 'Callias' an individual" (*On Interpretation*, Ch. 7).

DEFINITION 2.13 c is said to be an *individual construct* iff c is an individual construct in every context.

DEFINITION 2.14 c is said to be a *universal construct* iff c is a universal construct in every context.

Whether these last two concepts have any application must be left to other disciplines to find out. (Perhaps their only use is to occur in the conjecture that there are no such constructs.) Let us now turn to the comparison of reference classes.

DEFINITION 2.15 Two constructs are called *coreferential* (or *equirefetial*) in a context $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$ iff (i) they belong to the context $\mathbb{C}$ and (ii) they have the same reference class. Symbolically:

$$\text{If } c \text{ and } c' \text{ are in } \mathbb{C}, \text{ then } c \sim_r c' =_{df} \mathcal{R}(c)=\mathcal{R}(c').$$

Remark The relativization to a context is not really needed if one proceeds carefully – i.e. with hindsight. For example, in the context of nonrelativistic physics the concepts of mass and charge are equireferential: both concern only bodies. But in relativistic physics they cease to be coreferential (although they are still referentially commensurable). For, although the two concepts concern bodies, that of mass concerns now also reference frames, and it is possible to make certain fields serve as frames. Of course two different concepts of mass are involved in the two contexts even though the two are usually designated by the same word. Should this be overlooked, the relativization to a context would avoid further confusion. (More in Sec. 4.2.)

As is clear from Definition 15, the relation $\sim_r$ is an equivalence relation. As such it enables us to form equivalence classes. Thus it allows us to form

DEFINITION 2.16 The set $[c]_{\mathbb{C}}$ of *coreferentials* of a given construct c in a context $\mathbb{C}$ is

$$[c]_{\mathbb{C}} =_{df} \{c' \in \mathbb{C} \mid c' \sim_r c\}.$$

Example All of the theories of solids, no matter how different, have the same reference class, namely the set of solid bodies.

Being an equivalence relation, equireference induces a partition of the totality C of constructs, i.e. an exhaustive division of C into mutually disjoint classes of coreferentials. This partition or collection of equivalence classes is the quotient set of C by $\sim_r$, or $C/\sim_r$ for short. We may call $\Pi = C/\sim_r$ the *referential partition* of the conceptual universe. This concept allows us to elucidate the intuitive concept of semantic homogeneity of a theory (Bunge, 1967a, Ch. 7) by means of

DEFINITION 2.17 A theory will be said to be *referentially homogeneous* iff it is included in an element of the referential partition $C/\sim_r$, i.e. if its constructs are all in one of the equivalence classes of equireferentials.

DEFINITION 2.18 A theory will be said to be *referentially heterogeneous* iff it is not referentially homogeneous.

Example Psychology and physics are referentially heterogeneous. On the other hand, according to the identity theory, psychology and

neurology are referentially homogeneous since both concern animals.
Let us next specialize the reference functions.

4. FACTUAL REFERENCE

4.1. *The Factual Reference Class*

In the so-called empirical sciences we are particularly interested in a special concept of reference, namely reference to concrete (though perhaps hypothetical) existents. We therefore introduce

DEFINITION 2.19 Let $\mathscr{R}(c)=A_1\cup A_2\cup\ldots\cup A_f\ldots\cup A_n$ be the reference class of a construct c, where the A_i for i between 1 and $f<n$ are sets of non-conceptual items, i.e. such that $A_i\not\subset C$. Then the *factual reference class* of c is the union of the classes of factual items:

$$\mathscr{R}_F(c)=A_1\cup A_2\cup\ldots\cup A_f\subseteq\mathscr{R}(c).$$

Example 1 $\mathscr{R}_F$ (Light rays are represented by straight lines) = Light rays. The total reference class includes also the set of straight lines. *Example 2* Let $f: A\rightarrow B$ be a function from a set A of concrete systems to a set B of numbers. For example, f could represent the relative dilation of bodies. Then $\mathscr{R}_F\ (f)=A$, whereas $\mathscr{R}_p\ (f)=A\cup B$. *Example 3* Let $g: A\times B\rightarrow R$, where A is a set of concrete systems, B the set of conceivable scale-cum-unit systems associated to the magnitude g, and R the set of real numbers. Since B is conventional, it is included in the class of constructs, so that we are left with $\mathscr{R}_F(g)=A$.

Not all the constructs occurring in factual science have a factual reference. For one thing the logical concepts, such as "not" and "all", have no such reference. Nor do scale concepts, proportionality constants, and dimensional constants have referents (recall Sec. 2.4). It will therefore be convenient to coin a name for such constructs. The following conventions will do.

DEFINITION 2.20 A construct which is either tautologous or has an empty factual reference class is said to be *factually vacuous*.

DEFINITION 2.21 A construct which is not factually vacuous, i.e. which is neither tautologous nor has a void factual reference class, is called *factual*.

Example 1 ⌜1 m = 100 cm⌝ is factually vacuous. *Example 2* The state function ψ is a factual construct because it concerns physical entities. *Example 3* The semantic assumption ⌜ψ represents the state of an individual microsystem⌝ is a factual construct because it is nontautologous and includes the factual concept ψ.

Let us now restrict the concept of a context introduced by Definition 10:

DEFINITION 2.22 The triple $\mathbb{C}_F = \langle S, \mathbb{P}, D \rangle$ is called a *factual context* iff (i) it is a context and (ii) $\mathbb{P}$ includes a nonempty subset of factual predicates.

DEFINITION 2.23 Any context that fails to be factual is called a *formal context*.

DEFINITION 2.24 Let $\mathbb{C}_F = \langle S, \mathbb{P}, D \rangle$ be a factual context. The predicate in $\mathbb{P}$ with the largest factual reference class is called *maximal* in $\mathbb{C}_F$. Symbol: $P_{\max}$.

Remark 1 Logic, mathematics and semantics are formal contexts since they deal with constructs. On the other hand history, linguistics, epistemology and metaphysics are factual contexts. Mythology, religion and science fiction are factual contexts too. Their extension or domain of truth is another matter. *Remark 2* Definition 23 effects a dichotomy in the set of contexts. However, the factual/formal dichotomy is not universally accepted: to some even mathematics is *au fond* factual or empirical, while a few hold science to be mathematics with a narrow scope. The semantic method for settling this issue in particular cases is to perform a semantic analysis of the basic concepts of the context in dispute. If at least one such concept has a factual (nonconceptual) reference class then the context is factual – otherwise formal. This semantic analysis can be checked and supplemented by a methodological analysis: if at least one validation procedure is empirical (e.g. experimental) then the context is factual. But of course for such an empirical test to be possible the context must be factual to begin with. (Caution: computer simulations do not qualify as empirical even if they bear on factual contexts.) *Remark 3* We saw in Sec. 3.3 that singular tautologies, like ⌜Antarctica is cold or not cold⌝, can have a factual referent. It would seem then that logic is a factual context after all, contrary to our previous contention. Not so, because logic is concerned with the whole of the conceptual universe C, in particular with statements – not with their referents. (E.g. the reference class of a propositional connective is the class of statements on which it is defined.) And, as we saw in Sec. 2.1, the reference relation is not generally transitive.

Of all the factual contexts the most interesting ones, because the richest, are the factual sciences. A *factual science* is a science with a factual reference, i.e. it is a factual context capable of being tested in accordance with the scientific method. This quick characterization of a factual science is of a methodological character. A strictly semantic definition of science seems to be out of the question: a precise sense and a factual reference are necessary but insufficient to have a science, and a high degree of truth, though desirable, is neither necessary nor sufficient. For this reason we do not give here a formal definition of factual science: this is a matter for methodology (cf. Bunge, 1967a). But once we have settled for some characterization of factual science we can use our semantics to shed some light on certain aspects of the former. First of all the concept of subject matter of a scientific subject:

DEFINITION 2.25 Let $\mathscr{S}_F = \langle S, \mathbb{P}, D \rangle$ be a factual science. Then the *domain* (or *subject matter*) of $\mathscr{S}_F$ equals the factual reference class of the maximal predicate $P_{\max}$ in $\mathbb{P}$:

$$\mathit{Domain}\,(\mathscr{S}_F) = \mathscr{R}_F\,(P_{\max}).$$

Needless to say, a science need not have a homogeneous domain in the sense of Definition 3 in Sec. 2.3. And a science need have no precise deductive structure: it can be just a context, which is something slightly more structured than a mere set of statements, in that a given family of predicates is shared.

And now to the central referent of our semantics:

DEFINITION 2.26 T is a *factual theory* iff (i) T is a theory and (ii) T contains factual predicates.

We leave metamathematics, in particular the theory of theories, the elucidation of the concept of a theory. Our present concern is with the objects a factual theory is about:

DEFINITION 2.27 The *factual reference class*, or *universe of discourse*, of a theory T equals the reference class of the maximal factual predicate $P_{\max}$ in T:

$$\textit{Domain}\ (T)=\mathcal{R}_F\ (P_{\max})$$

Remark 1 Since theories in logic and pure mathematics contain no factual predicates, their factual reference classes are empty. *Remark 2* The factual reference class of a scientific theory is constituted by possibles not just actuals. For example, the genetics of a given biological species is about all possible genotypes of that species – only a tiny fraction of which are ever actualized. *Remark 3* The notion of a possible individual, or a possible factual item, is sometimes regarded as ghostly and at other times in need of modal logic. Yet it is not ghostly, for science handles it every day: thus mechanics is the study of the possible motions of possible bodies. And the concept cannot be characterized by modal logic, which is too poor a theory. But is easily defined in our semantics, namely thus: The factual item x is *possible according to the theory T* iff x belongs to the factual reference class *Domain* (T) of T. (In science we have no use for the absolute modalities handled by modal logics.)

4.2. *The Factual Reference Class of Scientific Theories*

The determination of the reference class of a factual theory is far from being a straightforward business. Scientific theories come usually unkempt: they are more or less haphazard collections of formulas accompanied by extrasystematic remarks. These hints are ambiguous and are often loaded with an obsolete philosophy, namely, operationism, which forces the observer, or experimenter, into every reference class. Our problem has a solution only if the theory is axiomatized with respect to both its form and its reference. We shall henceforth assume that the scientific theories which are the object of our analysis have been axiomatized in both respects. Not that this is necessary in order to use the concept of factual reference of a theory, but it is needed for computing the reference class with precision.

If the theory is formal, its axioms will determine the structure of the basic (primitive or undefined) concepts as well as their interrelations. For example, if one of the basic concepts of the theory is a binary associative operation on a certain set, then one of the axioms of the theory will state this much. But if the theory is factual such a formal characterization will be insufficient: it must be supplemented with semantic assumptions indicating the nature of the referents – whether they are seeds, or birds, or perhaps both. In other words, a factual theory will be a formal structure enriched with a set of assumptions concerning the referents of its basic concepts. In a nutshell, we stipulate

DEFINITION 2.28 T is an *axiomatic factual theory* iff (i) T is a factual theory (according to Definition 26), (ii) T is axiomatized and (iii) every basic (undefined) factual concept of T is explicitly assigned a definite nonempty reference class by some of the axioms of T.

This is the kind of axiomatics Hilbert and Bernays (1968) called *inhaltlich*, as opposed to *formal* axiomatics, which abstracts from the specific content of the original theory. An axiomatic factual theory is determined by both its formal (mathematical) axioms and by the nonformal (semantical) assumptions of the theory – roughly those that indicate the referents of the basic predicates in the theory. The first part of the preceding statement is a truism from the theory of deductive systems (Tarski, 1956, Ch. xii). The second part will be proved. As to the first part: calling $\mathcal{A}$ the axiom base of T, we symbolize that statement in the standard way

$$T = \mathcal{C}n(\mathcal{A})$$

which can be read: 'an axiomatic theory is the totality of consequences of its axioms'. In addition, the (nonformal) axioms of a factual theory determine not just the referents of its factual predicates but the reference class of the theory as a whole (as characterized by Definition 27). To show this we must start by construing the concept of an axiom base as the conjunction of all the axioms of the theory. We shall limit ourselves to a finitely axiomatizable theory, but infinitary logic can handle the infinite case. We stipulate then

DEFINITION 2.29 Let A_i, with $1 \leqslant i \leqslant n$, be the n axioms of a theory T. Then the *axiom base* of T is

$$\mathcal{A}(T) =_{df} \bigwedge_{i=1}^{n} A_i .$$

We can now state

THEOREM 2.1 Let $\mathscr{A}$ be the axiom base of a theory T. Then

$$\mathscr{R}(T)=\mathscr{R}(\mathscr{C}n(\mathscr{A})).$$

Proof sketch In an axiomatic theory no theorem contains predicates other than those occurring in its axiom base. In other words, every concept in an axiomatic theory is either defining (primitive) or defined. Hence deduction cannot change the kind or number of referents assigned the basic factual predicates.

THEOREM 2.2 The factual reference class (or universe of discourse) of an axiomatic theory equals the union of the factual reference classes of its axioms:

If $\mathscr{A}(T)=\bigwedge_{i=1}^{n} A_i$, then $\mathscr{R}_F(T)=\bigcup_{i=1}^{n} \mathscr{R}_F(A_i)$.

Proof By Theorem 1, Definition 9, and Definition 19.

Remark 1 The last theorem is the most important in our theory of reference. It may be called the theorem of *reference conservation* or reference invariance under deduction. It constitutes a partial justification of the dictum that the conclusions must be "contained" in the premises – a dictum that, as we shall presently see, is not generally valid. *Remark 2* The preceding theorem is far from trite: in fact it fails for nonaxiomatic theories. Indeed, in the latter new predicates, totally alien to the basic ones, can be adjoined at any step. This adjunction can be made in either of two ways: via the introduction of new assumptions or via deduction with the help of the principle of addition of formal logic. The former move is obvious: informal theories are forever under construction or repair. The second move is less obvious and deserves special notice. *Remark 3* Let t be a formula of an informal theory T. By the principle of addition, $t \vdash t \vee u$, where u is an arbitrary statement, i.e. one that need bear no semantical relation to t. In fact, as far as logic is concerned, the reference classes of t and u need not overlap, let alone coincide – i.e. t and u may fail to be coreferential. Thus t could be about stars and u about frogs – and yet u could be counted among the members of the open theory T. In general: in an open context, the reference of a consequence may be wider than that of the premises. This violates the principle of the Aristotelian organon according to which "the indemonstrable premises of a science (...) must be within one genus with its conclusions" (*Posterior Analytics*, Bk. I, Ch. 28, 88). If this principle, tacitly obeyed in most cases, is surrendered then anything can be claimed to be relevant to anything else. The result will be confusion or error or both. Such a move, hardly avoidable in informal theories (which are open contexts), is automatically precluded in axiomatic theories, which are closed contexts. While the former are semantically loose or open, hence both perfectible and corruptible, axiomatic theories are semantically tight or closed. This last expression is elucidated by

DEFINITION 2.30 A set S of statements will be said to be *semantically tight*, or *closed*, iff S has the same referents as its logical consequences, i.e. if

$$\mathcal{R}(S)=\mathcal{R}(\mathcal{C}n(S)).$$

Theorem 1 can now be restated in this way: *Axiom systems are semantically closed.* For this reason the axiomatic format, though usually unsuitable during the early construction stage, is mandatory for investigating the semantics of a theory: *it is only in axiomatic contexts that we know exactly what we are talking about.* This is because axiomatization involves fixing in advance the set of basic predicates, hence the universe of discourse, to be admitted in the given context. Thus axiomatization suffices to get conclusions that are semantically *relevant* to the premises. Should it be objected that the price to pay for semantic coherence or relevance – namely axiomatization – is too high, it may be rejoined as follows. First, price is irrelevant. Second, axiomatization is a means for attaining a number of other goals as well (see Bunge, 1973b). Third, the alternative procedure for trying to secure relevance is far more expensive than axiomatization, as it consists in adopting some system of relevant implication (cf. Anderson, 1972). This change in logic involves not only new rules of inference but also modalities – none of which seem to be called for by scientific work. And, despite commanding such a high price, this alternative procedure does not really guarantee semantic relevance, as it offers no criteria for it and it places no restrictions upon the principle of addition.

If we wish deduction to preserve reference even outside semantic contexts then we must keep a permanent watch on the consequences and screen out all those that violate semantic closure, i.e. that are not referentially germane to the premises. (One of the rare occasions on which such a precaution is taken explicitly, is in stating Craig's interpolation theorem. A standard formulation of this theorem is as follows. Let p and q be formulas such that $\vdash p \Rightarrow q$. Then there exists a third formula r, *containing only predicates occurring in p and q*, such that $\vdash p \Rightarrow r$ and $\vdash r \Rightarrow q$.) The very choice of premises in an argument should be regulated by the unspoken yet time honored *principle of relevance*: The premises should be not only mutually compatible in the formal sense but also semantically congenial. This principle of argumentation limits the range of applicability of the so called rule of augmentation of premises, according to which if p entails q then q follows also from p conjoined with an arbitrary premise r. This rule holds only if the additional premise is either idle or both formally and semantically coherent with the original premises. Once the initial assumptions have been chosen we may use a deduction technique that complies automatically with the requisite of semantical closure and has the additional advantage that it does not require guessing the conclusions beforehand, so that it may be used by a nonmathematician – e.g. a computer. (See, e.g., Hilbert and Ackermann, 1950, p. 24.) This *mechanical procedure for extracting reference preserving conclusions* is as follows. (i) Conjoin all the assumptions; (ii) expand the conjunction in conjunctive normal form, i.e. as a conjunction of binary disjunctions; (iii) detach every conjunct and every conjunction of such. The detached formulas constitute the desired set, i.e. the maximal set of consequences compatible with reference conservation. This subset of consequences is semantically closed and finite, hence a smallish subset of the infinite set of all the consequences of the given premises. We cannot have both all the infinitely many consequences of a finite set of premises, and semantical closure.

Our Theorem 2 of reference conservation allows us to determine the reference class of any factual theory cast in an axiomatic format and consequently it enables us to compare theories as to their domains. In fact the theorem backs up the following conventions.

DEFINITION 2.31 Let T and T' be two axiomatic factual theories. Then T and T' are said to be *referentially commensurable* iff their reference classes overlap, i.e. if

$$\mathscr{R}_F(T) \cap \mathscr{R}_F(T') \neq \emptyset.$$

DEFINITION 2.32 Let T and T' be two axiomatic factual theories. Then T' is said to be *referentially bulkier* than T iff

$$\mathscr{R}_F(T') \supseteq \mathscr{R}_F(T).$$

Example 1 Particle mechanics and the theory of electromagnetic fields in a vacuum are incommensurable: they are not about the same things. *Example 2* Electrodynamics and mechanics are referentially commensurable: they have common referents – bodies. *Example 3* Relativistic mechanics is referentially bulkier than nonrelativistic mechanics because, unlike the latter, it concerns both bodies and electromagnetic fields. Hence they are referentially commensurable. Consequently they are comparable – *pace* Kuhn and Feyerabend.

Remark 1 If two theories are referentially incomparable then they are not comparable at all except in strictly formal respects. In particular they cannot be compared as to explanatory and predictive powers: they do not explain and predict any shared facts. *Remark 2* The concept of referential commensurability will be supplemented with that of methodological commensurability in Sec. 5.1. *Remark 3* Our concept of referential commensurability is at variance with Kuhn's (1962). For Kuhn two theories are incomparable iff they fit different theory paradigms and thus are conceptually different even though they may concern the same things. Behaviorist and cognitivist learning theories would be incommensurable in this sense. But, since they concern the same kinds of animal, to us they are referentially commensurable and thus comparable. If they were not they could not be regarded as rival. *Remark 4* Nor does our criterion of theory commensurability agree with Feyerabend's, which is the sharing of *statements*, hence of concepts. It is of course true that relativistic mechanics "does not, and cannot, share a single statement with its predecessor" (Feyerabend, 1970, p. 82). But it is also true that both refer to bodies (cf. Example 3 above). Moreover the basic concepts of classical mechanics can be retrieved from the corresponding relativistic concepts: for example the classical mass function is a certain restriction of the relativistic mass function (see Bunge, 1970b). Therefore the two theories are commensurable, hence comparable – which is why they are being compared all the time. If this were not the case then there would be no more ground for preferring one of the theories over the other than for preferring Newton to Vivaldi. *Remark 5* The overlapping of two theories, i.e., their sharing some statements (Feyerabend's criterion) is not only unnecessary for their commensurability: it is not even sufficient. In fact two factual theories with different referents may have the same mathematical formalism, as is the case with certain theories of epidemics and of rumor propagation. It would be preposterous to declare such theories semantically commensurable even though they share infinitely many statements. What is decisive (necessary and sufficient) for theory commensurability is not the mere sharing of statements but the sharing of semantic assumptions, for these are the ones that point to the referents or their properties. *Remark 6* The moral of the preceding remarks is this. The interesting problem of comparing rival scientific theories and ascertaining their meaning diversity cannot be approached on the basis of spotty historical remarks: it requires a full fledged semantics of science and an analysis of scientific theories in the light of the former.

4.3. *Spotting the Factual Referents: Genuine and Spurious*

The preceding examination of the factual reference class of a scientific theory presupposes that the latter has been formulated in a correct way, both formally and semantically, so that finding its referents is a straightforward operation. In other words, we have assumed that the theory to be analyzed contains detailed analyses of every one of its variables: in this case Theorem 2 solves our problem. Unfortunately this situation is exceptional rather than typical: in most cases the referents of a theory are hinted at in extrasystematic remarks dropped in motivating the theory or, as we saw in Sec. 1, they are the subject of spirited controversy.

In other words, semantics can be of little help in spotting the genuine referents of a theory unless the latter has already been axiomatized in such a way that those referents are clearly exhibited. But at least semantics can help us to dig up the referents of an untidy theory and can assist us in formulating the semantic assumptions of the theory. These tasks are performed in the light of a criterion that, unlike Theorem 2, concerns unkempt theories. Here it is:

CRITERION An object is a *genuine factual referent* of a scientific theory iff it is involved in at least one of the law statements in the theory.

Otherwise, i.e. if an object falls under no law of the theory, then it is a *spurious referent* of it, no matter how many authorities may claim the opposite. For example, if a theory of electrons fails to contain law statements about instruments sensitive to electrons, then the theory does not refer to such instruments, much less to those in charge of the latter. It will not do to claim on philosophical grounds that some reference to instruments or to observers *must* be "implied" or "presupposed" by the theory, for otherwise the latter would be neither meaningful nor testable.

The preceding criterion suggests adopting the following

DEFINITION 2.33 A nonconceptual object x is a *genuine factual referent* of an informal theory T iff (i) T contains at least one law statement involving one or more variables concerning x; (ii) such law statements cease to hold upon the removal of the variable(s) in question, and (iii) T can be adjoined, without introducing any contradiction, assumptions effecting a more precise characterization of the variable(s) referring to x.

Whatever passes for referent but is not genuine is a *spurious referent*. Contemporary science contains several theories with spurious referents, i.e. that purport to but in fact do not refer to certain entities. Such theories may be called *ghostly*. We proceed to exhibit three ghosts.

Example 1 Probability is sometimes interpreted in a subjectivist or semisubjectivist way, occasionally even in the context of natural science. For instance, it is sometimes held (e.g. by Brillouin 1962) that the distribution function (or else the partition function) in statistical mechanics, and the various probability densities in quantum mechanics, concern our own information (or rather want of it) instead of either objective (though potential) properties or objective random distributions. If this contention were true then statistical mechanics and quantum mechanics would concern the cognitive subject and his mental states at least as much as autonomous physical entities. By our Criterion, if the cognitive subject were a genuine referent of those theories then these should contain law statements enabling us to explain and predict our own behavior. But they do not. Consequently the cognitive subject is a spurious referent of those theories. Equivalently: those theories are about autonomous physical systems. This conclusion is reinforced by the consideration that one learns about such systems by studying them rather than by the method of transcendental meditation. *Example 2* The so called measurement theories found in the foundations of mathematical psychology happen to be concerned with certain types of scientific concept not with the empirical operation scientists call 'measurement'. So much so that they do not involve any laws of either the measured object or the measuring instrument, whence they are of no help in designing and interpreting any measurement proper or even in estimating random errors of measurement (see Bunge, 1973c). *Example 3* It is usually held that the quantum theory of measurement (or some variant of it) accounts for actual measurements and moreover concerns the system-apparatus-observer compound. However, this theory fails to contain variables representing any properties of the observer. *A fortiori* the latter does not occur among the referents of the law statements of the theory – to the point that the author of the standard quantum theory of "measurement" acknowledged that the observer "remains outside the calculation" in his theory (von Neumann, 1932, pp. 224, 234). And although variables alleged to represent properties of an instrument do play a role in this theory, they fail to concern real instruments. As a consequence none of the formulas of this theory predicts any experimental results. A genuine measurement theory concerns a specific set-up, hence it contains specific law statements accounting for the peculiar structure and composition of the apparatus and its coupling with the measured thing. Such a specificity shows up in the constitutive equations or, equivalently, in the occurrence of non-universal parameters and constants, such as the refractive index, the electric resistivity, or the magnetic permeability. The quantum theory of "measurement" contains no such constitutive equations, hence it can refer to no genuine measurement set up. In sum, the quantum theory of "measurement" is ghostly: both the observer and the apparatus are spurious referents of it. (For details see Bunge, 1967b, Ch. 5; 1973b, Ch. 4.)

4.4. *The Strife over Realism in the Philosophy of Contemporary Physics*

The assumed referents of a scientific theory may be physical, chemical, biological, social, or what have you. Whatever their kind, the referents can be regarded in a number of alternative ways in their relation to the cognitive subject. The main doctrines that dominate the current philosophy of science in this respect can be summarized as follows.

(i) *Conventionalism* Scientific theories have no referents: they are just data summarizing and data processing tools – in particular they are prediction devices.

(ii) *Pragmatism, operationism, phenomenalism* Scientific theories are about phenomena, i.e. facts in which some cognitive subject is involved and such as they appear to him: they concern neither the subject alone (subjectivism) nor an autonomous object (realism).

(iii) *Realism* If the referents of a scientific theory exist at all then they exist on their own, i.e. independently of their being perceived or conceived: the cognitive subject creates, tests and applies hypotheses and theories instead of either creating their referents or posing as the latter.

The defense of any such stand is usually dogmatic: it consists in quoting authorities. At most it is pragmatic: it derives its strength from the heuristic power of the given philosophical doctrine, as when operationism is defended on the ground that it helps in the conceiving of experiments, or when realism is tolerated because it assists to invent "theoretical entities". Such lines of defense are weak and they foster sterile controversy. We need a different strategy, one relying on a semantical and methodological analysis of the theories concerned. We should be able to use a theory of reference to disclose the genuine referents of a scientific theory and thus evaluate the conflicting doctrines concerning such referents. How this can be done will be sketched presently.

From a semantic viewpoint conventionalism is false, since a theory with no factual reference whatever may qualify as a mathematical theory, hardly as a scientific theory. It is true that most of the formulas of a scientific theory do not involve explicitly the object variables or referents discussed in Sec. 2.4, so that the formulas look reference free, as if they were formulas in pure mathematics. But the factual reference is usually indicated or suggested by the accompanying text, sometimes called 'the prose of the theory'. And when these extrasystematic remarks are incorporated systematically into the theory, as so many semantic assumptions, the referents are brought to light. In short conventionalism, plausible as it may look in relation to the bare mathematical bones of scientific theories, is mistaken in relation to suitably axiomatized factual theories. So much for a semantic criticism of conventionalism.

The preceding semantic considerations are reinforced by the following methodological remarks. First, by refusing to make a semantic (or referential) commitment, conventionalism fails to draw the line between the various sciences and even between science and mathematics. (More on semantic formalism in Ch. 6, Sec. 3.1.) Second and consequently, conventionalism is incapable of telling us what kind of data are relevant to a given theory. Third and consequently, conventionalism does not help us to devise empirical tests, as every test of a scientific theory presupposes our knowing its reference class. Therefore the conventionalist view that scientific theories are data processing contraptions fails to do justice to both theories and data.

If conventionalism is discarded then only two serious contenders remain: phenomenalism and realism. (The truth might of course belong to a further party not involved in the current strife, but it will turn out that semantics and methodology favor just one of the current rivals.) Before the days of relativity and quanta, physics was usually interpreted in a realist way. Thus the length $L(b)$ of a bar b (or rather its length relative to a length standard) was regarded as an intrinsic and objective property of the body b. With the advent of special relativity (1905) length became a joint or mutual property or two physical systems: the body b and a reference frame f. Absolute, i.e. frame-free lengths, were swept aside in principle though not in practice. In other words, the definite description '$L(b)$' was replaced by '$L(b, f)$', short for "the length of b in (or relative to) the frame f". That is, a new length function was introduced: one with a different reference class. While the reference class of the nonrelativistic length concept was the set of physical systems, the reference class of the relativistic length concept is the union of the set of physical systems and the set of reference frames.

Now, the term 'reference frame' may be construed in either of two ways: as a physical system of a special kind, or as an observer. If the former, then nothing changes from an epistemological point of view: a property that had been regarded as absolute (or frame independent) turned out to be relative (or frame dependent). Equivalently: a relational metric property was substituted for an intrinsic one. But if reference frames are conceived as sentient beings equipped with yardsticks, clocks, mirrors, and other pieces of apparatus, then length ceases to be a strictly physical property to become a property of compound systems with a human component. And this is epistemologically revolutionary – or rather counter-revolutionary, as it reinstates anthropocentrism. Thus the expressions 'apparent length' and 'the length measured by a moving observer' were coined to indicate that the theory concerns appearances (to observers) not autonomous reality. The facts that all basic law statements are required to be frame free (or covariant), and that many magnitudes (such as the spacetime interval, the electric charge, and the entropy) are invariant, i.e. the same in (relative to) all frames, were not taken as evidence against this operationist interpretation. They were just ignored.

Two decades later quantum mechanics suffered a similar fate: its formulas were read in the light of the then dominant philosophy of physics. According to the usual or Copenhagen interpretation of quantum mechanics, every formula of the theory is about some microsystem under the action of an experimental set up controlled in an arbitrary fashion by an observer. Because of this alleged control and of the supposed docility of microsystems, which are imagined to behave as commanded by the observer, the apparatus-observer complex is usually called "the observer" – even if the whole experiment is automated. And dynamical variables are christened "observables". In this way no objective physical properties would seem to remain: they all become, just as with the operationist interpretation of relativity, observer dependent. For example, an eigenvalue is construed as a possible measurement result, an eigenstate as the corresponding observed state, a superposition of eigenstates as symbolizing our own uncertainty concerning the state of the system for not being under observation, and so forth. Consequently phenomenalism is pronounced victorious and realism dead. From here on the transition to strait subjectivism is easy: "the basic principles of physics, embodied in quantum-mechanical theory, deal with connections between observations, that is, contents of consciousness" (Wigner, 1970).

Do these non-realist interpretations of contemporary physics have any ground other than authority? Could semantics help us to make a rational choice between phenomenalism and realism? It can indeed, namely by supplying the criterion and the definition of factual reference given in Sec. 4.3. To reveal the genuine factual referents of a theory pick its basic predicates, analyze them and disclose the way they function in the central law statements of the theory – i.e. before the latter is applied or tested. Of all the alleged independent variables only those will qualify as genuine which are characterized by the theory and occur in the latter's law statements: all others make no difference and thus are ghostly, i.e. they concern spurious referents. Let us see how this criterion works in weeding out ghostly variables in a couple of important cases.

Example 1 Consider the famous Lorentz "contraction" formula

$$L(b, f)=L(b, b)\,[1-u^2(b, f)/c^2(w)]^{1/2} \tag{SR}$$

where b denotes a body (in fact any physical system), f a reference frame, and w an electromagnetic wave in a vacuum. The formula gives the length of b in (relative to) f, in terms of the length $L(b, b)$ of b relative to b itself, and of the ratio $u(b, f)/c(w)$ of two velocities: the velocity of the body with respect to the frame, and the (absolute) speed of light $c(w)$ in void. The phenomenalist construes f as an observer and interprets $L(b, f)$ as the apparent length measured by f. But, according to our criterion, this interpretation is inadmissible because the theory gives a strictly physical characterization of f, i.e. one that contains no psychological and sociological concepts. In sum, the referents of SR are b, f, and w, all three physical objects. Hence realism is upheld in relation to special relativity.

Example 2 Look at Heisenberg's indeterminacy formula:

$$\Delta_{\psi(\sigma, \sigma')}p(\sigma)\cdot\Delta_{\psi(\sigma, \sigma)}p(\sigma)\geqslant h/4\pi \tag{QM}$$

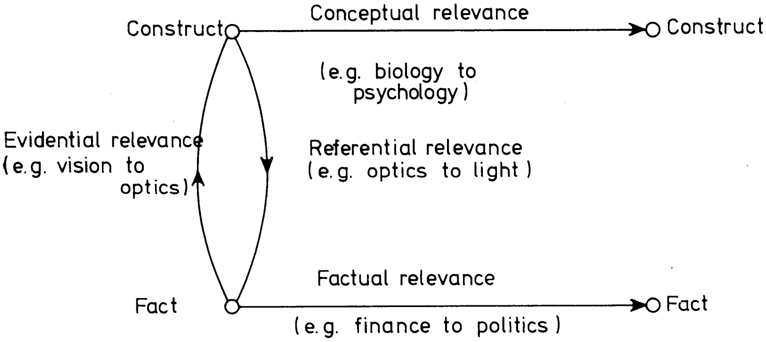
If a correct deduction from first principles is performed and analyzed, it is seen that $\psi(\sigma, \sigma')$ represents the state of a microsystem σ (e.g. an iron atom) in an environment σ' (e.g. a magnetic field) at a given instant of time. It is further realized that $\Delta_{\psi(\sigma, \sigma')}p(\sigma)$ represents the width of the momentum distribution of the microsystem σ when the system-environment complex is in the state represented by $\psi(\sigma, \sigma')$. Similarly $\Delta_{\psi(\sigma, \sigma')}q(\sigma)$ stands for the width of the position distribution of the microsystem. In short the object variables or referents of the formula QM are σ and σ'. The phenomenalist claims that σ' is the observer-*cum*-apparatus complex. However, (*a*) the formula holds even in the absence of an environment, i.e. when σ' happens to be the null individual; (*b*) the formula holds whether or not σ' includes a measurement device – for example it holds for the atoms in a star; and (*c*) the theory does not specify the properties of either observers or measurement devices: it is a strictly physical theory and a thoroughly general one, married to no particular laboratory, let alone to a particular mind. Conclusion: the phenomenalist or operationist interpretation of quantum mechanics is groundless: as with the case of relativity, that interpretation is a superstructure that the formulas of the theory fail to support.

In conclusion: there are two main ways of looking at a scientific theory. One is through a semitransparent mirror, like operationism, that exhibits the superposed images of the referent and of ourselves. The second way is by using the non-reflecting magnifying lenses of axiomatics and semantics applied to the theory itself regardless of its philosophical wrapping. The second method alone guarantees the objectivity characteristic of science. (For details see Bunge, 1973a and 1973b.)

5. RELEVANCE

5.1. *Kinds of Relevance*

The term 'relevance' is very much in vogue these days but it is seldom analyzed. In particular it is not always realized that relevance is a relation and that its relata can be of various kinds, as shown in the following diagram.



Construct
Conceptual relevance
Construct
(e.g. biology to psychology)
Evidential relevance (e.g. vision to optics)
Referential relevance (e.g. optics to light)
Factual relevance
Fact
Fact
(e.g. finance to politics)

The relevance relations involved in the preceding diagram are these:

(i) construct-construct as regards form, i.e. *formal relevance*;
(ii) construct-construct as regards reference, or *semantical relevance*;
(iii) construct-fact, or *referential relevance*;
(iv) experiential fact-construct, or *methodological relevance*;
(v) construct-action, or *pragmatic relevance*;
(vi) fact-fact, or *factual relevance.*

The last two kinds of relevance may be characterized as follows. A fact may be said to be relevant to another fact if and only if the former makes some difference to the latter. And a construct may be regarded as being pragmatically relevant to an action iff the former is part of a view or theory that is instrumental in bringing forth or preventing the given action. We shall be concerned only with the first four types of relevance. They will be characterized in the following way.

DEFINITION 2.34 Let c and c' be two constructs. Then c is said to be *syntactically relevant* to c' iff there is a context in which c is logically related to c' in such a way that c determines c' at least in part.

Example 1 In a definition, the definiens is syntactically relevant to the definiendum. *Example 2* In an argument, the premises are syntactically relevant to the conclusions. *Example 3* In a function, the independent variables are syntactically relevant to the dependent variables. If the function has an inverse, the relevance is mutual.

DEFINITION 2.35 Let c and c' be constructs. Then c is said to be *semantically relevant* to c' iff (i) c is syntactically relevant to c' and (ii) c and c' share referents, i.e. $\mathscr{R}(c)\cap\mathscr{R}(c')\neq\emptyset$.

Example 1 The specific gravity function is relevant to the weight function. *Example 2* Let c concern a gene in an organism and c' a molar or phenotypical trait of the same organism. Then c will be semantically relevant to c' just in case genetics happens to contain a law according to which c determines c' at least in part. *Example 3* The biological variables are irrelevant to the psychological ones in the context of behaviorism.

DEFINITION 2.36 A construct c is said to be *referentially relevant* to a fact (thing, state, event, process) f iff f is in the reference class of c, i.e. if $f\in\mathscr{R}(c)$.

Example Pure mathematics is syntactially relevant to science, which is in turn referentially relevant to reality. *Example 2* According to the Copenhagen interpretation of the quantum theories, the latter are relevant to the human mind, while according to the realist interpretation they are not. *Example 3* The concept of thinking (or ideation) is referentially relevant to neural activity.

We may take a further step and introduce an absolute and a comparative concept of degree of referential relevance:

DEFINITION 2.37 The degree of *referential relevance* of a theory T to a domain F of facts is equal to $\mathscr{R}(T) \cap F$.

DEFINITION 2.38 Let T and T' be two theories that are referentially relevant to a domain F of facts. Then T is *referentially more relevant* to F than T' iff $(\mathscr{R}(T) \cap F) \supset (\mathscr{R}(T') \cap F)$.

Example Biology is referentially more relevant than ethics to the facts of animal aggression, altruism, and cooperation; and political science is more relevant to war than either biology or ethics.

These concepts should not be mixed up with the methodological concept of evidential relevance, that can be elucidated by

DEFINITION 2.39 An empirical fact e is *evidentially relevant* to a construct c iff there is another construct c' such that (i) c' is syntactically relevant to c and (ii) c' is referentially relevant to e.

Example 1 The conceptual basis of the common lie detector is the hypothesis that increase in hand sweating is an index of lying. *Example 2* Dreams are (so far) irrelevant to the study of personality because there is no scientific theory in which dream contents and personality traits are related. *Example 3* Prior to the theory of evolution the differences among species were not normally regarded as pointing to (or against) the hypothesis of evolution.

In Sec. 4.2 we elucidated the concept of semantic commensurability. We can now supplement this notion with the one of methodological commensurability, which has recently come to the fore with reference to scientific revolutions. We first stipulate

DEFINITION 2.40 Let T and T' be two factual theories. Then T and T' are said to be *methodologically commensurable* iff there are empirical facts that are evidentially relevant to both T and T'.

DEFINITION 2.41 Let T and T' be two methodologically commensurable theories. Then T is said to present a *larger methodological exposure* than T' iff the set of empirical facts evidentially relevant to T includes the one evidentially relevant to T'.

Example 1 Relativistic mechanics presents a greater methodological exposure than classical mechanics because it is inextricably related to electrodynamics. *Example 2* Molecular genetics presents a greater methodological target than Mendelian genetics because it is sensitive to an additional set of evidence, namely that of the molecular structure of genes. *Example 3* Any neuropsychological theory presents a greater methodological exposure (hence more risks) than the corresponding behaviorist theory (if any) because it can claim both behavioral and neurophysiological evidence pro and con.

Now, testing a theory presupposes knowing what the theory is about – not the other way around. In other words, contrary to the verification tenet of meaning, we hold that the semantics of a theory must precede its methodology (recall Sec. 2.6). More explicitly, we lay down the methodological

THESIS 2.4 If two scientific theories are methodologically commensurable then they are semantically (referentially) commensurable as well.

The converse is false. Hence referential and methodological commensurability are inequivalent. Thus two rival theories about ghosts are singly untestable, hence methodologically commensurable in the trivial sense that no fact of experience is relevant to either. The above principle contradicts the claim – originally put forth by Kuhn and Feyerabend – that every new revolutionary theory is methodologically incommensurable with its predecessor: that is is accepted for reasons other than having been shown to be truer. On the other hand our principle fits in with the actual practices of (*a*) comparing only semantically commensurable theories, (*b*) looking for evidence relevant to the reference class shared by the rival theories, and (*c*) making rational (though perhaps wrong) choices among rival theories after having weighed their respective empirical (predictive) performances. This does not entail that factworthiness is all-important: but it is necessary.

In examining the performance and the value of alternative factual theories it is usually taken for granted that they are semantically and methodologically commensurable. That is, one uses tacitly

DEFINITION 2.40 Two factual theories are *commensurable* iff they are referentially as well as evidentially commensurable.

A final convention: Two theories may be regarded as being *semantically rival*, or *competing*, iff, being commensurable, they have different senses, i.e. if they do not 'say' the same. (Examples: rival theories of learning, or of social mobility.) If two theories had the same sense then they could differ only in the organization of the material: in this case they would be just different formulations or presentations of one and the same body of knowledge. But the concept of sense lies far ahead.

Before applying the preceding ideas on relevance we note that they are relevant to the intuitive notion of a "category mistake" (Ryle, 1949). In the light of the preceding considerations it is clear that there are no absolute category mistakes: that whether or not a given association of predicates is mistaken depends on the theory that is adopted. It is equally clear that any such mistakes are epistemic not linguistic mishaps: they do not consist in violations of linguistic rules but in departures from accepted bodies of substantive knowledge. Thus while in the context of behaviorist psychology (adopted by Ryle) the coupling of mentalistic concepts to either behavioral or neurological ones would constitute an unforgivable category *faux pas*, in either a more backward or more advanced psychological context such predicate combinations might be correct. The science of the day, not either grammar or literary criticism, is competent to judge whether any given predicate association is right or wrong. In short, category mistakes are scientific mistakes.

5.2. *The Paradox of Confirmation as a Fallacy of Relevance*

Consider the empirical generalization ⌜All ravens are black⌝, or $\ulcorner(x)\,(Rx \Rightarrow Bx)\urcorner$ for short. This statement amounts to $\ulcorner(x)\,(\neg \mathrm{Rx} \vee \mathrm{Bx})\urcorner$ as well as to $\ulcorner(x)\,(\neg Bx \Rightarrow \neg Rx)\urcorner$. At first blush, finding anything that is not a raven, such as a book, or anything black, such as a tunnel, or even that is not black, such as a carrot, would seem to count as positive evidence for the generalization. But then almost anything would so count no matter where we look. Hence experience will have little if any value: confirmation will be so cheap as to be worthless. This is one of the paradoxes of confirmation (Hempel, 1945).

This paradox, which occurs neither in real science nor in our semantics, illustrates the fallacy of irrelevance. Indeed the statement that all ravens are black happen to concern birds not anything else: this is how ornithologists understand it. Therefore to put it to the test the ornithologist will scan only the *relevant evidence*, i.e. data about birds, without bothering about nonbirds, whether black or colored. This procedure is consecrated by our semantics, in particular by Definition 2.9 (iii) and Corollary 2.4b. Indeed, the reference class of the universal conditional ⌜$(x)\ (Rx \Rightarrow Bx)$⌝ equals the reference class of the molecular predicate $R \Rightarrow B$. And this predicate is defined on the intersection of the domains of its components R and B, as stipulated in Ch. 1, Sec. 2.3. Now,

$$\text{Dom } R = \text{Birds}, \quad \text{and} \quad \text{Dom } B = \text{Things}$$

hence

$$\mathscr{R}_s\,(\text{All ravens are black}) = \text{Birds} \cap \text{Things} = \text{Birds}$$
$$\mathscr{R}_s\,(\text{Anything is either not a raven or black}) = \mathscr{R}_p\,(\neg R \vee B)$$
$$= \mathscr{R}_p\,(R \vee B) = \text{Birds}$$
$$\mathscr{R}_s\,(\text{All nonblacks are nonravens}) = \mathscr{R}_p\,(\neg B \Rightarrow \neg R)$$
$$= \mathscr{R}_p(B \Rightarrow R) = \text{Birds.}$$

Therefore only an examination of birds will be relevant to the given generalization and thus be in a position to confirm or infirm it. (The discovery of albino ravens has refuted the generalization anyway.) *Moral 1*: If semantics is to be relevant to actual science it must be consonant with the methodology of science. *Moral 2*: It is not helpful to jump from the syntax (or logic) of science to its pragmatics (or methodology) without stopping over its semantics.

Our analysis of the empirical generalization about ravens carries over to statements in theoretical science. A typical example of a simple conditional occurring in the latter is ⌜All metals are conductors⌝, or ⌜$(x)\ (Mx \Rightarrow Cx)$⌝ for short. This is a law proper for, in addition to being well corroborated, it belongs to a definite scientific theory, namely solid state theory. (For the underlying criterion of lawfulness cf. Bunge, 1967a, Vol. I, Ch. 6, Sec. 6.6.) This theory accounts for conductivity (both thermal and electrical) in terms of metal structure: it explains why metals should be conductors. In the terminology of the preceding section: M is semantically relevant to C because there is a definite context, namely solid state theory, where (*a*) M and C have common referents and (*b*) M determines C. On the other hand in ⌜All ravens are black⌝ the predicate "is a raven" is so far semantically irrelevant to "is black": at the time of writing there seems to be no confirmed scientific theory explaining the blackness of ravens in terms of any of their basic properties. In other words, in the context of present day ornithology "raven" and "black" are syntactically irrelevant to each other, and *a fortiori* semantically irrelevant as well. This situation, atypical of science, is typical of ordinary knowledge: it suggests Hume's and James' ontology of universal ontic irrelevance. Such a metaphysics can hardly avoid fallacies of irrelevance. Not so the ontology of science, which is a web of laws. But this is a different matter. In any case our semantics may be of help when the metaphysician goes astray.

6. CONCLUSION

The notion of reference, though central to the semantics of factual science, is of little interest to logicians and mathematicians, whence it has been neglected by semanticists. The only serious attempt to analyze reference in exact terms seems to have been Goodman's. Unfortunately the definition he offered was exceedingly complex and at the same time it did not require predicates to be analyzed as functions from individuals to statements. Consider: "*S* is *absolutely about* *k* if and only if some statement *T* follows from *S* differentially with respect to *k*". In turn "a statement *T* follows from *S* differentially with respect to *k* if *T* contains an expression designating *k* and follows logically from *S*, while no generalization of *T* with respect to any part of that expression also follows logically from *S*" (Goodman, 1961, p. 7). The notion of aboutness is thus made to depend upon the concepts of consequence and denotation, but the latter is left unanalyzed. If only for this reason the elucidans turns out to be more obscure than the elucidatum (Patton, 1965). No wonder Goodman's criterion has not been applied to solve any of the genuine problems of referential ambiguity listed in Sec. 1.

Our approach to the problem of reference has been direct: we have been concerned with solving the problems mentioned in Sec. 1 and with proposing a solution that could be checked. Our proposed solution has consisted, in a nutshell, in bringing to light the domain of the predicate of interest. Since the responsibility for the characterization of a factual predicate rests ultimately with a scientific theory, it is to the latter that we should turn for an identification of the entities it purports to be about. Mark: to the theories themselves rather than to any extrasystematic ("philosophical") comments about them – the more so since such comments are often philosophically biased. If somebody claims that a theory *T* is about entities of kind *K*, let him formulate *T* in such a way that *K* occurs in the domain of at least one predicate in *T*: otherwise the claim will be groundless. But even showing that a theory refers to entities of some kind does not prove that it describes or represents them. For example, a theory of the effects of food deprivation in children will refer to food without describing or representing it. But the concept of representation deserves a separate chapter: the next.

CHAPTER 3

REPRESENTATION

According to a realist semantics, scientific theories represent their referents. They constitute *conceptual representations* of actual or hypothetical bits of reality – or rather of some of their traits. The same holds for some of the predicates and some of the formulas of a scientific theory. Just for some: not all of them represent. Thus, while a distance function may represent the spacing of things, not every one of the infinitely many functions of a given distance function will represent something. Likewise not every line in a deduction within a scientific theory represents some aspect of a thing: some statements are purely mathematical. What makes some constructs representational and others not? This is, in a nutshell, the problem of the present chapter.

1. CONCEPTUAL REPRESENTATION

There is an analogy between scientific theories and pictures. In both cases the represented object may be given (rather than invented) and the representation may be more or less accurate or truthful. This analogy is the basis for the expressions 'Scientific theories depict (or portray) their referents' and 'Science mirrors (or reflects) reality'. However, these are just metaphors, hence they may not go to the heart of the matter. Indeed, the manner of representing differs in either case. First, while a pictorial representation is itself a physical object, a conceptual representation is a thing of reason. Second, while in the former case only appearances can be pictured and all else can at best be hinted at, scientific representations do not pause at the skin of reality: they aim at representing the real, which is mostly hidden to the senses and alien to ordinary experience. Third and consequently, scientific representations are symbolic (yet not metaphoric) rather than pictorial even though they may contain a few pictorial ingredients. Fourth, while a picture is bound to be interpreted (and often also felt) in as many ways as there are beholders in different moods, a scientific representation is supposed to be objective. Fifth, while the aim of the arts is to arouse or to lull, to entertain or to edify – in any event to play up on our emotions – the aim of a scientific representation is to describe its referents in a truthful way. Whatever aesthetic emotions a scientific representation may arouse derive from realizing its logical and methodological virtues or shortcomings.

In view of these important differences between pictorial representations and conceptual representations, it seems advisable to speak of *conceptual reconstructions* rather than *images* of reality. Reconstructions are constructions, artifacts resulting from hard and often ingenious work, not just impressions and images – which can be had for free. Flies have an image of reality and so have scientists, but the latter possess, in addition, what they create, namely the conceptual representations of objects that cannot be grasped with the senses. These representations are only partial and at best approximately true but they can be checked and either improved or replaced by truer ones. What is more, unlike images they are built with mathematical bricks: one more reason for not calling them 'pictures'. More on the issues of critical realism in Ch. 10, Sec. 3.3.

Not every construct represents. To begin with logical concepts are nonrepresenting even when they are referential. Thus on our theory of reference (Ch. 2, Sec. 3.2) disjunction concerns propositions. But it represents nothing. And analytic statements may refer to anything but they describe or represent nothing except logical objects: logic does not mirror reality but rather the structure of human knowledge (cf. Bunge, 1974a). Likewise with other formal objects: they too are nonrepresentational. For example the number 8 fails to represent anything. True, 8 happens to be the number of genuine planets in our solar system and thus looks as if it did represent a property of a concrete thing. Not so: 8 is not the property of any one aggregate although it may be construed as the class of all octuplets. This is why it may pop up in any context, whether formal or factual. In other words, although the number of planets equals 8,8 is not identical with the number of planets. (That is, the relation of equality involved in ⌜The number of planets equals 8⌝ is not symmetrical, hence it cannot be the one of identity. Consequently instead of writing 'Card (set of planets) = 8' we should adopt the Algol convention and write 'Card (set of planets) := 8'. Likewise to indicate that we assign x the value 8, or that we set x equal (not identical) to 8, but not *vice versa*, we should write '$x := 8$' instead of '$x = 8$'.) In any event formal constructs need not, and often cannot, represent anything – except perhaps further formal constructs, as when a point in a manifold is represented by an *n*-tuple of numbers, or when a function is represented by a series.

A neutral construct, such as a set, may represent some concrete thing or aggregate of things. Thus a portion of a continuum may be made to represent a body, and a graph may be assumed to represent an institution. But such constructs stand on their own feet and are portable from one field of inquiry to another. Hence it is not by analyzing them that we may discover what if anything they represent. This can be found out only by examining the role such constructs play in scientific theories. Such roles are sometimes assigned explicitly, namely by semantic assumptions, as will be seen in Sec. 4. In any case reference and representation are independent since nonreferential constructs, such as sets, may be made to represent while referential constructs, such as tautologies, may not represent anything. In other words it is not the case that whatever represents refers and conversely. What is true is that scientific theories both refer and represent.

Moreover not every factual statement, i.e. one with factual referents, represents facts. Consider the irreducibly negative propositions. We shall call a statement *irreducibly negative* if it cannot be transformed into an equivalent positive statement except by the trick of introducing negative or disjunctive predicates – none of which can represent properties of real things. Thus ⌜Snow is not blue⌝ is irreducibly negative although it can be converted into ⌜Snow is nonblue⌝, which is grammatically affirmative but semantically negative, since "nonblue" represents no color. Likewise ⌜There are no ghosts⌝ can be transformed into ⌜Everything is nonghostly⌝, but since "nonghostly" corresponds to no property that can be pinned down as being possessed by a thing, the statement is irreducibly negative. Our two examples illustrate a class of statements with factual reference and moreover true, but that fail to represent any facts. In general: If a proposition p represents a fact f, then $\neg p$ is just the denial of p, not a representative of non-f. (See Kraft, 1970.) In other words there are no negative facts: negation is a purely conceptual operation without an ontic correlate. We must resist the attempt to save the view that language is a picture of reality by introducing the fiction of the negative fact (Russell, 1918). The number of facts cannot be duplicated by just issuing a semantic decree. In conclusion: irreducibly negative statements do not represent anything even when true. Hence not everything that refers represents.

On the other hand every positive statement does constitute a partial representation of its referents. In particular a positive factual statement represents a fact or rather some facet of it. Thus ⌜*b* grows faster than *c*⌝ refers to *b* and *c* and represents (truly or falsely) the fact that *b* grows faster than *c*. The negate of the same proposition has the same reference class, namely $\{b, c\}$, but does not represent the "negative" fact that *b* fails to grow faster than *c*: it is just the denial of the former statement.

The distinction between reference and representation is no idle philosophical technicality: it is relevant to our understanding of topical scientific controversies. For example, biologists are still arguing about the authentic referents of the synthetic (neodarwinian) theory of evolution. So far they have produced no conclusive argument for either of the theses in dispute: that the theory is concerned with individual organisms, or with populations, or with species. However, a semantic glance at the typical formulas of the mathematical theory of evolution shows the following. First, the theory *refers* to populations or aggregates of coexisting and interacting members of a given kind (species). Hence it uses all three concepts: those of individual, species, and population. Second the theory *represents* both individual and collective traits – among other things the occasional changes in kind (speciation and extinction) occurring in a population. The failure to realize that there is no incompatibility among the three concepts, because they perform different and complementary roles, may be blamed not only on the obsolete dichotomy Platonism-nominalism, but also on the backwardness of semantics, which has never helped science find its way.

The difference between reference and representation becomes particularly clear in advanced theories such as those in physics. For example, here a probability function will *refer* to some system or some state(s) of it, while the values of that function may be taken to *represent* certain dispositions of the system – much as the mass function M refers to bodies while a particular value $M(c)$ of M will represent the mass of the body c. In quantum mechanics, every dynamical property of a system, such as its linear momentum, is represented by some operator in a Hilbert space. That is, the operator represents a property of its referent. In statistical mechanics the partition function of a multicomponent system refers to the latter but fails to represent any single property of it. It accomplishes much more: it generates the conceptual representatives of all the thermodynamic properties of the physical system. And in electromagnetic theory the value $E(\phi, x, t)$ of the vector valued function E at the field ϕ at the place x and the instant t, represents the strength of the electric component of the referent ϕ at x and t. There are infinitely many constructs in the theory, such as the powers and derivatives of E, all of them with the same referent but which represent no trait of it.

To sum up. While in factual contexts the reference relation pairs a construct off to a thing as a whole, or to a collection of things, the representation relation matches a construct with some aspect or property of the thing or collection of things. Just as we read '$\mathscr{R}cf$' as 'c refers to f', so we may abbreviate 'c *represents* f' to '$c \mathrel{\hat{=}} f$'. If c happens to be a quantitative construct we may also read '$c \mathrel{\hat{=}} f$' as 'c *represents* the strength of f', where f is a property not a whole thing or a whole fact. For example, in mathematical neurobiology the element a_{mn} of a certain matrix is assumed to represent the strength of the action (excitatory or inhibitory) of neuron m on neuron n. Table 3.1 exhibits some typical examples of conceptual representation that will guide our subsequent investigation.

2. THE REPRESENTATION RELATION

2.1. *A Characterization*

The relation $\mathrel{\hat{=}}$ of conceptual representation pairs some constructs off to some objects, whether conceptual or factual. We shall restrict our study to the case when the represented object is factual, i.e. when it is a thing or an aggregate of things, a property of either or a change in one or more properties of a system – i.e. an event. The main types of representative and their respective representees are shown in Table 3.2.

A few comments are in order. Firstly, we have included no individual constants in our list. And this because they can denote but not represent. Thus the man Socrates is denoted by his name but is represented only by certain propositions about him as well as by some definite descriptions of him. And an unspecified individual thing (an arbitrary element of a set of things) is likewise denoted by an individual variable but not represented by it. Only a collection of statements can represent an unspecified individual thing. Individual things, whether specific or unspec-

TABLE 3.1

Constructs: representing and nonrepresenting

	Construct	Represents	Refers to
Nonreferential concepts	3	—	—
	Open set of R^n	Open set of an n-manifold	—
	Region of a 3-manifold	Body or force field	—
Referential concepts	$Q(b)$	Charge of b	Body b
	$P(s)$	Probability of s	System in state s
	$6n$ dimensional manifold	Dynamical states of a system with n components	System with n components
	Partition function	—	Multicomponent system
Statements	The lake froze.	A freezing of the lake	The lake
	The lake felt cold.	Joint property of lake and subject	Lake and subject
	There are no green people.	—	People
Theories	Maxwell's field theory	Structure and spreading of electromagnetic fields	Electromagnetic fields
	Theory of evolution	Emergence, evolution and extinction of populations belonging to different species	Populations or organisms
	Theory of social mobility	Changes in occupation, social class, income bracket, or dwelling place	Groups of people

TABLE 3.2

What represents what

Representing construct	Represented object
Set of statements (e.g. theory)	System (individual or aggregate)
Predicate or structure (e.g. a set together with a relation on it)	Property of a system, relation or connection among systems
Set of singular or existential statements	Fact involving one or more systems (state, circumstance, or event)
Set of universal statements (e.g. law statements)	Pattern of a system's composition, structure, or change

ified, are best represented by logically organized sets of statements, i.e. by theories.

Secondly and as a consequence: sets devoid of structure do not represent either. Thus we may stipulate that 'E' denotes the population of African elephants, but E is incapable of representing anything. Only a structured set, such as a set together with certain functions, or a family of subsets of a given set, can represent something. And structured sets are structures, such as a semigroup or a topological space.

Thirdly, we have included existential statements among the representing constructs. It might be objected that a proposition such as ⌜There are flies⌝ hardly represents a fact. Yet it does represent a condition of the world, albeit in an imprecise fashion. ⌜There are flies in this room⌝ is a more precise statement – quite apart from its truth value. A whole sequence of such statements, each more precise than its predecessor, can be imagined. They will have different contents but every one of them, even the first statement of unqualified existence, may be regarded as representing. In sum an existential statement, if referring to some things, does constitute a partial albeit hazy representation of some facts involving those things.

Fourthly, note that we distinguish between a law statement and that which such a proposition is supposed to represent – an objective pattern. We distinguish, that is, between a law and a law statement. This distinction, emphasized by the physicist-philosopher Ampère and denied or overlooked by a number of philosophers (notably Hume, Kant, Peirce, Boutroux and their respective followers), is necessary to account for the fact that each objective pattern can be represented in a number of different ways, as will be seen in Sec. 2.2. It is also needed to explain both the process of theory construction and the history of science – which history may be regarded as a sequence of attempts to build improved conceptual representations of objective patterns or laws.

We summarize the preceding remarks in the following rather informal

DEFINITION 3.1 The relation $\hat{=}$ of *factual representation* is a relation from constructs to facts (i.e. such that $\mathscr{E}(\hat{=}) \subset C \times F$) subject to the following conditions:

(i) the properties of real things (including their interactions with other things) are represented by predicates (in particular functions);

(ii) real things are represented by sets structured by relations, functions, or operations;

(iii) facts (e.g. events) are represented by sets of singular or existential statements;

(iv) the stable (recurrent and invariant) patterns of the constitution and behavior of real things are represented by sets of universal statements.

Aside from this, as here construed $\hat{=}$ has no simple properties. In particular it is not symmetric: the represented objects do not represent back their representatives. Consequently $\hat{=}$ is not reflexive: constructs do not represent themselves. And the question whether $\hat{=}$ is transitive is pointless, since facts do not represent anything.

When the representing construct is a theory (hypothetico-deductive system) we try and be more precise, speaking of a representation function rather than just relation. In fact we propose

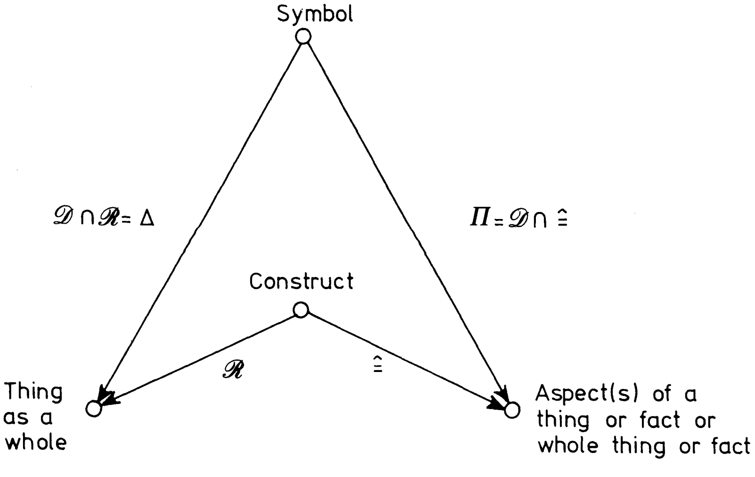
DEFINITION 3.2 Let T be a theory about entities of kind K and call $S(x)$ the collection of possible states (i.e. the state space) of thing $x \in K$. Further, call $S = \bigcup_{x \in K} S(x)$ the union of the state spaces of all the members of K (so that an arbitrary state of an arbitrary element of K is in S). Then T is said to be a *representation* of K's iff there exists a function $\hat{=} : S \rightarrow T$ assigning to every state $s \in S$ a statement $t \in T$. In this case '$t = \hat{=}(s)$' is read 't represents s'.

Now, a representation may be poor, fair or good, depending upon how complete and true it is. The ideal is characterized by

DEFINITION 3.3 Let $\hat{=} : S \rightarrow T$ be a representation of things of some kind. Then $\hat{=}$ is said to be *accurate* iff (i) it is bijective and (ii) $\hat{=}(s)$ is true for every $s \in S$.

As a matter of fact there are no accurate theoretical representations of real systems: every theory misses some possible states, or it includes some impossible states, or the formulas of it are only approximately true. Nevertheless one often reads that probability does constitute an isomorphic and true representation of chance events. The argument usually runs like this. Consider the possible outcomes of a random experiment such as the simultaneous flipping of two coins. Form the set E of all possible outcomes, such as getting at least one head, or not getting any head in the trial. It is easily seen that E has a Boolean structure. Now form the set T of statements describing such possible events. This set, too, will be a Boolean algebra. Hence there is a bijection $\hat{=}$ that maps E on to T in such a way that, if e_1 and e_2 are in E, then $\hat{=}(e_1)=t_1 \in T$, $\hat{=}(e_2)=t_2 \in T$, $\hat{=}(e_1 \cap e_2)=\hat{=}(e_1) \,\&\, \hat{=}(e_2)$, $\hat{=}(e_1 \cup e_2)=\hat{=}(e_1) \vee \hat{=}(e_2)$, and finally $\hat{=}(\bar{e})=\neg\hat{=}(e)$. The weakness of this reasoning is, of course, that E is not a set of actual facts but of possible facts: actual events are "positive" and "definite" (simple or composite but never alternative). Hence there is no bijection mapping actual chance events on to a theory. What is true is, that probability theory is part of the formal background of any stochastic theory furnishing a (never fully accurate) representation of some factual domain.

We postpone a fuller discussion of $\hat{=}$ to Ch. 6, Sec. 3. Here we note the relations between $\hat{=}$ and other semantic relations, as summarized in Figure 3.1.



Symbol
$\mathcal{D} \cap \mathcal{R} = \Delta$
$\Pi = \mathcal{D} \cap \hat{=}$
Construct
$\mathcal{R}$
$\hat{=}$
Thing as a whole
Aspect(s) of a thing or fact or whole thing or fact

Fig. 3.1. Relations between designation (D), reference ($\mathcal{R}$), denotation (Δ), representation ($\hat{=}$), and proxying (Π).

The new relation occurring in the diagram, i.e. the intersection Π of designation $\mathcal{D}$ and representation $\hat{=}$, can be interpreted as the relation of *proxying* or deputizing. Thus we may say that, in a certain context, the symbol 'V' designates the (or rather a) velocity concept, which in turn

TABLE 3.3

Theory of the vibrating string: its main constructs and what they represent

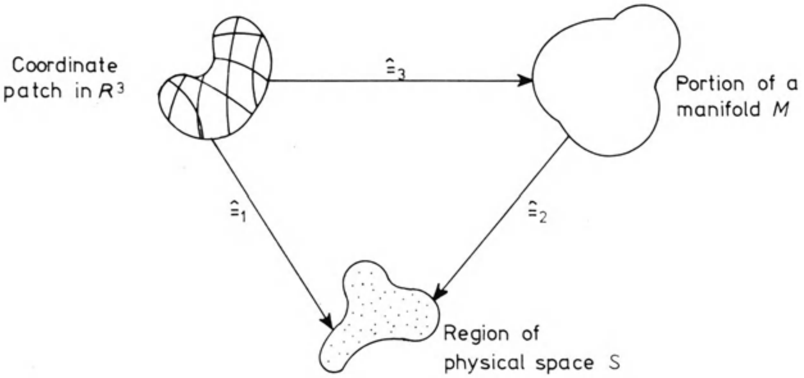
Construct	Represents	Status
x	Projection of arbitrary point of string on Ox axis	Basic concept
l	Length of projection of string on Ox axis	Basic concept
t	Arbitrary instant of time	Basic concept
$u(x, t)$	Vertical displacement of arbitrary point of string at time t	Basic concept
T	String tension	Basic concept
ρ	String mass density	Basic concept
$(T/\rho)^{1/2}$	Velocity of travelling waves	Defined concept
$\frac{1}{2}\rho(\partial u/\partial t)^2\,\mathrm{d}x$	Kinetic energy of element dx of string	Defined concept
$\frac{1}{2}T(\partial u/\partial x)^2\,\mathrm{d}x$	Potential energy of element dx of string	Defined concept
$E =_{df} \frac{1}{2}\int_0^l \mathrm{d}x\,[\rho(\partial u/\partial t)^2 - T(\partial u/\partial x)^2]$	Total energy of string	Defined concept
$\mathscr{L} =_{df} \frac{1}{2}[\rho(\partial u/\partial t)^2 - T(\partial u/\partial x)^2]$	Excess of kinetic over potential energy densities (lagrangian density)	Defined concept
$\int_{t_1}^{t_2} \mathrm{d}t \int_0^l \mathrm{d}x\, \mathscr{L} =$ maximum or minimum	Pattern of all vibrations of string as a whole over an arbitrary time interval $[t_1, t_2]$ (global law)	Basic law statement
$T(\partial^2 u/\partial x^2) - \rho(\partial^2 u/\partial t^2) = 0$	Pattern of all vibrations of an arbitrary point of string at an arbitrary instant (local law)	Derived law statement
$u_1 = \phi_1(x - Vt)$	Wave travelling along Ox axis from left to right with speed V	Derived law statement schema (arbitrary ϕ_1)
$u_2 = \phi_2(x + Vt)$	Wave travelling along Ox axis from right to left with speed V	Derived law statement schema (arbitrary ϕ_2)
$E = \mathrm{const}$	Total energy of string remains constant in course of time	Derived law statement
$\left.\begin{aligned} u(x,0) &= f(x) \\ (\partial u/\partial t)(x,t) &= g(x) \end{aligned}\right\}$ (Initial conditions with f and g given)	Initial shape of string	Subsidiary hypothesis or datum
	Initial velocity of arbitrary point of string	Subsidiary hypothesis or datum
$u(0, t) = u(l, t) = 0$ (boundary conditions)	Ends of string fixed at all times	Subsidiary hypothesis or datum

represents speed. But we may also say that (in the same context) 'V' stands for, or proxies, speed.

We close this section with Table 3.3, that exhibits the many items of one of the simplest and most characteristic of specific scientific theories. It shows clearly that the representation assumptions are an integral part of the theory: without them the latter reduces to a mathematical formalism.

2.2. *The Multiplicity of Representations*

Representations are not unique: one and the same factual item may be represented in alternative ways. Some such alternatives are equivalent, others not. For example, a region of physical space S may be represented as a subset of a certain manifold M, which may in turn be mapped onto some subset of the collection R of triples of real numbers. Hence physical space can be represented either as a portion of M or as a portion of R^3: see Figure 3.2. These two representations are inequivalent. But in turn every region of the number space may be mapped onto some other region of the same space by means of a coordinate transformation. Since there are infinitely many possible coordinate transformations, there are infinitely many possible representations of a given region of the manifold M, hence just as many numerical representations of the original region



Coordinate patch in R^3
$\hat{=}_3$
Portion of a manifold M
$\hat{=}_1$
$\hat{=}_2$
Region of physical space S

Fig. 3.2. The coordinate patch constitutes a construct representing another construct, namely a region of a manifold. And each of them constitutes a *sui generis* representation of a region of physical space.

of physical space. The latter representations, i.e. the various coordinate patches mirroring one and the same region of M (or of S), are mutually equivalent. Consequently the choice among them is a matter of convenience not of truth. (Hence if meaning were dependent on truth, as conventional semantics has it, coordinate transformations should be pronounced meaningless.)

To compare alternative representations we need, at the very least, definite criteria for deciding whether any two given representing constructs represent the same factual item in different though equivalent ways. Physics abounds in such criteria, which are of a considerable epistemological and methodological interest. *Example 1* In classical mechanics any two solutions of the equations of motion, referring to the same system but to different reference frames, are equivalent representations of the same state of motion of the system provided they can be converted into one another by a Galilei transformation. *Example 2* In the relativistic theory of gravitation it is postulated that two solutions of the field equations referring to the same field and which can be transformed into one another by a continuous coordinate transformation represent the same state of the field. *Example 3* In the theory of the spinning electron every component of the electron spin is represented by an operator that is in turn representable by alternative matrices. Two such matrices represent the same spin component provided there exists a unitary transformation that carries one into the other.

Every one of the preceding criteria of equivalent representation has a definite place in some theory or other: there seems to be no theory free criterion. In any case the definitions we shall presently propose are theory bound. The first of them will concern alternative constructs in a theory, the second will handle the translation code relating mutually equivalent representations, and the third will concern equivalent theories.

The first of our forthcoming definitions hinges on the concept of basic law statement. This is a metascientific rather than a semantic concept, but we owe no apology for such an intrusion: it is unavoidable if our semantic theory is to be relevant to science. In any case the concept in question can be elucidated in the philosophy of science (Bunge, 1967a, Ch. 6). A hypothesis is called a *law statement* if and only if (i) it is universal in some respect (rather than restricted to a finite number of cases), (ii) it is systematic, i.e. a member of some hypothetico-deductive system, and (iii) it has been corroborated in some domain by scientific methods. And a proposition of this kind is called a *basic* (or *fundamental*) *law statement* of a theory T if and only if it derives from no other statement in T. We are now ready to state

DEFINITION 3.4 Let c and c' be two representing constructs belonging to a factual theory T. Then c and c' are *equivalent representations* of the same factual item [state, event or process] if and only if they can be freely substituted (i.e. substituted *salva significatione* and *salva veritate*) for one another in all the basic law statements of T, i.e. if the latter are invariant under the exchange of c for c'.

Example 1 The choice of different coordinate systems ensues in different representations of physical quantities. These representations are equivalent if they satisfy the same laws of motion and field laws. *Example 2* Let P and Q be two quantum mechanical operators representing dynamical variables. They will represent the same property of a physical system provided there exists a similarity transformation S between them, i.e. iff $Q=SPS^{-1}$. Proof: Similarity transformations leave operator equations invariant. For example, $P^2+P+I=0$, where I stands for the identity operator, goes over into $SPS^{-1}SPS^{-1}+SPS^{-1}+SIS^{-1}=0$. Calling $SPS^{-1}=Q$, we retrieve the original statement in a different notation, i.e., $Q^2+Q+I=0$. *Example 3* Let the hamiltonian of a two component system be $H=H_1+H_2+H_{12}$. Perform a canonical (unitary) transformation of the Q's and P's that "eliminates" the unperturbed energies, i.e. that makes H collapse into H_{12}. The new variables constitute the so called 'interaction representation' of the system.

Definition 4 bears on a basic aspect of concept formation in factual science, namely the representation of properties of concrete systems. Chief among such representatives are physical magnitudes such as force, stress, concentration, and temperature. Every magnitude or quantity is representable by at least one function whose values depend not only upon the physical system itself but perhaps also on the conventional units agreed upon. In other words, magnitudes and their corresponding units (a whole class of them per magnitude) must be introduced at one stroke: the set of possible units for any given magnitude should occur in the very domain of "definition" of the function. For example, in elementary electrostatics the electric force F between any two point charges is a certain function $F: B \times B \times U_F \to R^3$, where B is the set of bodies, U_F the set of force units, and R^3 the set of ordered triples of real numbers. There are infinitely many units in U_F. Every choice among them will ensue in one force value. Similarly for every other magnitude provided it is endowed with a dimension.

A way of solving this problem in a general manner is by adopting, for every scalar quantity and every component of a vector or a tensor valued quantity, the following assumption (Bunge 1971a):

AXIOM Let $A, B, \ldots, N$ be n kinds of physical system endowed with a (mutual or joint) property P. And let R designate the real number system and $\mathscr{P}(R)$ the power set of R, i.e. the family of all real number intervals. Then for every property P there exists a nonempty set U_M, called the set of *M-units*, and there is at least one function

$$M: A \times B \times \cdots \times N \times U_M \to V, \quad \text{with} \qquad V \subseteq R \quad \text{or} \quad V \subseteq \mathscr{P}(R)$$

called a *magnitude*, such that M represents P.

At first sight this assumption is redundant since, for every domain D, there are infinitely many functions "defined" on D with values in R or in $\mathscr{P}(R)$. (There are R^D such functions in the first case and $(\mathscr{P}(R))^D$ in the second.) But our axiom is not concerned with such functions except in their representative capacity. It postulates that, given any property of a system, whether known or unknown, there is at least one function that will *represent* it, i.e. that will satisfy the law statements that characterize the system. This postulate is almost in the nature of a hope: there might well exist a property not so representable. But then we would not know of its existence, for our knowledge of things and their properties *consists in* our representations of them. Furthermore the postulate does not assert that the representation of every property is unique: realistically enough the existential quantifier in it is indefinite. Different theories are likely to represent differently one and the same property. It is not up to semantics to decide which is the best representation of a given property: this is a task for science. What philosophy can do is to render explicit and systematize the criteria at work in the choice among the possible representations of a given property. One such (methodological) criterion is this: Given a property of a complex system, the best representation of it will be the one occurring in the truest and most numerous law statements concerning the given system.

2.3. *Transformation Formulas and Equivalent Theories*

To go back to the equivalent representations of a given set of factual items: how are those representations related? The answer is supplied by

DEFINITION 3.5 A statement in a theory T is called a *transformation formula* of T iff the statement relates equivalent representations of the same factual items [in accordance with Definition 4].

Example 1 The Lorentz transformation formulas relate the spatiotemporal coordinates of one and the same physical system in relation to equivalent frames of reference: they are transformation formulas of special relativity physics. *Example 2* The canonical (or contact) transformations relate different representations of the generalized coordinates and momenta of a system. Since they leave the basic (canonical) equations invariant, they are among the transformation formulas of any canonical theory.

Some remarks are in order. First, transformation formulas are not law statements and they are not data either, even though they belong in every factual theory containing spatiotemporal concepts. They just relate different representations. This point, which is obvious in the light of the preceding discussion, is very often misunderstood. Thus the Lorentz (and also the Galilei) transformation formulas are often interpreted as representing the switching on of a uniform motion – which of course would correspond to an acceleration not to a uniform relative motion. And at one time the quantal theory of canonical (unitary) transformations was regarded as the very kernel of the physical theory, whereas in fact it has no factual content of its own, being just the collection of bridges among different but equivalent representations.

We are now in a position to elucidate the notion of equivalent theoretical representation, which came to prominence in Galilei's trial and has been at the center of the realism vs. instrumentalism dispute ever since. (In fact one of the thesis of Cardinal Belarmino was that Galilei erred in holding that the heliocentric "system of the world" was true to fact while the geocentric system was false: he should have said instead that the two systems were equivalent. The same view has been advocated in recent times by conventionalists like Poincaré and by positivists like Frank and Reichenbach. However, the very notion of theory equivalence was never too clear in these debates.) We propose the following elucidation:

DEFINITION 3.6 Let T and T' be two theories with the same factual referents. Call $\mathbb{P}$ and $\mathbb{P}'$ their respective predicate bases. Then T and T' are said to be *semantically equivalent* (or to constitute *equivalent representations* of their referents) if and only if there exists a set of transformation formulas for $\mathbb{P}$ and $\mathbb{P}'$ that effects the conversion of T into T' and *vice versa*.

Example 1 Lagrangian and hamiltonian dynamics are equivalent representations of systems in general even though their formalisms are different. Indeed, there is a bridge or transformation formula between the two theories, namely $H=p\dot{q}-L$, that leaves the content invariant. *Example 2* On the other hand the geocentric and the heliocentric "systems of the world" are not semantically equivalent if only because the former has no equations of motion (but only equations for the trajectories). Only the planet trajectories, when written in geocentric or in heliocentric coordinates, are equivalent representations. Since such trajectories is all one can observe, an empiricist must conclude to the overall equivalence of the two representations. However, they are really different in every other respect: "factual" and "empirical" are not identical concepts. For example the Copernicus-Kepler-Newton representation of the solar system refers not only to the bodies in the system but also to the gravitational field that keeps them together, which the Ptolemaic representation did not. (Cf. Bunge, 1961c.)

We close this section by laying down some tenets that are germane to the preceding considerations although they belong in the pragmatics of science rather than in its semantics. Whichever their proper location here they come.

*P*1 For any factual item (thing, thing property, event) it is possible to build at least one construct that represents it.

*P*2 Given any representing construct it is possible to form at least one other construct that is semantically equivalent to the former.

*P*3 Given any representing construct it is possible to build a semantically stronger construct.

3. MODELING

3.1. *From Schema to Theory*

A single predicate, such as "round" or "competitive", can represent a trait of a complex system, never the total system. An adequate representation of a whole system, even if either is comparatively simple, requires a cluster of concepts – better, a whole theory, i.e. a body of logically interconnected statements. However, for ordinary life purposes as well as for restricted scientific purposes a mere list of salient properties is often sufficient. For example, "Brunette, medium height, 35-25-35, pretty, witty" can pass for a representation of a girl – actually a whole class of girls. Beyond this our conceptual representations of things actual or hypothetical come in all degrees of complexity and generality. It is convenient to distinguish the following kinds of representation of a system, in order of increasing complexity and generality (cf. Bunge, 1973a and 1973b).

1 *Schema* or *model object* = List of outstanding properties of an object of a given species. *Example* A neutral pion is a particle with mass 135 MeV and half life 10^{-16} sec, that decays mostly into two gamma photons.

2 *Sketch* or *diagram* = Graph of the components of an object of a given species and their functions and relationships. *Example* Flow diagram of a factory.

3 *Theoretical model* or *specific theory* = Hypothetico-deductive system of statements representing some of the salient features of a thing of a given species. *Example* A stochastic learning model.

4 *Framework* or *generic theory* = Theory representing the features common to all things of a given genus. *Example* The theory of evolution.

To put it more briefly: a schema lists items; a sketch displays in outline the relationships among the items of a schema; a theoretical model spells out the sketch; and a generic theory is a theory free from specifics but convertible into a theoretical model (specific theory) upon being adjoined a schema or model object. All four constructs are supposed to represent some real thing but each of them is necessarily incomplete as well as, at best, fairly faithful (true). These two shortcomings of our conceptual representations of the world cannot be helped except little by little and in two ways. First, by multiplying the number of conceptual representations (e.g. theoretical models) of the same object, having each of them focus on a different aspect of it: that is, by varying the viewpoint. Second, by improving on each of these partial representations. Actually this is what happens: at any given moment we have a stack of snapshots of an object, and at successive moments we have different and thicker stacks. (Proviso: that research be continued.) But enough of metaphors.

The various kinds of conceptual representation can also be characterized as follows.

FRAMEWORK (GENERIC theory) T_G
Referents: objects g of genus G
Primitive base: $\mathscr{B}(T_G) = \langle G$, Representatives of generic basic properties of the g's$\rangle$
Axiom base: $\mathscr{A}(T_G)$ = Basic assumptions "defining" $\mathscr{B}(T_G)$

THEORETICAL MODEL (SPECIFIC THEORY) T_S
Referents: objects s in species S
Primitive base: $\mathscr{B}(T_S) = \langle S$, Representatives of basic properties of the S's$\rangle$
Axiom base: $\mathscr{A}(T_S)$ = Basic assumptions "defining" $\mathscr{B}(T_S)$

SKETCH (DIAGRAM) D_S
Referents: objects s in species S
Concepts $= \mathscr{B}(T_S)$
Hypotheses: The bare bones of $\mathscr{A}(T_S)$.

SCHEMA (MODEL OBJECT) M_S
$M_S = \mathscr{B}(T_S)$.

The relations and differences between the four kinds of conceptual representation are now clearer. They can be summarized as follows:

(i) Whereas a schema is just a bunch of concepts, a sketch is a structure such as an oriented graph. A sketch includes a schema.

(ii) There is no logical difference between a theoretical model and a generic theory: both are hypothetico-deductive systems. The difference resides in their respective reference classes, and is reflected in the greater specificity of the basic assumptions of a theoretical model. Briefly, whereas $\mathscr{R}(T_G)=G$, $\mathscr{R}(T_S)=S\subset G$.

(iii) $\mathscr{B}(T_S)=\mathscr{B}(T_G)\cup M_S$, i.e. $\mathscr{B}(T_G)=\bigcap_{S\subset G}\mathscr{B}(T_S)$.

(iv) $\mathscr{A}(T_S)=\mathscr{A}(T_G)\cup H_S$, where H_S is a set of assumptions representing the specific characteristics of the members of S as outlined by the corresponding sketch or diagram.

(v) Neither is a picture of its referent: conceptual representations are all symbolic. Even scientific diagrams are symbolic and can be replaced by sets of statements. No theory can possibly resemble its referents. Thus there is no analogy whatever between a field and the differential equations representing it. Even Bohr's pictorial representation of the atom symbolizes but a small part of Bohr's model: it leaves out the equations of motion, the quantization conditions, and the resulting jump equations.

Table 3.4 displays some examples of the four kinds of construct we have just characterized.

TABLE 3.4

Some examples of conceptual representation

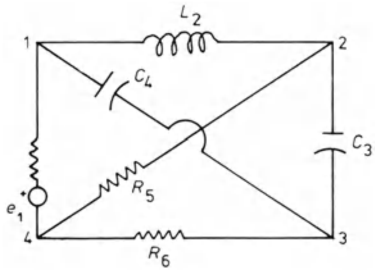
Object	Schema	Sketch	Theoretical model	Generic theory
Coin flipping	Ideal coin = ⟨Head, Tail⟩	Random sequence of Heads and Tails	Theory of Bernoullian sequences	Probability theory
Hierarchically organized group	Partially ordered set	Dominance graph or dominance matrix	Theory of dominance	———
Prey-predator system with 2 components, e.g. foxes & rabbits	Instantaneous numbers of foxes and rabbits	Numbers of foxes and rabbits in successive generations	Theory of fox-rabbit economy	Volterra-Lotka theory of predator-prey system
Corpuscle attached by spring	Mass, position, velocity, elastic force	Hamiltonian of system	Theory of the harmonic oscillator	Particle mechanics
Deuteron	Proton and neutron	Potential well	Quantum mechanics of potential well	Quantum mechanics

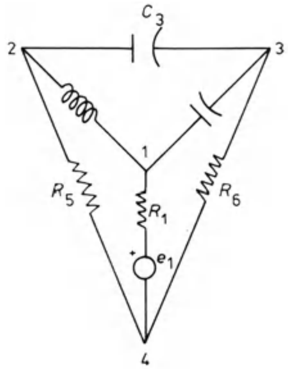
3.2. *Problems of Modeling*

The conceptual representation of things raises a number of interesting problems, some semantical, some methodological, and some technical, i.e. tractable with the resources of a special science. We can only mention a few such problems.

1 Given two representations find out whether they are *equivalent* rep-

resentations of the same system. For example, find out whether these two network diagrams are equivalent. (They are: see Seshu and Reed, 1961, pp. 1–2.)





2 Given two inequivalent representations find out whether they concern *the same* system. For example, let Δ be a block diagram of an organism. This sketch is built with objects (e.g. sets) and mappings (e.g. functions) taken from a certain category A (e.g. the category of sets or the category of topological spaces). Now consider another category B and a functor F from category A to category B. Call $F(\Delta)$ the image of the original block diagram under the functor F. This image is an alternative block diagram of the same system just in case F satisfies rather restrictive conditions: if it is faithful, regular, and multiplicative (Rosen, 1958).

3 Given a real system decide which of its traits to chop off and which ones, going beyond the data at hand, to invent. The decision will depend on the goal no less than on the available information and on the conceptual tools accessible to the theoretician: there is no unique solution to this problem because there are no recipes for building theoretical models.

4 Given a real system decide which kind of representation to build: (*a*) a black box (exogenous variables only), (*b*) a grey box (both exogenous variables and internal states), or (*c*) a translucid box (both exogenous and endogenous variables, the latter representing features of the inner workings of the system). In this case an additional factor intervenes – namely the theoretician's philosophy. Thus while positivism favors the black

box, realism encourages translucid boxes – and spiritualism cares for neither.

Finally let us list a few topical problems in the current philosophy of science involving the concept of representation.

1 Is it necessary for a successful concrete representation of some object, i.e. for a simulate, to resemble the modeled object? Undoubtedly, for otherwise the simulate would not qualify as such: it could not possibly take the place of the original in any respect. However, resemblance is required only in the respects we want to imitate. For example, a blueprint of a house must respect the relative positions of the components of the house, and so must a ball and spoke model of a molecule. Other kinds of simulate of the same objects will seize on different features, such as behavior or gross output. For example a binary digital computer bears no detailed anatomical resemblance to a brain but its net behavior is in some sort of correspondence with the functioning of a brain engaged in algorithmic thinking.

2 Does every conceptual representation have to resemble its referents? No, it need not share any properties (substantial analogy) nor need it be a homomorphic image of the represented thing (formal analogy). For example, the theory of evolution does not resemble evolution.

3 Can a theoretical model represent every trait of each of its referents? Of course not. A basic procedure of scientific theorizing, in contrast to describing, is the discarding of details and idiosyncrasies, e.g. the treatment of equivalents as if they were identicals. In other words, it is a basic methodological principle of theoretical science that equivalents (or genidenticals) be represented as being identical.

4 Are theoretical entities real or fictitious? This is an ill conceived question. First, because the "entities" concerned are not entities at all but constructs occurring in scientific theories. Second, because they may not concern entities but properties of (hypothesized) entities, such as the energy of a collapsing star. The correct question is not whether "theoretical entities" are real but whether our theoretical concepts refer to real entities and, if so, which of them represent them correctly and, if so, to what extent. And these are hardly questions that can be answered with exclusively philosophical resources: they are matters for experimental science.

5 It has been claimed, without any supporting arguments, that "what

we have called the laws of nature are the laws of our methods of representing it. The laws themselves do not show anything about the world" (Watson, 1950, p. 52). True or false? Neither: just confused. The goal of natural science is to represent nature – an objective it achieves when finding its laws. The investigation of the patterns of representation, on the other hand, belongs to psychology, epistemology and methodology. An analysis of both laws statements and the concept of representation would have avoided the confusion.

To conclude: all science aims at producing conceptual representations of its referents. (See however MacKay (1969) for the claim that the making of representations is the concern of information theory.) In the process of building such representations scientists meet challenging methodological problems that cannot be appraised if hypothesizing, modeling and theorizing are conceived as data summarizing. Whereas some such problems are peculiar to the given field of research others are undisguised epistemological problems. Philosophy can help in understanding them or at least in realizing that they involve philosophical problems.

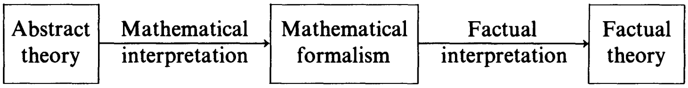
4. SEMANTIC COMPONENTS OF A SCIENTIFIC THEORY

4.1. *Denotation Rules and Semantic Assumptions*

In contemporary science theories are expressed by systems of symbols, or symbolisms. What these symbols stand for is more or less clear from (*a*) the formulas in which they occur and (*b*) the explicit designation rules that assign constructs to those symbols. An example of a *designation rule* (or proposal) is: ⌜Let '*S*' designate (name, represent, stand for, symbolize) a set⌝. Such rules are conventional in the sense that the precise symbol chosen to represent a construct is immaterial as long as every time the symbol occurs it be assigned the same construct. The resulting mathematical formalism is not an abstract mathematical theory (e.g. the general theory of groups) but an interpreted one – e.g. a theory describing a group of transformations of the Euclidean plane.

Such a mathematical *formalism* is by itself neutral with respect to matters of fact. So, unless the formalism is "read" in factual terms, it will "say" nothing about reality. Take, for example, the mathematical theory of natural selection – the hard core of the contemporary theory of evolution. As Waddington (1967, p. 14) says in colorful terms, "the whole real guts of evolution – which is, how do you come to have horses and tigers, and things – is outside the mathematical theory (...) The sheer mathematical statement is largely vacuous. The actual way it is applied, not by the mathematical theorist but by the biologist working with the subject, is not vacuous at all". This does not mean that "the whole real guts" of a scientific theory has to remain detached from its formalism: it can and must be blended with it. That is, the mathematical formalism becomes a factual theory, or rather one of a number of possible factual theories with the same underlying formalism, if the suitable factual interpretation is supplied.

The typical situation is exhibited in the following block diagram. (For a detailed analysis see Ch. 6.)



The factual interpretation of a theory is superimposed on a mathematical framework with a definite mathematical meaning and is determined by two disjoint sets of semantic rules. One is formed by the *denotation rules* or symbol-thing correspondences identifying the referents of the theory. This set constitutes what Campbell (1920, pp. 122–128) called the "dictionary" of the theory. The other is the set of *semantic assumptions* or function-property correspondences. Whereas the former point to and baptize the referents of the theory, the semantic assumptions link constructs to factual items by indicating the traits of things that the constructs are supposed, rightly or wrongly, to represent. A few examples will help getting these ideas across.

Example 1 In mechanics we find, among others, the following semantic formulas:

*DR*1 π *denotes* (names, stands for) a particle.

*SA*1 $X(\pi, f, t)$ *represents* (or measures) the position of the particle π relative to the reference frame f at the instant of time t.

Example 2 In the genetics of populations we meet

*DR*2 Let *a be* (denote, name, stand for) an allele.

*SA*2 *W dt represents* the total increase in fitness of the population of interest through the time interval *dt*.

Example 3 In mathematical sociology we come across

*DR*3 Let *k denote* a rung in a hierarchy.

*SA*3 $\sum_k k \cdot n_k$ *represents* the status of an individual with n_k subordinates on the *k*th rung of the hierarchy.

Because names are conventional, denotation rules are partly conventional. That is, the same factual items might be relabelled without qualms, as this would ensue in a different symbolism not in a new body of theory. However, inasmuch as the denotation rules indicate the hypothetical referents of the theory, they are not conventional: the theory might turn out to refer to different entities or to no real entities at all. And it is even clearer that the semantic assumptions are full blown hypotheses not just a matter of notation. They are not hypotheses about reality but about the theory-reality correspondence. Consequently a change in the semantic assumptions of a theory will ensue in a different theory with the same mathematical formalism. For example *SA*1 above is unacceptable to an operationist, who would reformulate it in terms of the measurable position values obtained by an observer attached to (or constituting) the frame *f*. As to *SA*2, it might not hold in a theory other than Fisher's mathematical theory of natural selection. Finally *SA*3 might read differently in an organization theory focusing on effective power instead of status.

The distinction we have drawn is seldom made explicitly in the scientific literature. Here one finds careless statements such as ⌜*T* is the absolute temperature⌝, which may be interpreted either as a designation rule or as a semantic assumption. It behooves the semanticist and the foundations worker to find out in each case whether the blanket word 'is' is intended to stand for "designates", "denotes", or "represents". Such distinctions are not pedantic: they make the difference between convention and conjecture. And this difference is of course of paramount methodological difference. Yet it is not made in the contemporary philosophy of science, where semantic rules and semantic hypotheses go by the common name of *correspondence rules.*

Since denotation rules are only partly conventional and semantic assumptions are wholly hypothetical, they ought not to be accepted on authority as they sometimes are. It should be possible to argue about them and even to put them to the test – though not independently of the mathematical formalism they serve. Let us try and explain. A theory constitutes no factual theory unless it includes a set of semantic formulas interpreting its basic concepts in factual terms. (Whether these semantic ingredients are displayed within the body of the theory, or hinted at in casual remarks, they are attached to the mathematical formalism.) Consequently it is the theory as a whole, i.e. the mathematical formalism together with the set of semantic formulas, that is subject to empirical tests. Fancy sending either a fleshless formalism or a boneless semantics to the laboratory.

If the empirical tests prove favorable and are themselves reliable, the formalism-semantics composite is declared confirmed until new notice. Otherwise there are three possibilities: to blame the formalism, to blame the semantic formulas, or to scrap both. The former alternative invites mending the formulas without touching the interpretation: this is a common enough procedure and one that succeeds often. The third alternative calls for a fresh start and may end up in a scientific revolution such as the founding of quantum mechanics. The middle alternative, viz., repairing the semantic formulas, seems to be less well known to philosophers but it is tried more often than radical upheavals. The following examples are well known to physicists and they show how significant a change in the semantics of a theory can be.

Example 1 The main impact of special relativity upon classical electrodynamics was forcing it to abandon all reference to the mechanical ether. From then on the theory was deemed to refer to, and represent, electromagnetic fields. Consequently all the questions concerning the properties of the ether and motions relative to it disappeared overnight. *Example 2* In the beginnings of wave mechanics the ψ function was regarded either as a real wave or as a mere mathematical auxiliary (an intervening variable). Later on its square was assumed to represent the mass density of the system associated with ψ. Eventually the so called statistical interpretation was adopted on reasonable grounds and all the rival interpretations shown to be responsible for consequences incompatible with the empirical evidence. *Example 3* Yukawa's theory of nuclear forces assumed that it was concerned with μ-mesons. But the latter refused to conform to the theory. Eventually it was found that π-mesons did satisfy the theory reasonably well. Accordingly the original semantic assumption was changed.

The semanticist cannot decide whether to change the formalism or the semantics of a scientific theory in the face of adverse empirical evidence. All he can do is to insist that the semantic formulas be formulated explicitly and clearly in order to better keep them under control. He can also alert to the philosophical concomitants of any given semantic – but this point deserves another section.

4.2. *Philosophical Commitment of the SA's*

The foregoing examples of semantic formulas (denotation rules and semantic assumptions) suggest laying down the following methodological

RULE In a well formulated scientific theory

(i) the referents should be indicated by explicit *denotation rules* bearing on the class symbols of the theory;

(ii) a denotation rule has the form: 'σ denotes a (member of the class or species) Σ';

(iii) explicit *semantic assumptions* should establish which if any property of the referent(s) does a basic predicate of a theory represent;

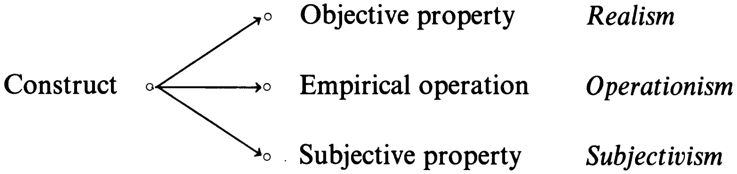
(iv) a semantic assumption has the form: 'P represents the… of a σ in Σ', where the blank names the property or relationship represented by the predicate P;

(v) the denotation of every defined symbol, as well as the representing function of every defined concept, should be consistent with the semantic formulas in which the defining items occur.

Needless to say, reference and property assignments must be consistent with the structure of the symbol or construct concerned. Thus if a single class symbol occurs in a theory then it can denote a single kind of entities rather than, say, the set of ordered pairs thing-apparatus or thing-observer. (This condition is ignored by the operationist interpretations.) And if a certain function is not time dependent then it cannot represent a change in the course of time. Secondly: it is not mandatory for every predicate in a theory to represent some property. Many predicates, particularly in sophisticated theories, represent no definite property even when (*a*) they have definite referents and (*b*) they help defining constructs that do represent. This is the case with lagrangians, partition functions, and the eigenfunctions of quantum mechanical operators other than the energy operator. Thirdly, denotation rules and semantic assumptions *sketch* factual meanings but do not exhaust them. No single piece of a factual theory, not even its semantic assumptions, gives a full characterization of the factual meaning of the theory: only the theory as a whole is fully meaningful. More on this in Ch. 5, Sec. 6.

The preceding rule can be implemented in alternative ways for any given theory. In other words, given a mathematical formalism and the above rule, there is still play enough to obtain a number of alternative factual theories – as many as alternative sets of semantic formulas be superimposed on the formalism. Which is just as well, for we want to try out different theories before we choose one of them.

Moreover, the implementation of the preceding rule depends upon one's philosophy. In particular, a semantic assumption may be construed in at least three different ways:



In the first case the theory, even should it refer to brains, would be assigned a strictly objective meaning, i.e. one independent of the cognitive subject or observer. In the second case the theory, even should it refer to galaxies far out of reach, would be assigned an operational meaning, i.e. every predicate in it would be correlated to an object-subject compositum. And in the third case the theory would concern the theoretician himself, e.g. his state of knowledge, the strength of his beliefs, and the span of his uncertainties.

These three lines in the semantic spectrum are particularly bright in relation with stochastic theories. Thus a transition probability $P(a \to b)$ from state a to state b of some system is usually interpreted in either of the following ways.

Realist SA $P(a \to b) \triangleq$ The *tendency* for the system to evolve from state a to state b.

Operationist SA $P(a \to b) =$ The *frequency* with which the system, when subject to some experimental condition, is *observed* to evolve from state a to state b.

Subjectivist SA $P(a \rightarrow b) \hat{=}$ My rational degree of *belief* in the system's transition from state a into state b.

Often either of these semantic assumptions is adopted on faith or on the strength (or weakness) of some philosophical tradition, and in any case with little concern for the structure of the concept concerned or for the role it plays in the law statements of the theory. If the probability function P occurring above is analyzed it is found that a and b denote states of some system quite apart from any experimental considerations: if there is a single object variable involved then there is no room for a second object variable such as an apparatus, much less for a third object variable representing an observer. The object variable must then represent either an external object or the theoretician (or his mind). If the former, then all the law statements in which P occurs must concern external objects whence they must be testable by handling and observing such objects. But if the referent of P is the theoretician himself, then all the statements in which P occurs must likewise refer to him (at least) and so the empirical tests of such formulas must include introspections.

We should then realize what our semantic assumptions commit us to and what their philosophical underpinnings are. And we must demand that every semantic assumption, far from being accepted on authority, be *testable* both conceptually and empirically, namely thus:

(i) A semantic assumption should *fit the structure* of the concept concerned and it should not violate any of the basic formulas in which the construct occurs. Checking this condition is of course a matter of pencil and paper: it is a conceptual test.

(ii) The construct involved in a semantic assumption should in fact describe what it is assumed to represent. Checking this condition calls for *empirical tests* of some of the formulas interpreted by the semantic assumptions.

Thus if a theory contains semantic assumptions of the operationist type, we should check (a) whether the mathematical formalism does make room for such assumptions (e.g. whether there are enough variables to represent not only the system but also the experimental set up and the observer), (b) whether the theory allows one to compute quantities representing properties of something that is not being subjected to experimental conditions, and (*c*) whether the experimental results are in fact critically dependent upon the observer and his equipment. And if the theory contains semantic assumptions of the subjectivist type, we should check (*a*) whether the theory does issue predictions about the theoretician's (or the observer's) mental states or behavior and (*b*) whether the available empirical data do bear on the cognitive subject himself rather than on objects external to him – e.g. other people. In conclusion, the semantic assumptions of a scientific theory are not conventions and they are not *dicta* beyond controversy: they are testable hypotheses. (Only, they cannot be put to the test separately from the formulas they endow a factual content with.) That they are hypotheses, and often controversial ones, can be seen from the debates on the interpretation of the mathematical formalisms of the quantum theories, to which we now turn.

4.3. *Application to Quantum Mechanics*

Quantum mechanics is probably the scientific field with the largest number and variety of semantic assumptions. (See Bunge (1956) and 'Quantum-mechanics debate', *Physics Today* **24** (1971), No. 4, pp. 36–44.) Quite often pairs of mutually incompatible semantic assumptions are nonchalantly attached to a given formula in one and the same paper. Table 3.5 exhibits a modest sample of such alternative semantic assumptions in relation to just two formulas of daily use. These formulas are

the *eigenvalue equation* $A_{op}u_k = a_k u_k$, where $A_{op} \hat{=} \text{Property } A$,

and

the *eigenfunction expansion* $\psi = \sum_k c_k u_k$.

Only a detailed analysis of the whole theory enables one to side with one or the other alternative set of semantic assumptions. An analysis performed elsewhere (Bunge, 1967b, 1967e, 1969) shows that only the realist interpretation is allowed by the mathematical formalism of quantum mechanics. We cannot go into details here but we will give a couple of reasons for rejecting the standard or operationist (or Copenhagen) version of the semantics of quantum mechanics.

A first reason why a semantic assumption cannot correlate theoretical constructs with empirical items is that the former are just not roomy enough to make place to instruments and observers. In other words, the

TABLE 5

Two sets of rival semantic assumptions (operationist and realist) for the eigenvalue equation and the eigenfunction expansion. A_{op}: operator other than hamiltonian

Symbol	Mathematical status	Operationist semantic assumption	Realist semantic assumption
A_{op}	Operator in a Hilbert space	Refers to an object-apparatus-observer block. Represents a dynamical variable of the whole.	Refers to a physical system irrespective of environment. Represents intrinsic property of system.
u_k	Function in a Hilbert space	Same referent as A_{op}. Represents state of block when measurement yields value a_k.	Refers to system (no environment). Represents nothing. (Eigenfunction expansions are mathematical auxiliaries.)
a_k	Real number	Possible value one finds upon measuring dynamical variable represented by A_{op}.	Possible value of dynamical variable A_{op}.
ψ	Function in a Hilbert space	State of observer's knowledge before performing any measurement.	State of physical system in some environment (eventually null or nonexistent).
$\|c_k\|^2$	Positive real number	Probability of getting value a_k upon measuring dynamical variable represented by A_{op}, or strength of one's belief that a_k will turn up upon measurement.	Propensity or tendency of value a_k of A

formulas do not contain enough variables that could refer to experimental situations: this is a semantic argument. A methodological reason why a semantic assumption cannot assign empirical items to a theoretical construct is that theories cannot possibly concern their own tests. Every empirical test ropes in objects other than those represented by the theory, namely pieces of apparatus. And these additional objects must be represented by additional theories. These, the auxiliary theories representing the object-experimental set-up complex, will differ according to the nature of the experimental set-up, which is rarely unique. For example, thermodynamics contains the pressure concept but no provisions for designing pressure gauges. And the latter are often employed in testing quantum mechanics but the very notion of pressure is absent from the latter. Another example: electromagnetic fields affect the growth of plants and their shape. Hence one might think of using plants as low sensitivity instruments for measuring some traits of the electromagnetic field. But it would be preposterous to claim that the electromagnetic theory, let alone quantum electrodynamics, represent plants. In general, any statements concerning the nature or the strength of the empirical evidence relevant to a scientific theory are built with the help of at least one other theory (Bunge, 1967a, 1973b). However, this is another matter – one for methodology not semantics.

5. CONCLUSION

In this chapter we have initiated an investigation of the notion of representation which will be completed in Ch. 6, Sec. 3. This notion is conspicuously absent from the conventionalist, formalist, and empiricist semantics of science. In particular the latter, which is the best known, has no use for the concept of representation because it rejects the realist thesis and holds nonlogical concepts to be ultimately percepts or logical constructions out of the latter. According to empiricism scientific theories have an observational or empirical content given them by the "correspondence rules" of the theory, which rules link the theoretical terms to observational terms, which are in turn theory-free. The notion of a real or autonomous thing, which to the realist is the object of both theory and scientific experience, does not occur at all in that doctrine.

An analysis of real specimens of scientific theory would have shown that the sole support enjoyed by empiricist semantics is tradition – a tradition of exact analyses and careful reconstructions of a nonexistent science. A case study work of the type sponsored by Törnebohm's Institutionen för Vetenskapteori in Göteborg would have shown that (*a*) the aim and outcome of theorizing is not canning sensations or even data but representing selected aspects of putatively real things, (*b*) theoretical concepts are sophisticated mathematical constructions that can neither be defined in terms of empirical operations nor construed as logical functions of observational concepts, and (*c*) empirical tests, which are conducted in order to estimate the truth value of hypotheses and theories, consist in operations planned in the light of further theories – a process that Agassi has aptly named a *bootstrap* operation.

Experience – controllable not subjective, refined not coarse – is the methodological link between theory and reality. This link does not belong to the theory: if it did then either of them would be redundant. And it is not the sole bridge that spans the chasm between theory and reality: there is also the semantic bridge constituted by the semantic assumptions of the theory. (We do not include among them the semantic conventions or designation rules, which are conventional symbol-construct links.) Those hypotheses are of two kinds:

(a) *denotation rules* of the form "Symbol s denotes thing θ";

(b) *representation assumptions* of the form "Function F represents property P of thing θ".

The semantic assumptions of a scientific theory couple symbols and their designata with supposedly real things and their properties. Since they have putatively real referents and fail to be tautologous, by Ch. 2, Sec. 4 our semantic assumptions are factual statements. Hence they have a factual content. Moreover since they are the only systematic indication concerning whatever the theory is supposed to represent, the semantic assumptions determine, at least in outline, the factual meaning of the extralogical constructs involved in them. In other words, the corrigible assumptions concerning what concepts in a theory represent which features of the world contribute to endowing a scientific theory with a factual content. Which takes us to the subject of the next chapter.

CHAPTER 4

INTENSION

⌜People make mistakes⌝ and ⌜People learn to correct some mistakes⌝ have the same referents but different senses. They represent different traits of mankind, and this quite apart from their truth values. Yet the senses of these two statements, whatever 'sense' be taken to signify, cannot be disjoint since the second proposition implies the first. The question is: What exactly are their senses and how are they related? This is the problem we face in this chapter. However, a complete solution to it will ensue only as a merger of the present chapter with the next: in this chapter only one sense of "sense" will be investigated.

1. FORM IS NOT EVERYTHING

1.1. *Concepts of Sense*

Whereas the concept of form is presumably clear, that of content is reputedly obscure. However, there is no denying that we handle contents all the time. Thus we are likely to praise logic (or to debase it, as the case may be) for being content free, hence for treating ⌜Dolphins are mammals⌝ on a par with ⌜Fractions are real numbers⌝. But it is equally clear that in order to find out the form of a construct we must know something about its content or lack of it. Change the content and the form may alter. For example, *prima facie* "longer than" is a dyadic relation but, when analyzed in relativistic physics, it proved to be triadic: here we must write ⌜x is longer than y relative to z⌝.

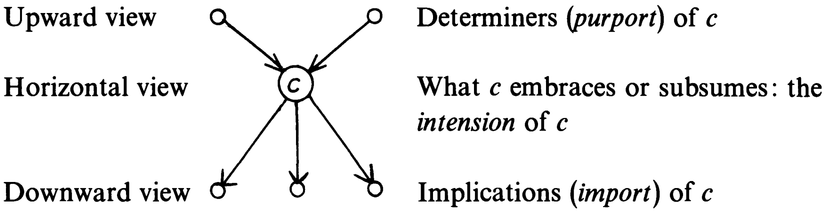
Scientific constructs come with both a form and a content. These two aspects can be distinguished but not separated: only logic can afford to deal with pure form. But distinguished they must be if we wish to understand what makes logic different from the rest, and if we are to explain the recurrence of the same mathematical structures in different fields. Take for instance "fitter than" and "more intelligent than". The two are isomorphic in the sense that they are different interpretations of the relation $>$, and so they have different contents. Even coextensive concepts, i.e. concepts with the same instances, may have different contents. For example, "mammal" and "hairy" are isomorphic and coextensive, yet they have ostensibly different contents. Likewise "avian" and "feathery", "the successor of 1" and "the smallest prime number", and so on and so forth. In short, a scientific construct is not characterized by its form and extension alone.

Granted then that, outside logic, there is something, variously called 'content', 'sense', 'intension', or 'meaning', that is not to be written off. Granted also that reference and extension are of little if any help in determining contents, as coreferentials and even coextensives, such as "human" and "cruel", can have different senses. Granted, in sum, that contents or senses are *sui generis* objects, distinct from forms, reference classes, and extensions, and thus far more difficult to pin down than either of these. The question is: What do we do with those elusive objects? Two attitudes are possible: retreat or attack. The former is argued for in this way: "Senses have always been obscure. They have defied the best philosophical minds. Therefore they are hopelessly obscure. Consequently we had better give up any attempt to clarify them". The outcome of this policy is to allow the beast to roam in the wilderness of obscurantist philosophy: after all, "man is a sense-making animal" (Quine, 1966, p. 175), and nothing human is reputedly alien to philosophers. We refuse to adopt the defeatist stand. We propose to launch an attack with a view to taming the wild beast. Our motto will be "Divide and conquer".

In fact our point of departure is recognizing that there is not a single concept of sense but rather three different concepts. We shall show later on that they are related, but we begin by distinguishing them as so many dimensions of sense. Indeed we shall propose and explain the thesis that a construct may have the following kinds of sense:

(i) the totality of its conceptual determiners, or *purport*:
(ii) the set of constructs it subsumes or embraces – its *intension*;
(iii) the totality of its *implicates*, or *import*.

In each case the sense of a construct is a set of constructs. (Note the difference with respect to both reference and extension: a scientific construct will refer to, and extend over, sets of factual items.) In each case the content of a construct is logically related to the construct itself. (Note again the difference with respect to both reference and extension.) But in the case of purport we look upwards, at the impliers; in the case of intension we look horizontally, into the construct; and in the case of import we look downwards, at the consequents:



Upward view
Determiners (*purport*) of *c*
Horizontal view
c
What *c* embraces or subsumes: the *intension* of *c*
Downward view
Implications (*import*) of *c*

Example The concept Δ of Euclidean triangle.

Purport (Δ) = The (finite) set T of statements in Euclidean geometry sufficient to characterize all the properties of Δ.
Intension (Δ) = $\{\Delta$ is a closed plane figure with 3 rectilinear finite sides$\}$.
Import (Δ) = $\{\Delta$ is a polygon, The inner angles of Δ add up to π, etc., etc.$\}$
Referents (Δ) = The (infinite) set of plane figures.
Extension (Δ) = The (infinite) subset of plane figures satisfying the conditions T of triangularity.

Of these three concepts of sense that of purport seems to be new although it sounds quite natural. It will be shown to embrace the concept of gist, or basic purport, of everyday use. The second concept of sense, viz., "intension", seems to elucidate the *significatio* of Medieval logicians as well as the *compréhension* of the Port Royal *Logique* (Arnauld and Nicole, 1662). The latter was translated by Sir William Hamilton as *intension*, a term that has been with us – and often against us – ever since (see Kneale and Kneale, 1962). A similar concept occurs in Bolzano (1837), Meinong and many others as *Inhalt*. Frege used it under the label of *Sinn* (sense) though without subjecting it to an exact theory. And, at least formally, our concept of intension is close to the *L-content* of Carnap (1942). Finally the third dimension of sense, namely import, is near the *C-content* of Carnap (1942), the *intension* of Lewis (1944, 1951) and of Castonguay (1971), and the *truth content* of Popper (1963b, 1966).

Our three concepts of sense have then roots in common sense or in technical philosophy. However, our theories of them exhibit important differences with respect to previous theories. For example, our theory of import does not involve any notion of truth: it is a purely syntactic theory employing the algebraic theory of filters. Besides, our calculus of import joins with our views on the nature of a factual theory, to yield new ideas on factual content as well as on meaning changes. Moreover we shall show that the three concepts – those of purport, intension, and import – are interrelated. (For example, purport and import are mutually dual in the algebraic sense, and in the case of axiomatic systems the intension is included in the union of purport and import.) Finally it will be seen that none of our concepts of sense can be equated with that of semantic information, and that they must also be kept separate from the concepts of testability.

Since we shall deal systematically with three different concepts, we may expect one theory for each. In point of fact we shall evolve the three theories independently and shall explore their relations at the end. We shall find it convenient to start at the middle, i.e. from intension. Purport and import will be tackled in the next chapter. But before proceeding to build a theory of intensions we must show why we need one and we must guard against confusing 'intensional' with 'intentional', 'nonextensional', and 'non truth functional'.

1.2. *Extension Insufficient*

The set theoretic and model theoretic treatments of mathematical concepts have been so effective, and they have had such a clarifying and unifying power, that they have buttressed the belief that only extensions (domains of individuals) matter. This belief may be spelled out in the following tenets:

E1 Every mathematical entity is either an individual or a set.

E2 Reference is the same as extension.

E3 Senses or intensions are either ghostly or reducible to extensions.

Criticism of E1 This thesis is particularly apparent in the theory of relations as treated in set theory. Here it takes the form: "Every relation may be defined simply as a set of ordered *n*-tuples". This claim is exaggerated: the predication relation in logic (i.e. the relation between a predicate and its subject or subjects, as in $\ulcorner Pa \urcorner$), the membership relation in set theory, and the relation of satisfaction in model theory, are not definable as sets of ordered couples. Hence although sets, in particular the extensions of relations, are extensional objects, their theories are not purely extensional. What is true is that, in *most* cases in *pure* mathematics (not so in factual science), only the extension of a relation *need* be taken into consideration for purposes of *proof*. In any case it is incorrect to identify a relation with its graph or extension. Bourbaki, for one (or rather many), draws a careful distinction between a relation and its graph (extension), in particular between a correspondence (e.g. a function) and its graph. A correspondence between the sets A and B is defined as a certain triple $F=\langle G, A, B\rangle$, where G is the graph of F (Bourbaki, 1970, Sec. 3). Finally, it is not true that all mathematical theories are reducible to set theory – nor, *a fortiori*, that they can dispense with intensions. The basic concepts of category theory, namely those of object and morphism, are not so reducible. It is rather the other way around: the set theoretic predicates may be defined in categorial terms (Lawvere, 1966). In sum, the extensionalist program of reducing every mathematical object to either an individual or an aggregate of individuals subject to the postulates of (some) set theory, though remarkably successful, is not fully feasible.

Criticism of E2 To begin with, while both predicates and propositions can be assigned referents, only predicates are normally said to have an extension. And even in the case of predicates a distinction between extension and reference class is needed. For example,

$$\mathcal{R}\,(\text{Prime number}) = \text{Natural numbers},$$
$$\mathcal{E}\,(\text{Prime number}) = \text{Prime numbers}.$$

The difference is even more pronounced outside mathematics. Thus

$$\mathcal{R}\,(\text{Flying on a broomstick}) = \text{Witches},$$
$$\mathcal{E}\,(\text{Flying on a broomstick}) = \emptyset.$$

A more respectable example is this:

$$\mathcal{R}\,(\text{Rational}) = \text{Mankind}, \ \mathcal{E}\,(\text{Rational}) \subset \text{Mankind}.$$

Finally an example from recent science: while the (hypothetical) reference class of "parton" is the set of partons, nobody knows what the actual extension of that theoretical predicate might be, not even whether it is nonvoid. In conclusion, *Reference* $\neq$ *Extension*. And, as we shall see in Ch. 9, Sec. 1.1, in general extensions are not subsets of reference classes: only the extensions of unary predicates are.

Criticism of E3 The thesis that senses can be written off altogether is false even for set theory, the paradigm of a "purely extensional theory". Indeed set theory distinguishes a predicate from its extension. So much so that it devotes an entire axiom (schema) to the relation between a predicate and its extension, namely the principle of abstraction or its improved version the principle of separation (*Aussonderung*). According to this axiom schema, to every well formed formula Px of the lower predicate calculus and to every set A there corresponds another set B whose elements are exactly those members x of A for which Px holds (cf. Suppes, 1960, p. 21):

$$(\exists B)\,(x)\,(x \in B \Leftrightarrow x \in A \;\&\; Px).$$

In our terminology A is included in the *reference class* of P while $B = \mathscr{E}(P)$ is the *extension* of P. In the case of monadic predicates, like the one involved in the previous formula, $\mathscr{E}(P) \subseteq \mathscr{R}(P)$. *Example.* Let $A = \mathbb{Z} =$ The set of integers, and $Px = \ulcorner x$ is prime$\urcorner$, with $x \in \mathbb{Z}$. Then $\mathscr{R}(P) = \mathbb{Z}$ and $\mathscr{E}(P) =$ The set of prime numbers $\subset \mathbb{Z}$. The axiom of separation is not a device for getting rid of whatever sense a predicate may have: it just clarifies the *relation* between a predicate (whichever its sense may be) and its extension. Finally, the extensionalist program fails altogether in factual science. For example, the predicates "metallic", "good thermal conductor", and "good electric conductor" have the same extension although their senses are obviously different. If only for this reason the predicates occurring in theoretical science cannot be defined *within* set theory, i.e. in the last analysis solely in terms of membership in some set, as Suppes (1967, 1969) has been advocating untiringly. We also need semantic assumptions concerning reference and representation, as we have seen in Chapters 2 and 3.

To sum up, the extensionalist thesis is false even within mathematics: we may refrain from looking at intensions for a while but we cannot suppress them. Nor should we mistake them for other characters, such as psychological intentions and modalities. This confusion deserves a separate subsection.

1.3. *'Intensional': Neither Pragmatic nor Modal*

Principia Mathematica (Whitehead and Russell, 1927, pp. 72ff and 659ff) misled several generations of philosophers by its quaint use of the word 'intensional'. What *PM* meant by this term was not one of the *semantic* concepts of sense but a certain class of *pragmatic* concepts, often called 'propositional attitudes', "such as what somebody believes or affirms, or the emotions aroused by some fact". Typical "intensional" terms would be 'doubts', 'is puzzled by', 'believes', 'knows', and 'asserts', which designate relations between a person and a proposition. Correspondingly a statement of the form $\ulcorner x$ believes that $y\urcorner$ is often called an *intensional context.* And any attempt to clarify and systematize such pragmatic statements is often said to belong to *intensional logic.*

To find out what such misnomers designate let us examine a typical example of an "intensional context". Consider the statements

$$p = \ulcorner\text{Milk is good}\urcorner \tag{1}$$

and

$$q = \ulcorner\text{Baby believes that } p\urcorner. \tag{2}$$

Whereas p is allegedly a perfectly "extensional" construct, q would be an "intensional" one, for its truth value is not a function of the truth value of the subordinate statement p alone. If it were, the truth value of q would remain invariant upon replacing p by any of its equivalents – which is not the case. Indeed, p is equivalent to

$$r = p \,\&\, (s \vee \neg s) \tag{3}$$

which, substituted for p in (2), yields

$$t = \ulcorner\text{Baby believes that milk is good and } (s \vee \neg s).\urcorner \tag{4}$$

which, unlike q, is false.

All this has nothing to do with intensions although it might be claimed to concern intentions. In fact, since tautologies are void of content, p and r above have the same intension. But they fail to have the same effect on all persons: whereas to a logician the utterance of r conveys just as much information as p does, to a layman r may sound more informative than p and to a baby r is likely to sound as gibberish. (More on information in Sec. 3.2.) All of this is pragmatics not semantics.

The actual situation is simply this. The statement q in (2) depends not just on the statement p but also upon a person, namely Baby, and a circumstance or time t. In brief, $q = B(\text{Baby}, p, t)$ where 'B' stands for the belief function. In general, pragmatic statements involving propositions are of the form: $q=P(\text{person}, p, t)$, where 'P' stands for a pragmatic function such as that of knowing. No wonder logic cannot cope with such hybrids. Little wonder that the truth value of such a statement q depends not just on the truth values of its subordinate statement p but also on the background knowledge and the state of the person concerned. In other words P is not a truth function – more accurately, it is not a truth preserving map. P is a *non truth preserving pragmatic function* – or, if preferred, an inten*t*ional function. To call it 'inten*s*ional' is to equivocate.

Pragmatic functions constitute a subclass of the class of non truth preserving functions. Some of the latter may not involve any person in an overt way. For example, ⌜*p* is conceivable⌝, ⌜*p* is doubtful⌝, ⌜*p* is puzzling⌝, ⌜*p* is beautiful⌝, ⌜*p* is suggestive⌝, ⌜*p* is useful⌝, and ⌜*p* is provable⌝ are not ostensibly pragmatic statements. Yet they can be construed as covert pragmatic statements. For example, ⌜*p* is conceivable⌝ may be construed as short for ⌜There is at least one person who can conceive of *p*⌝. But this is irrelevant to semantics. What is relevant to it is what all such statements have in common. And this is that they resist the substitution of equivalents. More explicitly: In all of these cases the subordinate proposition may not be replaced by any of its logical equivalents *salva veritate*, i.e. with preservation of the truth value of the total proposition. To paraphrase *PM*: A function of a construct will be called a *truth preserving function* when its truth value with any argument is the same as with any formally equivalent argument. Otherwise it will be called a *non truth preserving function* – by no means an "intensional function".

Modal statements are of course the best studied of all those that violate the principle of the substitutivity of equivalents. Since they, too, fall outside ordinary ("extensional") logic, Lewis and Carnap concluded (probably misled by the unorthodox use of 'intensional' in *PM*) that they must obey some systems of "intensional logic". Thus we have a first confusion: "Whatever is modal is intensional". Now indulge in the most common fallacy and obtain "Whatever is intensional is modal". These two mistakes engender the now rather popular misconception that modal logic is the key to whatever boxes ordinary logic cannot open: not only possibility but also intensions and "propositional attitudes". This conflation of "modal" with "intensional" can only vitiate semantics.

We shall keep clear of these confusions and will make no use of that all purpose tool, modal logic. The very idea of an "intensional concept", as opposed to an extensional one, is a misfit: if a concept has an intension it also has an extension even if nil. (The converse is false: sets have no intensions.) Hence the expressions 'intensional function' and 'intensional context' are misnomers. Frege's name for them, namely *ungerade* (oblique), and Quine's 'referentially opaque', are preferable. However, since 'referential opacity' has at least three different significations (Sharvy, 1972), we prefer the longer but nonmetaphorical and more explicit name 'non truth preserving'. And we shall gladly leave the study of non truth preserving functions (or inten*t*ional concepts) to pragmatics, epistemic logic, modal logic, and any other discipline that be deemed competent to handle them.

We now turn to a study of intensions conceived as semantic objects.

2. A CALCULUS OF INTENSIONS

2.1. *Desiderata*

Our aim is to build a calculus of intensions enabling us (*a*) to exactify the notion of intension and (*b*) to compute the intension of a complex construct, such as a conjunction, out of the intensions of its components. And we wish our calculus to formalize and articulate the following intuitive desiderata:

D1 All and only predicates and statements shall have an intension.

D2 The intension of a construct shall be a set.

D3 The intension of a construct in a context $C = \langle S, \mathbb{P}, D \rangle$ shall be comprised between $\emptyset$ and C, i.e. if $P \in C$, then $\emptyset \subseteq \mathcal{I}(P) \subseteq C$.

D4 If P and Q are both either predicates or statements, then

(*a*) $\mathcal{I}(P \,\&\, Q) \supseteq \mathcal{I}(P), \mathcal{I}(Q)$

(*b*) $\mathcal{I}(P \vee Q) \subseteq \mathcal{I}(P), \mathcal{I}(Q)$

D5 If $\mathcal{I}(P) \subseteq \mathcal{I}(Q)$, then

(*a*) $\mathcal{I}(P \,\&\, Q) = \mathcal{I}(Q)$

(*b*) $\mathcal{I}(P \vee Q) = \mathcal{I}(P)$

D6 If two constructs are identical so are their intensions.

D7 Tautologies are intensionally minimal and contradictions are intensionally maximal.

D8 The intension of $\ulcorner P \& (P \Rightarrow Q)\urcorner$ is the same as that of $\ulcorner P \& Q\urcorner$.

D9 Cointensives are coextensive – but not conversely.

D10 The smaller the intension of a construct the larger its extension.

We proceed to exhibit an axiom system that satisfies all these desiderata. (For interesting alternatives see Leonard (1967), Suszko (1967), Castonguay (1972), and Weingartner (1973).)

2.2. *Principles and Definitions*

Intension shall be construed as a certain function that assigns to every element of a conceptual universe of discourse a certain subset of the latter. More precisely, we lay down the following axiomatic

DEFINITION 4.1 Let U be a set of predicates or of statements. The *intension* function $\mathscr{I}$ is the function from U onto the family $\mathscr{P}(U)$ of subsets of U such that, for any P and Q in U,

(i) If $P \& Q$ is defined, then $\mathscr{I}(P \& Q) = \mathscr{I}(P) \cup \mathscr{I}(Q)$;
(ii) $\mathscr{I}(\neg P) = \overline{\mathscr{I}(P)}$;
(iii) If $P = Q$ then $\mathscr{I}(P) = \mathscr{I}(Q)$.

Example 1 $\mathscr{I}$(Female human) $= \mathscr{I}$(Female) $\cup\, \mathscr{I}$(Human). *Example 2* $\mathscr{I}$(Unattached) $= \overline{\mathscr{I}(\text{Attached})}$. *Example 3* Since $\ulcorner 1+2=3\urcorner$ is the same proposition (though not the same sentence) as $\ulcorner 3=1+2\urcorner$, $\mathscr{I}(1+2=3) = \mathscr{I}(3=1+2)$. Note that, pragmatically, the two sentences are different: while the first expresses the unique outcome of a correct addition operation, the second summarizes one of the possible results of a correct decomposition of 3.

Remark 1 The generalization of the first axiom to multiple conjunctions, whether finite or infinite, is immediate:

$$\text{If } \textstyle\bigwedge_i P_i \text{ is defined, then } \mathscr{I}(\bigwedge_i P_i) = \bigcup_i \mathscr{I}(P_i) \text{ for } P_i \in U,\ i \in N.$$

Remark 2 Definition 1 tells us, so to say, how intensions behave not what they are. Indeed, it fails to prescribe how to find the intensions of the constituents of the compound constructs. (Likewise truth functional logic shows us to compute the truth value of a compound statement given the truth values of its components.) The problem of determining the basic intensions will be faced in the next Chapter. *Remark 3* The converse of clause (iii) in Definition 1 is false. Thus ⌜Temperature $(b)=t$⌝ and ⌜Temperature $(b')=t'$⌝, though cointensive, are not identical (unless of course the referents b and b' happen to be the same).

We can now elucidate certain interesting derivative concepts.

DEFINITION 4.2 A construct is said to be *intensionally empty* iff its intension is equal to the empty set.

DEFINITION 4.3 A construct in U is said to be *intensionally universal in U* iff its intension equals U.

DEFINITION 4.4 If P and Q are in U, then P is said to be *intensionally included* in Q (or intensionally poorer than Q) iff $\mathscr{I}(P) \subseteq \mathscr{I}(Q)$.

DEFINITION 4.5 Two constructs in U are said to be *cointensive in U* iff their intensions are the same: $\mathscr{I}(P)=\mathscr{I}(Q)$.

DEFINITION 4.6 Two constructs are said to be *intensionally independent* ("perpendicular") iff their intensions are disjoint:

$$P \perp Q =_{df} \mathscr{I}(P) \cap \mathscr{I}(Q) = \emptyset .$$

DEFINITION 4.7 Two constructs are called *intensionally dependent* iff they are not independent – i.e. if their intensions overlap.

Before looking at the consequences of our assumptions and definitions let us note that an intensionally empty construct is a construct all right – not a nonconstruct. For example tautologies will prove to be intensionally void (Theorem 5). The intension function $\mathscr{I}$ is defined for predicates and statements and for them only, hence sets and nonconstructs fail to have a definite intension. One such nonconstruct results from the conjunction of predicates defined on disjoint domains, such as "wind" and "stupid". Our axiom (i) does not apply to "stupid wind" (Yeats) because there is no nonvoid domain on which "stupid wind", or any other such freak, is defined. In other words, for a predicate to have a definite intension, even a null one, it must be well constructed to begin with:

recall the rule in Ch. 1, Sec. 1.3. This does not entail throwing poetry away but just noting that some poetic expressions, though pragmatically significant, are semantically nonsignificant.

2.3. *Main Theorems*

Firstly an immediate consequence of Definition 1:

COROLLARY 4.1 For any constructs P, Q, R such that $P = Q \,\&\, R$ is defined,

$$\mathscr{I}(P) \supseteq \mathscr{I}(Q), \mathscr{I}(R).$$

Example By definition, $x < y = x \leqslant y \,\&\, x \neq y$. Since "$\neq$" equals "not $=$", $\mathscr{I}(\neq) = \overline{\mathscr{I}(=)}$ is nonempty. Hence $\mathscr{I}(<) = \mathscr{I}(\leqslant) \cup \mathscr{I}(\neq) \supseteq \mathscr{I}(\leqslant)$. Briefly, "$\leqslant$" is intensionally poorer than "$<$".

THEOREM 4.1 If P and Q are either predicates or statements, and $P \vee Q$ is defined,

$$\mathscr{I}(P \vee Q) = \mathscr{I}(P) \cap \mathscr{I}(Q).$$

Proof By logic $P \vee Q = \neg(\neg P \,\&\, \neg Q)$. By Definition 1(iii), $\mathscr{I}(P \vee Q) = \mathscr{I}(\neg(\neg P \,\&\, \neg Q))$. By (ii), the RHS is $\overline{\mathscr{I}(\neg P \,\&\, \neg Q)}$. By (i) the last formula equals $\overline{\mathscr{I}(\neg P) \cup \mathscr{I}(\neg Q)}$. Finally, by (ii) we get $\overline{\overline{\mathscr{I}(P)} \cup \overline{\mathscr{I}(Q)}}$ which, by one of de Morgan's theorems in the algebra of sets, gives the desired result.

Example Elucidate possibility of the conceptual kind as $\Diamond p =_{df} p \vee q$ with q indeterminate. Then $\mathscr{I}(\Diamond p) = \mathscr{I}(p) \cap \mathscr{I}(q) \subseteq \mathscr{I}(p)$. That is, possibility statements are intensionally included in their "extensional" bases – which is one reason for avoiding them (whenever possible!).

COROLLARY 4.2 If $\mathscr{I}(P) \subseteq \mathscr{I}(Q)$, then $\mathscr{I}(P) = \mathscr{I}(P \vee Q)$.

Proof By the algebra of sets $\mathscr{I}(P) \subseteq \mathscr{I}(Q)$ iff $\mathscr{I}(P) \cap \mathscr{I}(Q) = \mathscr{I}(P)$. Apply Theorem 1 to the LHS of the last equation.

Remark This result shows that the converse of axiom (iii) is false: cointensiveness does not imply identity. For, if it did, we should have $P = P \vee Q$. This suggests that our concept of intension does not coincide with that of sense. We shall see in Ch. 5 that the former is included in the latter.

THEOREM 4.2 If P and Q are either predicates or statements, then

$$\mathscr{I}(P \Rightarrow Q) = \overline{\mathscr{I}(P)} \cap \mathscr{I}(Q) = \mathscr{I}(Q) - \mathscr{I}(P) \subseteq \mathscr{I}(Q).$$

COROLLARY 4.3 If P and Q are either predicates or statements, then

$$\mathscr{I}(P \Leftrightarrow Q) = \mathscr{I}(Q) - \mathscr{I}(P) \cup \mathscr{I}(P) - \mathscr{I}(Q) \equiv \mathscr{I}(P) \mathbin{\Delta} \mathscr{I}(Q)$$

where 'Δ' designates the symmetric difference or Boolean sum.

We shall use this result in Sec. 2.6 in relation to differences in intension. It will turn out that "$\mathscr{I}(P) \mathbin{\Delta} \mathscr{I}(Q)$" is a good measure of the intensional difference between P and Q. Hence while the extension function $\mathscr{E}$ obliterates the differences between equivalents, the intension function $\mathscr{I}$ brings those differences into the open: see Figure 4.1

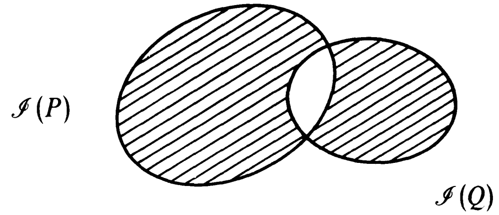


Fig. 4.1. The intension of an equivalence equals the (symmetric) difference between the intensions of the members of the equivalence (Corollary 3).

THEOREM 4.3 For any two predicates (or statements) P and Q, if $P \Rightarrow Q$ is defined then

$$\mathscr{I}(P \,\&\, (P \Rightarrow Q)) = \mathscr{I}(P \,\&\, Q).$$

Proof By Definition 1(i) and Theorem 2,

$$\begin{aligned}\mathscr{I}(P \,\&\, (P \Rightarrow Q)) &= \mathscr{I}(P) \cup (\overline{\mathscr{I}(P)} \cap \mathscr{I}(Q)) = \\ &= (\mathscr{I}(P) \cup \overline{\mathscr{I}(P)}) \cap (\mathscr{I}(P) \cup \mathscr{I}(Q)) \text{ by distributivity.}\end{aligned}$$

The first factor equals U and its intersection with the second factor equals the latter, which by Definition 1(i) in turn equals $\mathscr{I}(P \,\&\, Q)$.

THEOREM 4.4 For any predicate (or statement) P in U

(i) $\mathscr{I}(\neg\neg P) = \mathscr{I}(P)$;

(ii) $\mathscr{I}(P \vee \neg P) = \emptyset$;

(iii) $\mathscr{I}(P \,\&\, \neg P) = U$.

A generalization of Theorem 4(ii) is

THEOREM 4.5 Tautologies are intensionally void.

Proof Consider an arbitrary construct P and a tautologous one T. Because the collection of intensions is an algebra of classes, intersections determine greatest lower bounds or infima. Hence in particular $\inf\{\mathcal{I}(T), \mathcal{I}(P)\} = \mathcal{I}(T) \cap \mathcal{I}(P)$. By Theorem 1 the RHS equals $\mathcal{I}(T \vee P)$. Since the least intension is $\emptyset$, we have $\mathcal{I}(T \vee P) = \emptyset$. And, since the intension of P is comprised between $\emptyset$ and U, we conclude that $\mathcal{I}(T) = \emptyset$.

An obvious consequence of this theorem is that logic cannot alter contents. More precisely, we have

COROLLARY 4.4 Tautologies, if conjoined, do not add; if disjoined they deplete. I.e., for any predicate (or statement) P in U and any tautologous construct T of the same rank,

(i) $\mathcal{I}(P \,\&\, T) = \mathcal{I}(P)$
(ii) $\mathcal{I}(P \vee T) = \emptyset$

Proof By Definition 1 and Theorems 1 and 5.

COROLLARY 4.5 Contradictions, if conjoined, blow up; if disjoined they change nothing:

(i) $\mathcal{I}(P \,\&\, \neg T) = U$
(ii) $\mathcal{I}(P \vee \neg T) = \mathcal{I}(P)$.

Proof Similar to the previous proof.

COROLLARY 4.6 Repetition is futile:

$$\mathcal{I}(P \,\&\, P) = \mathcal{I}(P \vee P) = \mathcal{I}(P).$$

Consequently 'P', '$P \,\&\, P$' and '$P \vee P$' are not different concepts but different signs representing the same concept.

Finally a couple of results concerning the relations in intension between constructs that hold logical relations.

THEOREM 4.6 Whatever entails contains: If P entails Q, then P contains Q in intension and conversely:

$$\vdash P \Rightarrow Q \quad \text{iff} \quad \mathscr{I}(P) \supseteq \mathscr{I}(Q).$$

Proof First the left to right implication. By Theorem 2, $\mathscr{I}(P \Rightarrow Q) = \overline{\mathscr{I}(P)} \cap \mathscr{I}(Q)$. But by hypothesis the conditional is analytic and, by Theorem 5, analytic conditionals are intensionally empty. That is, $\overline{\mathscr{I}(P)} \cap \mathscr{I}(Q) = \emptyset$, which amounts to $\mathscr{I}(P) \supseteq \mathscr{I}(Q)$. Now the converse, i.e.: If $\mathscr{I}(P) \supseteq \mathscr{I}(Q)$ then $\vdash P \Rightarrow Q$. Assume the antecedent. Then, since $\mathscr{I}$ is by hypothesis a one to one map, there is a construct R such that $P = Q \,\&\, R$. And by logic $P \vdash Q$.

COROLLARY 4.7 If two constructs are analytically equivalent then they are coextensive and conversely:

$$\vdash P \Leftrightarrow Q \quad \text{iff} \quad \mathscr{I}(P) = \mathscr{I}(Q).$$

Contingent biconditionals, whether formal or factual, do not enjoy the same privilege – hence nonanalytic equivalents are not everywhere substitutable *salva significatione*. For example, in Euclidean geometry the propositional schemata "x is an equilateral triangle" and "x is an equiangular triangle" are equivalent but not analytically so – hence the two predicates are not cointensive. There would be little point in keeping the two concepts, as we do, if they were cointensive. As noted with reference to Corollary 3, the intension of an equivalence consists in whatever is not common to the equivalents. Coextensiveness is a bridge not a gate. This is a reason for not couching definitions, which are identities, in the form ⌜A iff B⌝. We shall return to this question in Ch. 10, Sec. 2.2.

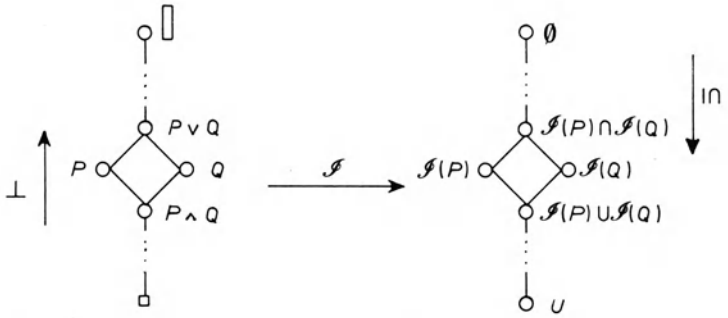

Fig. 4.2. The lattice of predicates and the lattice of intensions: anti-isomorphic.

Definition 1 and the preceding theorems and their corollaries show that there is a *duality*, or anti-isomorphism, between constructs and their intensions, in the sense that $\mathscr{I}$ carries meets into joins and conversely. Look at Figure 4.2.

2.4. *Intensional Difference and Family Resemblance*

The poorer the intension of a construct the more general it is. In other words, the more general (or less specific) of two constructs is the one with the smaller intension. Thus "atom" is more general than "helium atom" precisely because it is the weaker of the two. The difference in intension between a species concept S and a genus concept G, i.e. their *differentia specifica*, consists in whatever characterizes S but not G. Since in our semantics intensions are sets, it is natural to exactify the notion in this way:

$$\delta(S, G) = \mathscr{I}(S) - \mathscr{I}(G) \equiv \mathscr{I}(S) \cap \overline{\mathscr{I}(G)}.$$

The generalization of this concept to an arbitrary pair of constructs calls for the notion of symmetric difference, or Boolean sum, of sets. In this way we assure that the richer or stronger construct will show through. More explicitly, we introduce

DEFINITION 4.8 Let P and Q be either predicates or propositions. Then the *difference in intension* between them is the symmetric difference between their individual intensions:

$$\delta(P, Q) = \mathscr{I}(P)\ \Delta \mathscr{I}(Q) \equiv \mathscr{I}(P) - \mathscr{I}(Q) \cup \mathscr{I}(Q) - \mathscr{I}(P).$$

Example Let T and T' be two axiomatized theories with axiom bases (taken conjunctively) A and $A' = A$ & B respectively. T' is the stronger of the two theories, i.e. the one with the richer intension, whereas T is the more general (less specific). For example, T could be the general theory of groups and T' the theory of Abelian groups: in this case the extra axiom B would be the commutative law. The difference in intension between the two theories is $\delta(T, T') = \mathscr{I}(A \& B)\ \Delta \mathscr{I}(A) = \mathscr{I}(B) \cap \overline{\mathscr{I}(A)}$. This is the newness in intension, relative to A, contributed by the additional axiom. This enrichment in sense is balanced by a shrinking in coverage or extension: $\mathscr{E}(A \& B) = \mathscr{E}(A) \cap \mathscr{E}(B) \subseteq \mathscr{E}(A)$.

Let us apply the newly won concept to the case of independent or "perpendicular" constructs characterized by Definition 6:

THEOREM 4.7 The difference in intension between two intensionally independent construct equals the union of their separate intensions:

$$\text{If } P \perp Q, \text{ i.e. } \mathscr{I}(P) \cap \mathscr{I}(Q) = \emptyset, \text{ then } \delta(P, Q) = \mathscr{I}(P) \cup \mathscr{I}(Q).$$

Proof By Definition 8 and recalling that, if A and B are disjoint sets, then $A \cap \bar{B} = A$.

Example Aristotle's metaphysical categories (substance, quality, time, etc.) are intensionally disjoint. Hence any two of them differ in whatever both connote.

Corollary 3 can now be reworded as

THEOREM 4.8 The intensional difference between two constructs equals the intension of their equivalence:

$$\delta(P, Q) = \mathscr{I}(P \Leftrightarrow Q).$$

Proof By Corollary 3 and Definition 8.

Although equivalences obliterate extensional differences, they bring out differences in intension. This was to be expected in view of the anti-isomorphism between constructs and their intensions noted at the end of Sec. 2.3. Indeed, if the logical difference between two constructs is exhibited by their inequivalence, their semantical difference must be given by their equivalence. In other words, the function δ defined by Definition 8 does the opposite of its counterpart, the function $d: U \times U \to U$ that takes pairs of constructs into their inequivalences, i.e. such that

$$d(P, Q) = (P \,\&\, \neg Q) \vee (P(\neg P \,\&\, Q) = P \not\Leftrightarrow Q \text{ for } P \text{ and } Q \text{ in } U.$$

Furthermore any mapping $f: U^n \to U$ preserving all the values of the *logical* distance d may be regarded as a *tautological transformation*. On the other hand any mapping $g: U^n \to U$ that preserves all the values of the *semantical distance* δ may be interpreted as a transformation (whether logically valid or not) that does nothing to bring the constructs either closer together or farther apart. We shall not make a detailed investigation of the algebraic structure given to U by δ in analogy to the one induced by d on U. (For the latter see Blumenthal and Menger 1970.) For our purposes it will be enough to prove

THEOREM 4.9 Let U be a Boolean algebra of either predicates or statements. Then the family of their intensions, i.e.

$$\mathbb{I}=\{\mathscr{I}(P) \mid P\in U\}=\{\mathscr{I}(P)\in\mathscr{P}(U)\}$$

is a ring of sets to be called the *ring of intensions* of U.

Proof To begin with $\mathbb{I}$ is not empty: even if all the P's in U are tautologies, $\mathbb{I}$ contains the empty set. Next, by Definition 1, the union of any two intensions is an intension – namely the intension of a conjunction. Likewise for the differences. Consequently the intersection of two intensions is an intension. Hence $\mathbb{I}$ is a ring of sets.

This theorem is just a formal prerequisite for the following investigation, which is of interest to semantics. The set valued function δ is a non-numerical measure of the "distance" in intension between two constructs. This is no metaphor: we shall presently show that δ is formally similar to the distance function in a one dimensional quasimetric space. (While in a metric space two points are the same just in case they are not separated, in a *quasimetric* space distinct points need not be separated. In these spaces the weaker condition $\delta(x, x)=0$ holds instead of $\delta(x, y)=0$ iff $x=y$.) We shall call *pseudoquasimetric space* any nonempty set equipped with such a metric δ. We proceed to prove that intensions form such a space.

THEOREM 4.10 Let $\mathbb{I}$ be a ring of intensions. Then the structure $\langle\mathbb{I}, \delta\rangle$, where $\delta:\mathbb{I}^2\to\mathbb{I}$ is the difference in intension, is a pseudoquasimetric space, i.e. the function δ satisfies all of the following requisites:

(i) $\delta(P, Q)\supseteq\emptyset$;
(ii) $\delta(P, Q)=\delta(Q, P)$;
(iii) $\delta(P, Q)\,\Delta\delta(Q, R)=\delta(P, R)$;
(iv) $\delta(P, P)=\emptyset$

for any P, Q, R in the substrate U of $\mathbb{I}$.

Proof All four properties but the third are easily checked by recalling Definition 8. The "triangle equality" (iii) follows from the associativity of the Boolean sum and the equations: $A\Delta A=\emptyset$ and $A\Delta\emptyset=A$.

The interest of this theorem is twofold. First, it reinforces our decision to regard "$\mathscr{I}(P)\ \Delta\mathscr{I}(Q)$" as the difference or distance in intension between P and Q. We may now picture intensions as points on a line: see

Figure 4.3. Second, we can now define neighborhoods,

$\mathscr{I}(P) \leftarrow \delta(P, Q) \rightarrow \mathscr{I}(Q)$

Fig. 4.3. The intension space is one-dimensional

that will prove to be both mathematically and philosophically significant:

DEFINITION 4.9 Let $\mathbb{I}$ be a ring of intensions over an algebra U of constructs and call A a fixed subset of $\mathbb{I}$. Then for P in U we call

$$N_A(P) = \{\mathscr{I}(Q) \mid Q \in U \quad \text{and} \quad \delta(P, Q) \subset A\}$$

the *A-neighborhood* of P.

This concept of neighborhood in the space of intensions elucidates the fuzzy notion of *family resemblance* which the second Wittgenstein and his followers made so much of. Indeed, the A-neighborhood of a construct P is the collection of intensions such that their distance to the intension of P falls within the given intension interval A. Every $N_A(P)$ is thus a collection of constructs near P. The smaller A the closer the kinship.

Furthermore the neighborhoods introduced by Definition 9 generate two different topologies. More precisely, we can prove

THEOREM 4.11 The collections of neighborhoods

$$\mathscr{B}_1 = \{N_A(P) \mid P \in U \quad \text{and} \quad A \subset \mathbb{I}\}$$
$$\mathscr{B}_2 = \{N_A(P) \mid P \in U \quad \text{and} \quad A \in U\}$$

each constitute a base for a topology on U. That is, in each case (*a*) the union of neighborhoods equals U; (*b*) if a construct P belongs to the intersection of two given neighborhoods, then there is a neighborhood of P that is included in the intersection.

By virtue of the first clause of this theorem, no construct in a given universe of discourse is isolated, and the various families of constructs cover the entire universe. By virtue of the second clause any construct belonging to two families can be placed in a third family included in the overlap of the former and therefore constituting a set of close relatives. We shall not pursue this line here although it sounds promising because topology – rather than natural language – is the natural tool for refining concepts of vicinity and togetherness.

In closing we note that the semantic concept of family resemblance is not reducible to pragmatic (e.g. psychological or linguistic) concepts. Thus the semantic distance between two constructs is determined by the theory in which they occur not by the way they are conceived or mentioned by a subject under certain circumstances. In particular, semantic distance is unrelated to both psychological association and linguistic correlation. Whether or not two constructs are semantically close in a given context, they may be strongly correlated for some subjects and uncorrelated for others, particularly if they have never thought of them before. This being so, the attempts to account for semantic sense in psychological or in linguistic terms are bound to fail.

3. SOME RELATIVES – KINDRED AND IN LAW

3.1. *Logical Strength*

Our concept of intension is coextensive with that of logical strength. In fact, by Theorem 6 the stronger a construct the richer it is and conversely: $P \vdash Q$ iff $\mathcal{I}(P) \supseteq \mathcal{I}(Q)$. Moreover our calculus of intensions satisfies a number of conditions characterizing the notion of logical strength or deductive power. In particular, the desiderata D4, D5, D7, D8 and D9 listed in Sec. 2.1 are fulfilled by the two notions. In turn, the concept of logical strength coincides with that of specificity: the more specific (less generic) a construct the stronger it is. Thus the concept of reading skill is logically stronger and intensionally richer than the generic concept of skill. Consequently a theory of reading skill would be more specific (stronger) than a general theory of skills.

Although the concepts of strength and of intension are coextensive, they are not cointensive. (Logical strength is cointensive with import, to be studied in Ch. 5, Sec. 3.) In fact our Definition 1, which determines the intension of "intension", does not contain the concept of deducibility, which is on the other hand the very kernel of the concept of logical strength, and which defines both Carnap's and Popper's concepts of strength. This situation exemplifies our thesis that coextensives need not be cointensive or, for that matter, not even coreferential. A simpler example is this: ⌜Ormazd is unhappy iff Ahriman is happy⌝. A more sophisticated example: "consistency" and "satisfiability" (or "validity in a model") are coextensive, whence finding a model of a set of formulas proves the latter's consistency; nevertheless the syntactic notion is not cointensive with the semantic one.

We now turn to a few other notions that are often mixed up with that of intension.

3.2. *Information*

Intension is often equated with information content. Thus it is frequently asserted that, whereas synthetic propositions convey information, analytic formulas do not. No doubt there is a relation between intension and information: the greater the former the richer the latter. However, the two are not identical. To begin with a construct *has* a content whereas a signal, such as a written sentence, *conveys* (carries, transmits) information *to someone*. In other words, whereas intension is defined on the set of constructs, information is defined on the set of pairs signal-subject, where a subject is a viewer or hearer competent to decode the signal. Information, to be received, requires a receiver, i.e. a system equipped with suitable receiving and decoding devices. The sentence '$(-1)^2 = 1$', which expresses or conveys the statement that the square of minus one equals unity, transmits no information to a baby and it may convey the wrong information to a mathematician under the influence of LSD. In short, whereas the concept of intension is semantical, that of information is pragmatical: the former is subject free, the latter is tied to a subject.

Upon shoving aside the all important information receiver and the no less important information channel, it is possible to build an impersonal or semantic concept of information. In fact, upon removing the concept of a subject from the foregoing considerations and rendering them more explicit, we are left with the following principles.

INF 1 If a signal (mark, sign, inscription, sound, etc.) is a sentence or represents a sentence, then the *information conveyed by the signal* is the proposition designated by the sentence.

INF 2 If S and S' are sets of signals representing the sets of propositions P and P' respectively, then

(i) the information conveyed by S is *larger than or equal to* the one conveyed by S' iff $P \supseteq P'$;

(ii) the *information gain* accompanying the substitution of S for S' equals $P - P' \equiv P \cap \overline{P'}$.

These three propositions define what will be called our *semantic concept of information*. It boils down to this: The information or message conveyed by a signal consists of the proposition or propositions the signal stands for. It follows (*a*) that nonpropositional signals convey no information, (*b*) that the greater the content of a proposition the richer the information carried by the signal representing that proposition, and (*c*) that the truer a proposition the more accurate the information carried by the signal representing that proposition. These platitudes may be baptized *Simple Simon's semantic view on information*.

Simple Simon's view contrasts with the quantitative theories of semantic information proposed over the past two decades, from that of Bar-Hillel and Carnap (1953) to Hintikka's (1968, 1970). In particular, Simple Simon's view is at variance with the former, which initiated what is today a bulky body of literature on the subject. This theory boils down to identifying the amount of information conveyed by a statement s with its improbability:

$$cont\ s = 1 - Pr(s).$$

(For a similar proposal see Popper, 1963b.) Once this formula is accepted the whole of the elementary theory of probability can be rewritten in terms of the *cont* function and exploited for semantic purposes. The outcome is as tidy as the probability calculus, of which it is a rewrite – but it is, alas, hollow. Indeed the *cont* function can hardly be said to exactify any intuitive concept of content. For one thing contradictions turn out to have maximal content, while alternations such that the probabilities of the disjuncts are complementary are assigned zero content. For another the theory assigns coextensives the same probability, hence the same content, and is therefore at a loss to distinguish ⌜The grass is green⌝ from ⌜The weather has been mild and wet⌝, which do not even have the same referent. Worse, the theory is not applicable, because neither it nor inductive logic (with which it is sometimes associated) tell us how to assign probabilities to the constituent statements – nor even how to interpret the expression '$Pr(s) = p$'. Whence there is no point in claiming that every formula, for example the Schrödinger equation, conveys a definite amount of information lying between 0 and 1. Thou shalt not take the name of the Number thy God in vain.

Other quantitative theories of information are paraphrases of, or heavily indebted to, the much talked about but little understood mathematical theory of communication, or statistical information theory (Shannon and Weaver, 1949). The problem this theory set out to solve was to identify and measure the information carried by physical signals distorted by random perturbations causing noise. The basic notion in this theory is that of the probability of a random binary physical signal – not of a proposition or statement. This probability is a number that can be estimated provided something is known or assumed about the source-channel-receiver-environment system. It is, let us emphasize, the probability of occurrence of a *random physical event*, not the probability of a construct, let alone an orderly one such as a scientific hypothesis. The theory postulates that the amount of information carried by such a signal s_i, which pops up with probability p_i at the receiving end of a communication channel, depends only on this probability, namely thus:

$$I(s_i) = -\log_2 p_i \text{ bits.}$$

Consequently the average amount of information H conveyed by a string of N mutually independent random signals is given by Shannon's formula

$$H = \sum_{i=1}^{N} p_i I(s_i) = -\sum_{i=1}^{N} p_i \log_2 p_i \text{ bits/signal, with } \sum_{i=i}^{N} p_i = 1.$$

If all N signals are equally probable then $p_i = 1/N$, whence $H = \log_2 N$ bits/signal. In information theory H is often interpreted as a measure of the *unexpectedness* or *news value* of the message. Or, what is equivalent, the amount of information measures the ignorance or uncertainty of the receiver concerning the signal about to be received. All these are pragmatic or psychological concepts not semantic ones. Not even Kolmogoroff's generalization of Shannon's formula is relevant to semantics, as his information theoretic "entropy" is defined only for random variables, i.e. for variables associated with some probability distribution.

The preceding information theoretic concepts are far removed from the semantic concepts of intension and content. For one thing the concept of randomness, central to any application of probability theory, makes no sense with reference to propositions. (The idea of stumbling on a given proposition with a certain probability does make sense but only in the context of pragmatics – and in any case bears no relation to the content of the proposition.) For another the information theoretic concept of amount of information is in a sense the very opposite of the semantic concept of content, inasmuch as a signal conveying a proposition with a definite and rich content, such as a law of conservation of energy, has zero information content for a physicist, as it comes as no surprise to him. For all these reasons the statistical theory of information is irrelevant to semantics.

In view of the fundamental difficulties met by the quantitative theories of semantic information utilizing the statistical information theory, we shall stick by Simple Simon's concept of information. However we find no use for it precisely because it is a semantic concept, whereas information and communication belong in pragmatics. Whether or not a sign carries information to someone depends on the receiver's background knowledge and thirst for new knowledge as much as on the content of the statement being transmitted. Thus a tautology new to a given subject is informative to him, whereas a factual sentence he knows by heart is not. In any case neither the semantic concept of information nor any of the pragmatic concepts of information can be equated with the concept of intension.

3.3. *Testability*

Peirce, Frege, the Vienna Circle and the first Wittgenstein held the identity of meaning and verifiability. Carnap transformed this thesis into the equation of meaning with test procedures: "the meaning of a sentence is in a certain sense identical with the way we determine its truth and falsehood; and a sentence has meaning only if such a determination is possible" (Carnap, 1936). This thesis was subjected to such devastating criticisms (see, e.g., Williams, 1937; Russell, 1948; and Hempel, 1965) that it has now been almost abandoned by philosophers. (Quine, 1971, is about the only faithful left.) However, it survives among scientists and even, in a watered-down form, in Popper's thesis that "the degree of testability of a statement increases with its content" (Popper, 1963a, 1963b). *Prima facie* this thesis is plausible enough: tautologies have no content and are insensitive to empirical tests, whereas factual statements have a content and are presumably susceptible to such tests. Moreover, a disjunction is both intensionally poorer and less vulnerable to experience than either of its disjuncts, and "It is possible that *p*" says less and therefore risks less than "*p*".

It is difficult to assess the above thesis in the absence of a full fledged theory of degrees of testability (not just *a posteriori* confirmation) in relation to content – not to speak of a theory of content. However, the thesis is ruined by the following counterexamples. A singular observational statement such as "That apple is red" is both intensionally indigent and eminently testable. On the other hand any of the partial differential equations of physics has such a rich content that it is not fully testable. In fact one can check only a few of its (infinitely many) solutions at some of the argument values. Of course such a rich statement has more opportunities of being tested and clashing with data than a scientifically trivial statement such as "That apple is red", which can be checked at a glance. That is, the richer the intension of a statement the more tests it *calls for* in order to find out its truth value, i.e. the greater the target it offers to experience. But this can hardly be called 'testability'. It might be more aptly be called *un*testability: the more a statement "says" (the richer its sense) the more there is to be checked, hence the less fully can this task be performed. This capacity of a statement to come to grips, or making contact, with experience (Popper's 'testability') we shall call *empirical sensitivity* (or target or cross section). The empirical sensitivity of a statement (or of a collection of statements) is, intuitively speaking, inversely related to its testability proper, or capacity of being checked for truth.

This is not the place to elaborate on this problem. Therefore let me express telegraphically my views on the relations between sense and the methodological concepts we are discussing.

(i) The concepts of sense, empirical sensitivity, and testability, are *heterogeneous*, hence not mutually reducible. The first is semantic whereas the other two are methodological. The determination of sense is a theoretical affair and moreover it precedes the determination of both empirical sensitivity and testability. Besides, the degree of testability of a statement must be assessed in relation to a host of items, both theoretical and empirical, in the background knowledge.

(ii) The *empirical sensitivity* (target, cross section) a statement offers to data increases with its sense.

(iii) The *testability* of a statement is inversely related to its sense and increases with its systemicity, i.e. with the strength of the ties it holds to other members of a body of knowledge. (A strictly stray statement would be untestable. A statement belonging to a theory that partially overlaps with another theory may have the chance of being double checked: directly and via the other theory.)

(iv) The *degree of confirmation* (empirical validation, corroboration) of a testable statement decreases with its sense. Unlike empirical sensitivity and testability, which are estimated prior to tests, degrees of confirmation are assigned, if at all, *a posteriori*. And they bear no fixed relation to either empirical sensitivity or testability; in particular, a highly testable statement may prove utterly false. On the other hand degrees of confirmation depend critically upon test procedures: different techniques will corroborate (or infirm) a hypothesis to different degrees.

4. CONCLUDING REMARKS

Our theory of intensions boils down to the calculus in Sec. 2. This calculus enables one to clarify a number of obscure notions, such as those of intensional inclusion and intensional independence. We shall see in Ch. 9, Sec. 1.6, that our theory also allows us to state and even prove the reciprocal relation between intensions and extensions. Moreover, it enables us to compute the sense of a whole as a function of the senses of its parts – provided we either know the latter or do not care too much for them, for remaining satisfied with finding intensional relations. This shortcoming will be remedied in part in the next chapter, where we shall learn to find the full sense of a theoretical construct. It will turn out that the intension of a construct is included in its full sense.

Our theory construes intensions as basic or irreducible semantic objects. It is couched in set theoretic terms but it does not reduce intensions to either extensions or reference classes. Nor does our theory make use of modal concepts. In particular, our Definition 4 is at variance with the following construals of the notion of intensional inclusion (Lambert and van Fraassen, 1970):

> P is intensionally included in Q iff ⌜Necessarily, all the individuals which are P are Q⌝ is true.

and

> *P* is intensionally included in *Q* iff ⌜All (possible) individuals which are *P* are *Q*⌝.

We have kept our semantics free from modalities and independent of modal logics for several reasons. Firstly because we do not need them. Secondly because it is far from clear how modal prefixes should be interpreted. If all 'necessarily' is intended to mean is logical necessity, then the concepts of entailment do this job and much better: they elucidate a notion of relative (not absolute) necessity – the necessity of a conclusion relative to its premises and to the accepted rules of inference. And if what is meant is ontic (or physical) necessity, then it has no place in semantics – nor, for that matter, does modal logic supply an adequate elucidation of that concept. In sum, I find no use for modal logic in semantics. On the other hand semantics should be used to try and solve some of the riddles of modal logic, such as whether or not the statement ⌜That trick may work⌝ means the same as ⌜That trick may not work⌝.

So far we have looked into one of the dimensions of sense. We now turn to the remaining dimensions – purport and import.

CHAPTER 5

GIST AND CONTENT

Our analysis of sense in the previous chapter has been "local" or "horizontal": it was limited to the given construct with little regard for its logical relatives. The limitations of such an approach are obvious. For one thing it cannot do justice to propositions of the form $\ulcorner A$ means $B\urcorner$, where 'means' stands for "entails" or for "is entailed by". For example, that x is loved "means" (follows from) somebody loving x; it also "means" (entails) that x is lovable. In the present chapter we shall supplement the "horizontal" or "local" approach to sense with a "vertical" or "global" analysis. We shall in fact ask ourselves the questions: What is the ancestry (or set of implicants) of a construct?, and What is the progeny (or set of implicates) of a construct? In other words, we will elucidate the notions we have called *purport* and *import*.

We shall formalize the ideas (*a*) that the purport of a construct in a given context is the collection of constructs upon which it depends, or which determine it (logically), and (*b*) that the import of a construct in a given context is the collection of constructs that hang from it, or that are determined by it (logically). The concepts of purport and import are thus mutually dual. And both are context-dependent: the purport and the import of a construct depend on the body of knowledge in which it occurs. This relativization of sense to context curtails a certain freedom – the freedom to make arbitrary meaning shifts. The advantage of such a relativization is clear: it is well-nigh impossible to determine the exact sense of a stray predicate – whence the endless semantic disputes in the young growing fields as well as in the old undisciplined areas. Only systemic predicates and statements, i.e. constructs belonging to definite deductive systems, have definite purports and imports. (When transplanted to a different theory, if not rejected, a construct may well acquire a new sense – i.e. it may become a somewhat new construct.)

Finally the full sense of a construct in a given context may be taken to equal the union of its purport and its import in that context. Consequently the intension or "inner sense" of the construct will be included in its full sense. But, since enjoying a definite place in an axiomatic pecking order is the exception rather than the rule, we shall be well advised to keep the theory of intensions even if intensions are only parts of full senses.

1. CLOSED CONTEXTS

1.1. *Closed Contexts and Their Structure*

Recall the notion of a context introduced in Ch. 2, Sec. 3.4. A context $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$ is a construct composed of a set S of statements, the extralogical predicates occurring in which belong to a family $\mathbb{P}$ of predicates all of which refer to individuals in a domain D of objects.

A context may be amorphous or structured. See Table 5.1.

TABLE 5.1

Conceptual systems

Item	Structure	Semantics
Set of constructs	———	———
Context	———	Referential homogeneity
Closed context	Boolean algebra	Referential homogeneity
Theory	Filter	Referential homogeneity
Consistent theory	Ultrafilter	Referential homogeneity

We get a structured context if we keep D and $\mathbb{P}$ fixed and allow all and only logical operations in the sets $\mathbb{P}$ and S. Such a context will be closed both formally (syntactically) and as regards reference (semantically). The former because logical processing will produce nothing outside S, the latter because no referents foreign to D will be allowed to intervene in the course of that processing. (Such a double closure need not stifle research: we are always at liberty to leap to a different context.) More explicitly, we lay down

DEFINITION 5.1 The structure $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$ is called a *closed context* iff (i) $\mathbb{C}$ is a context and (ii) S is closed under negation, conjunction, disjunction, and generalization (both existential and universal).

From an algebraic point of view the statements in a closed context constitute a complemented lattice. Indeed every member s of S has its opposite number $\neg s$ in S and, for any two elements s and t of S, both the join $s \vee t$ and the meet $s \wedge t$ (i.e. the conjunction $s \,\&\, t$) are in S. Moreover $\vee$ distributes over $\wedge$ and conversely, so that the lattice is distributive in addition to being complemented. And because of the latter property S contains a null element □ as well as a universal element ▯. Every extensionally void statement equals □ and every extensionally universal statement equals ▯. In brief, we have

THEOREM 5.1 The statements in a closed context constitute a distributive complemented lattice with zero element and unit element – i.e. a Boolean algebra.

A similar result holds for certain subsets of the collection of predicates in a closed context. To prove this we recall how the basic connectives are defined for predicates (Ch. 1, Sec. 2.2).

DEFINITION 5.2 Let $\mathbb{C} = \langle S, \mathbb{P}, D \rangle$ be a closed context. If P and Q belong to $\mathbb{P}$, and are both defined on a subset $E \subseteq D$, then

(i) $\neg P : E \rightarrow S$, with $\neg Px = \neg (Px)$ for every x in E;

(ii) $P \wedge Q : E \rightarrow S$, with $(P \wedge Q)\, x = Px \wedge Qx$ for every x in E.

Consider now the totality of predicates in $\mathbb{P}$ with domain $E \subseteq D$, i.e. $\mathbb{P}_E = S^E$. Since by hypothesis S is a lattice and moreover a Boolean algebra, mathematics tells us that $\mathbb{P}_E = S^E$ has the same algebraic structure. In other words, we have

THEOREM 5.2 The totality of predicates defined on the same domain and belonging to a closed context form a complemented distributive lattice with zero element and unit element – i.e. a Boolean algebra.

By virtue of the algebraic similarity between the set S of statements and the subset $\mathbb{P}$ of predicates in a closed context, we may call the two by the generic name *closed set of constructs*. In this way Theorems 1 and 2 can be lumped into the

PROPOSITION Every closed set of constructs is a Boolean algebra.

This formal unification of statements and predicates will save us ink provided we remember that it is not the whole set $\mathbb{P}$ of predicates in a closed context, but only those subsets of $\mathbb{P}$ constituted by predicates with equal domains, that have the said Boolean structure. For example, "wave length" and "refractive index" belong to wave optics, which is a theory and therefore a closed context, but since they are not defined on a common domain they do not belong to a closed predicate context.

1.2. *The Logical Ancestry of a Construct*

Since the purport of a construct in a context will prove to be the principal ideal generated by the construct, it will pay to recall the ABC of ideals. An ideal in a lattice L is that subset I of L that contains all the predecessors of any given element of L as well as all the joins of any two elements of I (including of course the join of a member with its complement). More explicitly we have the following definition:

If L is a lattice, then I is an *ideal* in L iff I is a nonempty subset of L satisfying the following conditions:

*I*1 For all $x \in I$ and $y \in L$, if $y \leqslant x$ then $y \in I$.

*I*2 For all $x, y \in I$, $x \vee y \in I$.

Clearly every lattice is an ideal. (Even the singleton composed of the null construct is an ideal.) In particular, our closed sets of constructs are ideals. And removing the universal element $\Box$ from I turns I into a *proper ideal* $I \subset L$. Finally, making sure that $\Box$ is in a proper ideal authorizes us to pronounce it a *maximal ideal.* In other words, a proper ideal is a maximal ideal iff, for every $x \in L$, both x and its complement $\bar{x}$ are in I.

Let us apply these algebraic concepts to our lattices of constructs in closed contexts. Such an application requires only one more step, namely to identify the order relation. If the basic set happens to be one of either predicates or statements, then the order relation is that of entailment $\vdash$. That is, if x and y are in a closed set $\mathbb{C}$ of constructs, then

$$x \leqslant y \quad \text{iff} \quad x \vdash y.$$

It is now easy to check that every closed set of constructs from which the universal construct is missing, is a maximal ideal. For reference:

THEOREM 5.3 Let $\mathbb{C}$ be a closed set of constructs partially ordered by the relation $\vdash$ of entailment. Then $\langle \mathbb{C}, \wedge, \vee, \neg, \Box \rangle$ is a maximal ideal.

Every ideal can be analyzed into as many partial ideals (or subideals) as elements in the base lattice. Indeed, every element in the lattice drags the whole lot of its predecessors to form its own private ideal or family tree. More precisely, we have the following definition:

For every element x in a lattice L, the set $\{y \in L \mid y \leqslant x\}$ is called the *principal ideal* generated by x in L. Symbol: $(x)_L$.

The adaptation of these algebraic concepts to our needs yields the following

DEFINITION 5.3 Let x be in a closed set of constructs $\mathbb{C}$. Then the *logical ancestry* of x in $\mathbb{C}$ is the principal ideal generated by x in $\mathbb{C}$:

$$(x)_{\mathbb{C}} = \{y \in \mathbb{C} \mid y \vdash x\}.$$

Note that the ancestry of a construct depends on the context in which it occurs.

We proceed to put the preceding ideas to work in semantics.

2. SENSE AS PURPORT OR LOGICAL ANCESTRY

2.1. *Purport and Gist*

The purport of a construct, we said in Sec. 1, may be regarded as the totality of its conceptual determiners, i.e. the collection of constructs that "define" or prove it. A natural explication of this intuitive idea is that of logical ancestry introduced by Definition 3. More explicitly we stipulate

DEFINITION Let x be a construct belonging to a closed set of constructs $\mathbb{C}$. Then the *purport* of x in $\mathbb{C}$ equals the logical ancestry of x in $\mathbb{C}$, i.e. the principal ideal generated by x in $\mathbb{C}$:

$$\mathscr{P}\!ur_{\mathbb{C}}(x) = (x)_{\mathbb{C}} = \{y \in \mathbb{C} \mid y \vdash x\}.$$

For example, because different proofs of a given theorem may exhibit different connections, the purport of a theorem will depend on the premises employed to prove it. This change in purport is corresponsible for the diversity in pragmatic meanings, i.e. for the fact that the same theorem may mean different things to different people (cf. Wang, 1966).

Of all the determiners of any given construct x some may be more basic than others and, by the same token, they may point to whatever is essential in x. In other words, the set of ultimate determiners sufficient to determine x constitute the basic purport or gist of x. More explicitly, we make

DEFINITION 5.5 If x is a member of a closed set of constructs $\mathbb{C}$, then the *gist* (or *basic purport*) of x in $\mathbb{C}$ is the smallest subset of elements of $\mathbb{C}$ that entail x.

For example, the gist of "$\emptyset$" in the algebra of sets consists of two statements: one to the effect that the union of $\emptyset$ with an arbitrary set equals the latter, and the other to the effect that the intersection of $\emptyset$ with an arbitrary set equals the former. We shall return to the concept of gist in the next subsection.

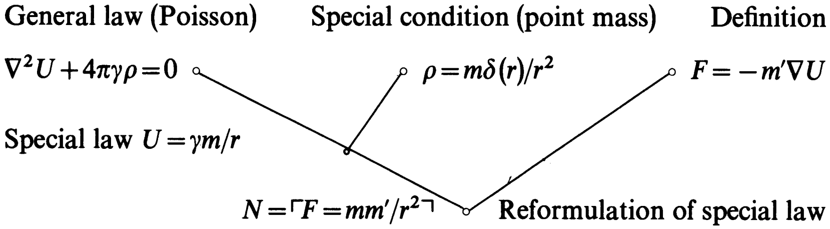
If an ideal containing the null element $\square$ is deprived of the unit element ▯, it turns into a maximal ideal. (Recall Sec. 1.2.) Now, removing the universal construct ▯ from a closed set of constructs amounts to keeping only the nontautologous constructs, i.e. the extralogical ones. This justifies

DEFINITION 5.6 Let x belong to a closed set of constructs $\mathbb{C}$. Then the *extralogical purport* of x in $\mathbb{C}$ is the maximal principal ideal generated by x in $\mathbb{C}$, i.e.

$$\mathscr{P}ur_{\mathbb{C}\bar{L}}(x)=\{y\in\mathbb{C}\mid y\vdash x \quad \text{and} \quad y\neq\text{▯}\}$$

Remark 1 The extralogical purport of a logical item in $\mathbb{C}=L$ is nil. *Remark 2* If $\mathbb{C}$ is a nonlogical theory (in the sense that it includes not only logical predicates but also extralogical ones), then the extralogical purport of any construct in $\mathbb{C}$ consists of a set of mathematical or factual items. *Remark 3* It is not that tautologies are taken out of the way of deduction in order to find the extralogical purport of some construct: if this were done then deduction would hardly be possible. Tautologies are removed once the deductive process is completed. They are counted as midwives or catalyzers rather than as ancestors of the constructs we are interested in.

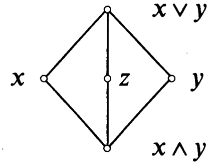
Example Consider the most famous, though not the best understood, of all law statements: Newton's law of gravitation $N=\ulcorner F=\gamma mm'/r^2\urcorner$. In the context of Newton's own theory of gravity the law is an axiom and thus constitutes its own purport. But in a wider context, such as the classical theory of gravitation, N is derived from a far more general law (Poisson's) as a special case, namely when the source mass m is concentrated at a point. In this case the mass density can be set equal to $m\delta(r)/r^2$, where δ is the Dirac delta. The skeleton of the deductive tree (i.e. if all the mathematical auxiliaries are discarded) is this:



General law (Poisson)
Special condition (point mass)
Definition
$\nabla^2 U + 4\pi\gamma\rho = 0$
$\rho = m\delta(r)/r^2$
$F = -m'\nabla U$
Special law $U = \gamma m/r$
$N = \ulcorner F = mm'/r^2 \urcorner$
Reformulation of special law

Purport of $N = \{\nabla^2 U + 4\pi\gamma\rho = 0,\ \rho = m\delta(r)/r^2,\ F =_{\mathrm{df}} -m'\nabla U,\ U = \gamma m/r,\ N\}$ (Actually this, when "read in factual terms", i.e. upon being enriched with the requisite semantic assumptions, is the *factual* purport of Newton's law of gravity: see Sec. 2.3.)

The next desirable step in the development of our theory would be to set up a calculus of purports enabling one to compute, say, $\mathscr{P}ur_{\mathbb{C}}(x \wedge y)$ out of $\mathscr{P}ur_{\mathbb{C}}(x)$ and $\mathscr{P}ur_{\mathbb{C}}(y)$. Yet, it is not apparent how this could be done: there are no obviously regular or lawful relations among the principal ideals in a given lattice. In particular, it is not the case that, for arbitrary elements x, y in a general lattice L, $(x \vee y)$ will equal either $(x) \cup (y)$ or $(x) \cap (y)$. A simple counterexample is this:



$x \vee y$
x
z
y
$x \wedge y$

$$(x \vee y) = (x) \cup (y) \cup (z)$$

The only apparent simple relations between purports are shown in

THEOREM 4 For any two constructs x, y in a set of closed constructs $\mathbb{C}$,
(i) $\mathscr{P}ur_{\mathbb{C}}(x) = \mathscr{P}ur_{\mathbb{C}}(y)$ iff $x = y$
(ii) If $x \vdash y$ then $\mathscr{P}ur_{\mathbb{C}}(x) \subseteq \mathscr{P}ur_{\mathbb{C}}(y)$.

2.2. *The Gist of a Basic Construct*

Let us now apply the foregoing considerations to the most important constructs in a well organized theory, namely its basic (primitive) concepts and its basic assumptions (axioms). Since such constructs have no logical ancestry other than themselves, they are their own purports and moreover their own gists. More precisely, we have the following

COROLLARY 5.1 In an axiomatized theory the gist of an axiom is the singleton constituted by the axiom itself, and the gist of a primitive concept is the set of axioms in which it occurs.

Example 1 In classical particle mechanics (as axiomatized in Bunge, 1967b) the gist of the primitive concept M of mass is determined jointly by the following postulates:

Mathematical axiom M is an additive function from the set P of particles to the non-negative real numbers.

Factual axiom Newton's second law of motion.

Semantic axiom $M(p)$ represents the inertia of particle $p \in P$.

Example 2 The gist of the concept $\rhd$ of biological ancestry, a primitive in the theory of evolution as axiomatized by Williams (1970), could be given by the following postulates:

Mathematical axiom $\rhd$ is a strict partial ordering of the set B [of organisms].

Factual axiom For every x in B: $\neg(x \rhd x)$.

Semantic axiom $\rhd \mathrel{\hat{=}}$ ancestry relation. [I.e. if x and y are distinct individuals in the set B of organisms, then '$x \rhd y$' designates $\ulcorner x$ is an ancestor of $y\urcorner$.]

Finally an important qualification. Since independent axioms (i.e. not interdeducible postulates) are separate objects, it makes sense to speak of their separate gists – i.e. of themselves. In some cases it is also meaningful to speak of the gists of distinct basic *concepts*, or primitives. For example, in a meet semilattice $\langle S, \leqslant, \wedge \rangle$ the gist of $\leqslant$ does not overlap with that of $\wedge$, as these two concepts are not only mutually independent but also subject to separate axioms. However, this situation is exceptional: usually an axiom contains two or more primitive concepts that determine one another, so that it becomes impossible to reckon their individual gists even though the concepts themselves are distinct and not interdefinable. In other words, in general mutually independent concepts fail to have disjoint gists. An example will make this clear.

Suppose we enrich a meet semilattice with the join operation $\vee$ to obtain a lattice $\langle S, \leqslant, \wedge, \vee \rangle$. Now the two operations, meet and join, intertwine in such a way that it is no longer possible to disentangle their separate gists. Better: they have no separate gists. In effect, on top of the separate axioms for $\wedge$ and $\vee$, such as those of associativity, we now have the typical absorption laws

$$x \wedge (x \vee y) = x, \quad x \vee (x \wedge y) = x.$$

We can still *distinguish* the two concepts: meets precede joins. But we cannot *disentangle* their individual senses, for they overlap. In other words, the meet and the join operations have no separate gists. Only the *theory* of $\wedge$ and $\vee$ as a whole, to wit, lattice theory, has a definite gist – namely the set of its postulates.

Because the gist of a construct is included in its full purport, which is in turn part of the full sense of the construct, we conclude that *the unit of sense is the whole body of theories in which the construct occurs.* A single statement never suffices and a single theory is often insufficient because a concept may do different things at different places. Unless this point is kept in mind, our thesis that purport is included in sense may be criticized by exhibiting alleged consequences that are counterintuitive (Castonguay, 1972). Thus take a biological theory B containing the assumption that all organisms contain carbon. If one forgets where "carbon" comes from, namely chemistry, one will set $\mathscr{P}ur$ ("carbon") = {"organism"}, which is obviously inadequate. The force of this argument against purport consists in its very weakness – i.e. that it ignores that the concept of carbon is not fully characterized by the biological theory B, which borrows it from chemistry. It is the latter that determines the gist (though not the full sense) of "carbon" as consisting of a set of statements containing *inter alia* the definite description "The element with atomic number 6". Our view is that the full sense of "carbon" is determined by the whole lot of theories containing this concept. B is one of them and it contributes just one of the genuine ingredients of the sense of "carbon", namely the statement that carbon enters the composition of all organisms. In conclusion, a meaning analysis of an isolated construct is bound to yield only a partial, hence misleading result.

Let us now take a closer look at the gist of theories.

2.3. *The Gist of a Theory*

We shall now apply the Definition 5 of gist to a theory, or hypothetico-deductive system. This is a very special kind of closed set of constructs: it is a set of statements glued by the relation of deducibility. (In algebraic terms to be clarified in the next section: A theory is a certain subset of a Boolean algebra of statements, namely that which does not contain the null element but contains all the followers of any given element as well as the meet of any two elements. A theory is, in short, a proper filter on a Boolean algebra of statements. And a consistent theory is an ultrafilter, i.e. a proper filter such that, for any element in the Boolean algebra, either the element or its complement is in the filter but not both.)

To determine the gist of a theory it is best to axiomatize the latter. Indeed, the process of tracing the logical ancestry of any formula in the theory leads to and terminates in some or all of the initial statements of the theory. Among such initial formulas we count not just the specific axioms of the theory but also all of its basic presuppositions, i.e. all the axioms belonging to different contexts and employed in the theory (e.g. as lemmas) without being questioned. The totality of such basic presuppositions may be called the *background* of the theory. For example, ordinary logic and variable portions of mathematics belong to the background of every scientific theory. Many scientific theories presuppose, in addition to such formal theories, other (more fundamental) scientific theories. For example modern solid state theories presuppose quantum mechanics. In sum the search for the gist of a theory must not overlook the background of the theory.

The preceding considerations justify

DEFINITION 5.7 Let T be a theory based on a set A of axioms and on a background B, and call L the set of tautologies included in A or in B. Then

(i) the *gist of* T equals $A \cup B$;
(ii) the *extralogical gist* of T equals $(A \cup B) - L$;
(iii) the *specific extralogical gist* of T equals A.

A theory will have a *factual purport* just in case it includes semantic formulas (in the sense of Ch. 3) specifying what factual items the basic concepts of the theory refer to and which if any traits of the referents those concepts are deemed to represent (whether accurately or not). Such semantic assumptions accompany two other sets of axioms in an axiomatized scientific theory (Bunge, 1967d, 1967f, 1973a, 1973b). One of the sets is constituted by the basic factual formulas of the theory, such as the hypotheses concerning the constitution, structure, and mode of change of the systems concerned. The other set of basic elements is formed by the assumptions concerning the mathematical nature of the concept occurring in the previous statements. In other words, the axiom base A of a scientific theory can be partitioned into the following sets:

M = *The mathematical postulates* (e.g. function differentiability)

F = *The basic factual formulas* (e.g. law statements)

S = *The semantic formulas* (designation and denotation rules and representation assumptions).

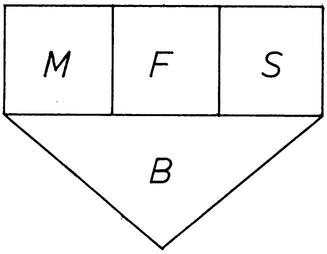


Fig. 5.1. The foundations of a scientific theory: the background B, the mathematical assumptions M, the factual hypotheses F, and the semantic formulas S.

Prima facie F is purely factual whereas M and S are nonfactual. However, a formula has a factual purport provided it is "read in the light" of both the mathematical postulates and the semantic assumptions: otherwise the formula is mathematically as well as factually senseless. Hence it is impossible to single out a subset of A as constituting the factual gist of T. Put in a positive way: All of the nonlogical axioms of a theory constitute its specific factual gist. To repeat with solemnity:

DEFINITION 5.8 Let T be a theory with axiom base $A = M \cup F \cup S$, where M is the set of mathematical axioms, F the specific factual assumptions, and S the semantic formulas of T. Then

(i) the *specific mathematical gist* of T equals $M \cup F$;

(ii) the *specific factual gist* of T equals $M \cup F \cup S$, i.e. the specific extralogical gist of T – in short the whole of A.

This is no concession to semantic holism. We are not claiming that the factual purport of a theory is unanalyzable, but that it is the outcome of combining three distinct reactants: mathematical postulates, factual hypotheses, and semantic formulas. We can distinguish these ingredients but not separate them: M is idle without F, F meaningless without both M and S, and S pointless without F. The three components are no less united and no less distinguishable than the sides of a triangle.

2.4. *Changes in Gist*

The 1960's heard a number of spirited quarrels concerning the changes in meaning accompanying scientific revolutions. Unfortunately there was more noise than light about them, for they were not preceded by an elucidation of what was rightly deemed to change, namely meaning. Let us see whether we can do any better with the help of the tools wrought in Sec. 2.3. (A fuller investigation of the question will have to wait until Ch. 7, Sec. 3.3.)

Our Definitions 7 and 8 provide a simple way of elucidating the concept of change in one of the components of meaning, namely basic purport or gist. Let us see how this works in a simple case before proceeding to a general definition.

The simplest algebraic structure is a set S together with a binary operation $\circ$ in S. This structure, called a *groupoid*, may be characterized by a single axiom;

$$A = \ulcorner \circ \text{ is a binary operation on the set } S. \urcorner$$

Let us now add the condition that $\circ$ be associative. The ensuing structure is called a *semigroup*. The axioms of the theory of semigroups are the previous statement A and

$$B = \ulcorner \circ \text{ is associative in } S. \urcorner$$

Consequently by Definition 7 the specific extralogical gist of the theory of semigroups is $\{A, B\}$. The only difference between this theory and the theory of groupoids is constituted by the additional postulate B. That is

$$\delta\,(\text{Semigroup theory, Groupoid theory}) = \{A, B\} - \{A\} = \{B\}.$$

The generalization suggests itself: The difference in basic purport (gist) between two theories consists of the axioms they do not share. More explicitly we propose

DEFINITION 5.9 Let T and T' be two nonlogical theories with axiom bases A and A' respectively. Then the *difference in specific extralogical gist* between T and T' equals the symmetric difference between A and A':

$$\delta(T, T') = A \Delta A' \equiv A - A' \cup A' - A.$$

It sometimes happens that two scientific theories share a mathematical formalism but interpret it differently: that is, they have the same M's and F's but different S's. At times this semantic difference is due to a difference in the referents, at other times the referents are the same but the predicates are assumed to represent different traits of their referents. An example of the first kind of semantic unlikeness is afforded by the theories of contagion and of the spread of rumours. An example of the second kind of semantic difference is the variety of rival interpretations of quantum mechanics. In either case the difference lies in the semantic formulas of the theory. More exactly we have

DEFINITION 5.10 Let T and T' be two theories with the same mathematical gist but different sets S and S' respectively of semantic formulas. Then the *difference in specific factual gist* between T and T' equals the symmetric difference between S and S':

$$\delta(T, T') = S \Delta S'.$$

From a semantic point of view it does not matter whether T and T' are coexistent or successive. Nor is it indispensable, in order ot use the concept of change in gist, to axiomatize the theories of interest. Axiomatization is needed only to determine the exact amount of change in basic purport or gist.

The problem of changes in both full sense and reference, i.e. the question of meaning change, will be taken up in Ch. 7, Sec. 3.3. We must now turn to the dual of purport, namely import, which is the other component of sense. (Since constructs deriving from the same source have the same purport, they must differ in import if they are to differ at all.)

3. SENSE AS IMPORT OR LOGICAL PROGENY

3.1. *The Logical Progeny of a Construct*

In Sec. 1 we characterized the import of a construct as its logical offspring. Since the concept of a filter will allow us to elucidate the notion of logical progeny, we may as well take a look at filters. We can do it quickly because a filter is the dual of an ideal – a character we met in Sec. 1.2.

In Sec. 1.1 we learned that every closed set of constructs is a Boolean algebra B and, *a fortiori*, a lattice. When tracing down the followers of an element (predicate or statement) in such an algebra we wish to avoid the surprise of ending up in the null element, for this spells disaster just as the unit element spells triviality. To get rid of $\square$ we take a certain subset of B known as a proper filter. But first the general notion.

A filter in a lattice L is that subset F of L which contains all the followers of any given element of L as well as the meets of any two elements of F. More precisely,

If L is a lattice, then F is a *filter* in L iff F is a nonempty subset of L satisfying the following conditions:

$F1$ For all $x \in F$ and $y \in L$, if $x \leqslant y$ then $y \in F$.
$F2$ For all $x, y \in F$, $x \wedge y \in F$.

If the null element is missing from F the filter is called *proper*. Since our construct lattices are Boolean, our filters are more than proper: they are ultrafilters. In other words, a proper filter F in a Boolean algebra B is called an *ultrafilter* just in case, for each $x \in B$, either x or its complement $\bar{x}$ is in F but not both.

Our closed sets of constructs are ultrafilters provided we remove the null construct from them. This will suffice to guarantee that they are consistent. For, if x is in F, then $\bar{x}$ will be automatically excluded from F, as a consequence of which $x \wedge \bar{x}$ will be out as well. In short, we have the following

LEMMA A closed set of constructs is *consistent* iff it is an ultrafilter.

Finally, a filter can be analyzed into partial filters (subfilters). Every member of the base lattice generates its own family, that constitutes the private filter of that element. Formally:

For every element x in a lattice L, the set $\{y \in L \mid x \leqslant y\}$ is called the *principal filter* generated by x. Symbol: $)x(_L$.

Since in the case of constructs the ordering relation is that of entailment, for our purposes we need

DEFINITION 5.11 Let x be in a closed set $\mathbb{C}$ of constructs. Then the *logical offspring* of x in $\mathbb{C}$ is the principal filter generated by x in $\mathbb{C}$:

$$)x(_{\mathbb{C}}=\{y\in\mathbb{C} \mid x\vdash y\}.$$

The offspring or progeny of a nontautologous construct depends on the context in which it occurs. (Tautologies, being deductively barren, have no progeny.)

It should come as no surprise the manner in which these concepts, taken from the algebra of logic, will presently be exploited for semantic purposes.

3.2. *Import*

We are now in a position to elucidate the idea that the import of a construct is the collection of constructs it generates or "contains":

DEFINITION 5.12 The *import* of a construct x in a closed set of constructs $\mathbb{C}$ equals the former's logical offspring, i.e. the principal filter it generates:

$$\mathscr{I}\!m\!p_{\mathbb{C}}(x)=)x(_{\mathbb{C}}=\{y\in\mathbb{C} \mid x\vdash y\}.$$

Example 1 The import of a tautology is nil. *Example 2* Take identity to be defined by Leibniz' law. Then the import of "=" includes the reflexivity, symmetry and transitivity of "=". (This would have puzzled Austin, who regarded "same" as being devoid of positive meaning. But this is excusable: neither Wittgenstein nor his followers had a semantic theory of meaning.) *Example 3* The import of the law of the vibrating string includes the superposition principle (⌜The superposition of any two oscillations is a third oscillation.⌝)

If $\mathbb{C}$ happens to be a *consistent* closed set of constructs, i.e. one in which no contradictions occur, then the import of a construct x in $\mathbb{C}$ will be the principal *ultra*filter generated by x in $\mathbb{C}$. Because filters are the duals of ideals, and ultrafilters the duals of maximal ideals, we see that import and purport are the dual of one another, hence mutually complementary rather than rivals. (More on this in Sec. 4.)

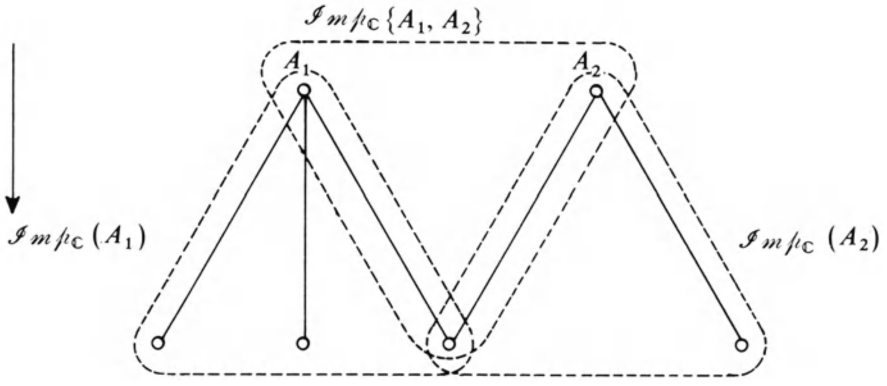
It would be pleasant, but it seems chimerical, to obtain general relations among the principal filters generated by arbitrary constructs in a closed set of constructs, so as to compute, say, the import of the conjunction of two statements in terms of their individual imports. A similar obstacle was met in Sec. 2.1 with reference to principal ideals. A definite algebraic structure is found only in each offspring of a given construct as well as in the total context. The only simple statement we can make about the relations in import between two constructs is the dual of Theorem 4, namely

THEOREM 5.5 For any two constructs x, y in a closed set of constructs $\mathbb{C}$,
(i) $\mathcal{I}mp_{\mathbb{C}}(x)=\mathcal{I}mp_{\mathbb{C}}(y)$ iff $x=y$;
(ii) If $x \vdash y$ then $\mathcal{I}mp_{\mathbb{C}}(x) \supseteq \mathcal{I}mp_{\mathbb{C}}(y)$

On the other hand it is possible and advantageous to extend the concept of import to both a set of constructs and their conjunctions. Let $\mathbb{C}_0$ be a subset of a closed set of constructs $\mathbb{C}$. Usually there will be a number of filters containing $\mathbb{C}_0$. And the intersection of any nonempty set of filters is a filter provided it is nonempty. It is, of course, the smallest filter containing $\mathbb{C}_0$ and for this reason it is called the *least filter generated* by $\mathbb{C}_0$. Accordingly we stipulate

DEFINITION 5.13 Let $\mathbb{C}_0$ be a subset of a closed set of constructs $\mathbb{C}$. Then the *minimal import* of $\mathbb{C}_0$ equals the least filter generated by $\mathbb{C}_0$ in $\mathbb{C}$.

Example Let $\mathbb{C}$ be a theory and $\mathbb{C}_0$ some of its axioms. Then $\mathcal{I}mp_{\mathbb{C}}(\mathbb{C}_0)$ is the smallest collection of theorems (including $\mathbb{C}_0$) entailed by $\mathbb{C}_0$. Look at the picture:



$\mathcal{I}mp_{\mathbb{C}}\{A_1, A_2\}$
A_1
A_2
$\mathcal{I}mp_{\mathbb{C}}(A_1)$
$\mathcal{I}mp_{\mathbb{C}}(A_2)$

We shall get a far more interesting semantic concept if we consider the offspring of a bunch of axioms taken jointly. Let us look into this.

3.3. *Theory Content*

Consider a scientific theory T based on a set $\{A_1, A_2, \ldots, A_m\}$ of specific axioms as well as on a background $\{B_1, B_2, \ldots, B_n\}$ of presuppositions. The latter include, among others, all the logical and mathematical theories underlying T. Let us conjoin all such initial assumptions and examine their import. Call

$$A = A_1 \,\&\, A_2 \,\&\ldots\&\, A_m,$$

The import of $A \,\&\, B$ is, of course, the offspring of $A \,\&\, B$. One part of this import is purely logical: it consists of the set L of tautologies included in B or entailed by $A \,\&\, B$. If we remove this part L we are left with the extralogical import, or *content*, of the axiom basis $A \,\&\, B$. More explicitly, we make $B = B_1 \,\&\, B_2 \,\&\ldots\&\, B_n$.

DEFINITION 5.14 Let T be a theory based on a conjunction A of axioms and another conjunction B of presuppositions, and call L the set of tautologies in B or in the offspring of $A \,\&\, B$. Then

(i) the *import* of the axiom base $A \,\&\, B$ equals the principal filter generated by $A \,\&\, B$, i.e.

$$\mathscr{I}\!mp(A \,\&\, B) =$$

(ii) the *content*, or *extralogical import*, of the axiom base $A \,\&\, B$ equals the complement of the import of $A \,\&\, B$ relative to L:

$$\mathscr{C}(A \,\&\, B) = \mathscr{I}\!mp(A \,\&\, B) - L.$$

Going into some details of the composition of a scientific theory will allow us to grasp the elusive concept of theory content. As may be recalled from Sec. 2.3, the axiom base of a theory in factual science consists of (a) purely mathematical axioms M, (b) specific factual premises (such as law statements and subsidiary hypotheses) F couched in the terms characterized by M, and (c) semantic formulas S. Is it possible to isolate the factual content of these basic assumptions from their mathematical ingredients? No, because the factual components cannot even be stated, let alone processed and interpreted, in isolation from the other two. What can be neatly detached is the mathematical content of the initial assumptions: this is done by simply removing the semantic axioms S and finding the progeny of the remaining premises. All this is encapsulated in

DEFINITION 5.15 Let T be a theory with background B, mathematical assumptions M, factual assumptions F, and semantic formulas S, where B, M, F and S are taken jointly. Then

(i) the *mathematical content* of the axiom base A & B, or *formalism* of the theory T, equals the offspring of B & M & F with exclusion of L, i.e.

$$\mathscr{C}_M(A \,\&\, B) = \mathscr{I}\mathscr{m}\mathscr{p}(B \,\&\, M \,\&\, F) - L;$$

(ii) the *factual import* of the axiom base, or *factual content* of the theory T, equals the offspring of B & M & F & S with exclusion of L, i.e.

$$\mathscr{C}_F(A \,\&\, B) = \mathscr{I}\mathscr{m}\mathscr{p}(B \,\&\, M \,\&\, F \,\&\, S) - L.$$

That is, the factual content of a scientific theory coincides with the factual import of its axiom base, which is in turn identical to its extralogical import. In other words, while scientific theories have detachable, hence portable mathematical formalisms, their factual content is not detachable from the formalism. (*A fortiori* they have no purely empirical or observational content.) The extralogical import of the axiom base of a theory in factual science is both mathematical and factual.

Note that the notion of content, though dependent upon the metalogical concept of deducibility, is independent of the semantic concept of truth of fact. Hence a theory with a rich content may well prove to be false whereas a more modest theory may turn out to be approximately true. Consequently, *pace* Popper (1966), the degree of truth of a theory cannot be measured by its content. If it were so measurable then no actual empirical tests for truth would be called for: a semantic analysis of a theory would determine its truth value.

We close by noting a possible application of the foregoing ideas to model theory. Intuitively the richer an abstract theory ("formalized language") the fewer models it is bound to have. Thus there are less examples of a semigroup with unit element than of a semigroup. This suggests introducing a comparative concept of theory versatility, or its dual, rigidity, namely thus:

DEFINITION 5.16 Let T and T' be two abstract theories with comparable mathematical contents $\mathscr{C}(T)$ and $\mathscr{C}(T')$ respectively. Then T is *more versatile* (or *less rigid*) than T' iff $\mathscr{C}(T) \subseteq \mathscr{C}(T')$.

3.4. *Empirical and Factual Content*

The various philosophies of science may be regarded as so many views on the content of scientific theories – i.e. as so many semantics of science. Here goes, in telegraphic fashion, a sample of the most interesting among those views:

(1) *Conventionalism.* Scientific theories are handy tools for the processing of experience (or the systematization of appearances). They have neither a factual nor an empirical content: $\mathscr{C}_F(T) = \mathscr{C}_E(T) = \emptyset$.

(2) *Positivism.* Scientific theories are economic summaries and articulations of data. They have an empirical (observational, operational) content only: $\mathscr{C}(T) = \mathscr{C}_E(T)$.

(3) *Mellowed positivism (standard view).* Scientific theories are systematizations of experience propped up by heuristic devices, i.e. the so-called theoretical terms, which have no representational function. Part of the content (our "import") of a statement s in a scientific theory is observational (empirical, phenomenal) provided s is linked to observational items via correspondence rules: $\mathscr{C}_E(s) \subseteq \mathscr{C}(s)$.

(4) *Empirical realism.* Theoretical constructs may refer to unobservables even though their meaning is given by the connections established within the theory between the constructs and observational statements built with the observational vocabulary of the theory. Every scientific statement s has both an empirical content and a factual one (its "surplus meaning"): $\mathscr{C}(s) = \mathscr{C}_E(s) \cup \mathscr{C}_F(s)$.

Of these four views the closest to our own is the last, according to which scientific hypotheses have "a surplus meaning over against their evidential basis" (Feigl, 1950). (For elaborations see Rozeboom (1962, 1970). For criticisms see Hempel (1950) and Nagel (1950).) Although timid realism is preferable to the previous forms of empiricism, it is not completely satisfactory: keeping the myth of the observational vocabulary as belonging to every theory and as the source of meaning of the theoretical vocabulary does violence to scientific theories, all the concepts of which are theoretical. Furthermore it has the fatal consequence that it becomes impossible to ascertain what exactly the theory is about: reference becomes indeterminate (Rozeboom, 1962, 1970). Rather than tolerate such reference uncertainty, as Rozeboom advocates, we regard it as sufficient for disqualifying the theory: reference indeterminacy makes not only for meaning indeterminacy but renders empirical tests impossible. We must either retreat to undiluted empiricism or go realists all the way. Since the former has proved a failure we shall try the latter.

We claim that no scientific theory could possibly embrace its own evidence, and that only theories concerning sentient organisms may be said to have an empirical content. The reasons for denying that the evidence relevant to a theory is part of its content have been given in detail elsewhere (Bunge, 1967a, 1969, 1973b). They will be summarized here. Firstly, the computing of a prediction with the help of a theory requires additional theoretical assumptions (e.g. on the particular composition or structure of the referent) as well as empirical data – and neither can be found in a theory unless it happens to be an *ad hoc* systematization of data. (If the special assumptions were already included in the theory then the latter would be inapplicable to further problems. And if the data were part of the theory then observations would be redundant.) Secondly, the production of empirical data that could serve as evidence for or against a theory calls for the cooperation of auxiliary theories employed in the design and interpretation of the empirical operations – i.e. the evidence could not have been predicted on the strength of the substantive theory alone. Should a scientific theory have an empirical content, then this content would not consist in any evidence but in statements concerning some sector of human experience, such as learning or working, considered as an external item. (More on this in a while.) These are some of the reasons for adopting a realist semantics.

Of the three other views sketched above, conventionalism is untenable if only because it renders empirical testing, as well as the quest for truer and deeper theories, utterly pointless. The second view, undiluted positivism, is still popular in scientific circles but it has been discredited by philosophers long ago, so it need not detain us. (Which does not mean disparaging catechisms for the conversion of the infidel.) Only the third view, which we have dubbed *mellowed positivism*, is still alive and influential though on the decline. It is also the only view that has been expounded and examined in detail (Carnap, 1956, 1963a, 1963b, 1966; Hempel, 1958; Braithwaite, 1959, 1962; Wojcicki, 1966; Przelecki, 1969;

etc.). The way this doctrine handles the concept of empirical or observational content is roughly as follows.

The standard view assumes, first of all, that every scientific theory contains not only theoretical terms, such as 'temperature', but also observational or phenomenal ones such as 'hot'. Second, only the theoretical terms are assumed to be subject to the theoretical statements Θ of the theory. They are interpreted, albeit only in part, by reference to the observational terms: this interpretation is performed by the so called "correspondence rules" C of the theory. Third, the content of a statement is, roughly, what we have called its import. And the observational (or empirical) content of a statement s is defined as the class of all nonlogically true observational statements implied by s – i.e. the set of all those consequences of s that contain observational terms but no theoretical ones. In particular, the observational content of s relative to a theory composed of theoretical statements Θ and correspondence rules C (both sets taken conjunctively), is the observational content of $s \& \Theta \& C$. (For a brief and lucid exposé see Carnap (1963b). For details cf. Suppe (1971). For the alleged definability of theoretical terms as functions of empirical ones: Carnap (1961, 1966).)

The root trouble with this view is, of course, that it rests on the unquestioned assumption that every scientific theory does contain observational or phenomenal terms such as 'hot', 'blue', and 'rough'. In point of fact theories contain only theoretical concepts and these are not interpreted with reference to qualia but to supposedly real things (e.g. genes) and their properties (e.g. the mutation frequency of a given gene). The semantic assumptions in a well constructed theory are not concept-concept affairs in which one of the two partners concerns an experiential item: they are concept-fact correspondences (Ch. 3, Sec. 4.1). Now, if there are no purely observational (hence unanalyzed) concepts in a scientific theory, then there is no observational (or phenomenal or operational or empirical) content left. And since (unlike Feigl) Carnap, Hempel and Braithwaite make no room for factual reference, no content at all is left.

This unintended disaster could have been averted if any real scientific theories had been analyzed in the light of the standard semantics, and if the quest for the Holy Grail of the empirical "basis" of science had been given up in time. If theories are regarded instead as partial and symbolic representations of reality, then a far simpler and realistic semantics of science emerges. Every concept in a theory is pronounced *theoretical* if it is elucidated by the theory or borrowed from the background of the theory. And if the concept has a factual reference then any statement that contains the concept has a factual sense. The facts referred to, or represented by, the theoretical statement are not those the empirical evidence is concerned with. (In fact an evidence statement is restricted to observational items, often under control with the help of instruments describable with the assistance of a number of theories.) No scientific theory is concerned with its own test, much less with the mental states of the experimenter. Finally, the factual content of a statement in a scientific theory is determined by all three basic components of the theory: M, F, and S. (Recall the preceding subsection.)

According to our view, then, all scientific theories have a factual content and none of them embraces its own evidential or empirical "basis". However, a scientific theory *can* have an empirical content – provided it *is* about experience. This is the case with most, perhaps all, theories in the sciences of man. Like all other scientific theories, those in psychology, sociology and history concern facts and so have a factual content (even if inaccurate). But (*a*) these facts are treated as external objects epistemologically on a par with physical facts – which is necessary for objectivity, and (*b*) those theories contain no reference to their own empirical tests – which alone renders tests significant. For example, a model of the decay of empires may refer to feelings and motives – of the imperial subjects not the historian's; and its evidence may consist in documents and material testimonials unearthed with advanced physical techniques – but the model won't be concerned with such means for its own validation or invalidation.

In summary, if s is a theoretical statement then the factual content of s equals its extralogical import. Should s belong in natural science, its empirical content will be nil. But if s belongs in the sciences of man, then s will have an *empirical content* included in its factual content and independent of any evidence relevant to s. No theory has an observational or experiential or phenomenal content: experience is lived through (*erlebt*) not beaten into theory. This view may be dubbed *realist semantics.* It boils down to shifting the focus from experience (always subjective) to fact, and consequently prevents us from falling into subjectivism. It suggests that we stop chasing the ghost of the alleged observational content of theories as well as its attendant ghosts – Ramsey sentences and Craig's reduction.

Now that operationism lies buried we can afford to write a nice epitaph on it. The deceased, though mistaken in the means it employed, was sincere in pursuing a worthy goal – namely the uprooting of inscrutables and the testability of hypotheses. This explains the large following it had and still has in the scientific community. Such a noble cause can now be defended in the following way: Although theoretical statements may lack an empirical import, they should acquire one when conjoined with suitable empirical statements relevant to the former. How this strategy can be implemented may be exemplified as follows.

Consider the statement schema

⌜There is a gravitational field in region *x*.⌝ (1)

belonging to some theory of gravitation. Although fields defy direct observation, according to operationism (1) *means* that, if somebody places a test body *y* in region *x*, he will observe *y* to move (cf. Carnap, 1936). But we know this to be a gross misinterpretation of (1), which refers only to a field, not to a test body, let alone to an observer. However, our construal of the notion of sense as import suggests the following repair: conjoin (1) with

⌜A body acted on by a gravitational field is accelerated & *y* is an observable body & *y* is at *x* [whether or not it was put there by somebody] & *z* is suitably equipped to observe *y* & *z* observes *y*.⌝ (2)

This new statement schema has one theoretical component, viz., the first conjunct, which is a law statement. The remaining components of (2) are empirical and moreover relevant to both the theoretical component and the original formula (1). As a consequence of this empirical ingredient, the conjunction (1) & (2) will entail observational statements and consequently will have an empirical import. Part of the latter will be

⌜*z* sees *y* moving⌝, (3)

which is in fact entailed by (1) & (2). In short, although the "operationally meaningful" statement (3) is not in the import of the original theoretical statement (1), it is in the import of the conjunction of the latter with further items, some of which are empirical. What holds for a single statement is true, *a fortiori*, of entire theories. That is, any substantive scientific theory can be enriched with further statements, at least some of them empirical, to yield observational consequences and thus get ready for observational tests. Thus the goal of operationism, namely to ensure testability, is saved without tergiversating the nature of scientific theories. *Requiescat in pace.*

3.5. *Changes in Import and Content*

The content of a theory is determined by its axiom base but is never known in its entirety. The content of a theory is fixed, however, once its axioms have been adopted. Moreover the content is infinite because so is the set of logical consequences of the axioms. And if the theory involves continua, then its content is nondenumerably infinite: the axioms generate an uncountable offspring. On the other hand the known part of the total content of a theory is of course finite and keeps growing as long as the theory stays alive – i.e. as more theorems in it are proved and fresh applications of it are made. This is the case not only with new theories but also with old theories that are still going strong, such as classical mechanics. There is growth in both cases although the growth *tempi* and mechanisms are not the same.

The growth of knowledge and its mechanisms, internal and external, is a fascinating subject but it lies outside the scope of semantics: they are the concern of the philosophy, history, psychology, and sociology of science. What the semanticist can do in this respect is to compare the import of alternative axiom bases, whether successive or contemporaneous. He can thus help other scholars by supplying measures of the net differences in import or in content, differences that may be interpreted as accompanying the replacement of one theory by another in the favor of the scientific community. Definition 15 will help us to contrive such a measure of change in scientific theories.

According to Definition 15, the factual content of a scientific theory equals the sum total of its nonlogical formulas. Hence the difference in content between two theories boils down to whatever nonlogical formulas the theories faill to share. More precisely, we introduce

DEFINITION 5.17 Let T and T' be two scientific theories with backgrounds B and B', mathematical assumptions M and M', factual assumptions F and F', and semantic assumptions S and S' respectively. Then the *difference in factual content* between T and T' equals the symmetric difference of their factual contents:

$$\delta(T, T')=\mathscr{I}\!\mathit{mp}(B \,\&\, M \,\&\, F \,\&\, S)\,\Delta\,\mathscr{I}\!\mathit{mp}(B' \,\&\, M' \,\&\, F' \,\&\, S')-L.$$

Since T and T' are infinite sets, their difference may prove infinite as well. On the other hand the gist differences introduced in Sec. 2.4 (Definitions 9 and 10) look more manageable because they concern only the axiom bases. However, this greater simplicity of the difference in gist does not render it more suitable as a measure of the difference in sense. In fact, since a theory can usually be axiomatized in alternative ways, the gists of two different axiomatizations of a given body of knowledge are bound to differ even though the total content of the theory is unaltered by the different axiomatic arrangement. Obviously we need both measures. And none of them is needed for practical purposes, such as rewarding the scientist who manages to produce the richest of two rival theories. The assumptions, definitions and theorems in our semantics serve only the modest purpose of elucidating some interesting metascientific ideas. (We shall come back to meaning change in Ch. 7.)

4. FULL SENSE

In the previous chapter we studied the content or interior of a construct apart from its exterior or extension and regardless of its place in a body of knowledge. The corresponding concept of sense, i.e. intension, is the one that suits constructs which, without being totally stray, belong to no definite system or closed context.

In the present chapter we have focused on systemic constructs and have distinguished two components of their sense – namely their purport and their import. The purport and the import of a construct are certainly not external to it but they are not strictly intrinsic either: they are essentially context-dependent. A closed context $\mathbb{C}$ may be pictured as a tree oriented from top to bottom. An arbitrary node or branching point x of $\mathbb{C}$, i.e. a systemic predicate or proposition, is assigned two basic sense components. One is its purport or upward sense $\mathscr{P}\!\mathit{ur}_{\mathbb{C}}(x)$, which equals the principal ideal generated by x in $\mathbb{C}$. The other component is the import or downward sense $\mathscr{I}mp_{\mathbb{C}}(x)$, equal to the principal filter generated by x in $\mathbb{C}$. See Figure 5.2.

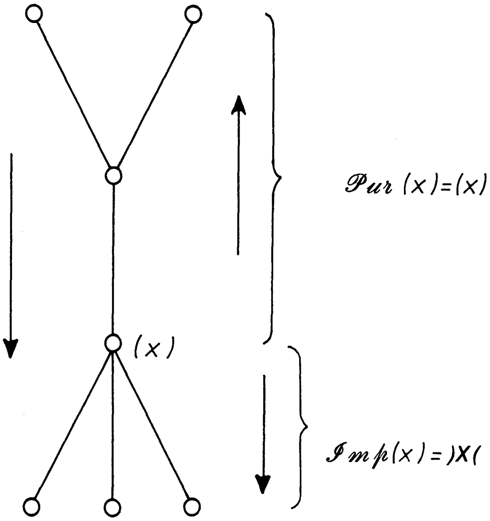


Fig. 5.2. A fragment of a conceptual system. The two components of the sense of a construct x in the system: the purport $\mathscr{P}ur(x)$ and the import

The sense of a construct in a closed context has no components other than its purport and its import. Since both are sets, or may be taken as such, we can build their union. It seems natural then to regard this union as the full sense of the construct of interest. More precisely, we offer

DEFINITION 5.18 Let x be a construct in a closed set of constructs $\mathbb{C}$. Then the *full sense* of x in $\mathbb{C}$ is the union of the purport and the import of x in $\mathbb{C}$:

$$\mathscr{S}_{\mathbb{C}}(x)=\mathscr{P}ur_{\mathbb{C}}(x)\cup\mathscr{I}mp_{\mathbb{C}}(x)=(x)_{\mathbb{C}}\cup)x(_{\mathbb{C}}.$$

This decomposition of the total sense of a construct is consonant with the scientific practice of regarding meanings as being either assumed or derived. Thus if it is *assumed* that the values of a certain function X of time represent positions (or concentrations or population densities), then it can be *inferred* that the value of its time derivative $\dot{X}$ at $t=0$ represents the initial velocity (or rate of change of concentration or population density). For this reason only the factual primitives of a theory need be assigned a factual sense by semantic formulas: the derived (defined or proved) constructs get their meaning from the source, i.e. the axiom base. In other words, in a scientific theory *sense flows downwards*, from assumption to consequence – not upwards, as the positivist doctrine has it.

Since a tautology follows from any proposition and entails all of the other tautologies in a given logic, the full sense of a tautological construct in a context equals the totality of propositions in it plus the underlying logic. Likewise all contradictions are interdeducible, so that the sense of any of them includes all; and since a contradiction entails anything, its sense is the totality of propositions in its context. That is, we have proved

COROLLARY 5.2 Let t be an analytic construct occurring in the logic L underlying a context $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$. Then

(i) $\mathscr{S}_{\mathbb{C}}(t)=S\cup L$;
(ii) $\mathscr{S}_{\mathbb{C}}(\neg t)=S$.

In a strictly logical context, i.e. for $S=L$, the sense of a tautology equals logic itself. In other words, logical truths "say" nothing when confined to logical theories and they "say" too much – in fact everything – when associated with extralogical bodies of knowledge.

Because an arbitrary proposition entails all of the tautologies, it falls between the above extremes of minimal and maximal sense:

COROLLARY 5.3 Let p be a statement occurring in a context $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$ with underlying logic L. Then

$$L\subseteq\mathscr{S}_{\mathbb{C}}(p)\subseteq S\cup L.$$

To obtain the extralogical (in particular factual) sense of a proposition we must then subtract L from its full sense:

DEFINITION 5.19 Let p be a proposition in a context $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$ with underlying logic L. Then the *extralogical sense* of p in $\mathbb{C}$ is

$$\mathscr{S}_{\mathbb{C}\bar{L}}(p)=\mathscr{S}_{\mathbb{C}}(p)-L.$$

If we know the full senses of two constructs we can ascertain whether they are comparable and, if so, which contains which. Thus the sense of "river" is included in that of "mountain river": the latter is the richer of the two. In general we have

DEFINITION 5.20 Of two constructs with comparable senses, the *richer* (or *more complex*) is the one including the other:
If c and c' are in $\mathbb{C}$, then c is *richer* than $c' =_{\mathrm{df}} \quad \mathcal{S}_{\mathbb{C}}(c) \supseteq \mathcal{S}_{\mathbb{C}}(c')$.

The richer of two concepts is also the more specific and complex, i.e. the less generic and less simple. The last convention serves then as a definition of *semantic complexity* – or its dual, semantic simplicity. But of course even if two constructs are not comparable in sense they may share a grain of sense. This notion of sense overlapping is exactified by

DEFINITION 5.21 The *core sense* of a set $\{c_i \in \mathbb{C} \mid 1 \leqslant i \leqslant n\}$ of constructs equals their shared sense:

$$\mathcal{S}_{core}\{c_i \in \mathbb{C} \mid 1 \leqslant i \leqslant n\} =_{df} \bigcap_{i=1}^{n} S(c_i)$$

Example Each of the different explicata e_i, for $1 \leqslant i \leqslant n$, of a given coarse or intuitive concept c, is supposed to recapture a part of the sense of the latter:

$$\mathcal{S}(c) \supseteq \mathcal{S}_{core}\{e_i \in \mathbb{C} \mid 1 \leqslant i \leqslant n \;\&\; e_i \text{ explicates } c\}.$$

If we focus on the specific contribution a basic construct makes, and brush aside the background of the theory, i.e. if the search for ancestors is stopped at the basic construct a itself, the purport of a will include just a, which is already included in its principal filter or import $\mathcal{I}mp_T(a)$. Hence we have

COROLLARY 5.4 The full specific sense of a basic construct a, characteristic of an axiomatized theory T, equals the import of a, i.e.

$$\mathcal{S}_T(a) = \mathcal{I}mp_T(a).$$

Hence the import of a construct measures its importance. On the other hand the greater the purport of a construct, i.e. the larger its dependence upon other constructs, the smaller its importance.

Because in a closed context $\mathbb{C}$ there is no source of sense other than $\mathbb{C}$ itself, intension has no separate existence in it: it is part of the full sense. More explicitly, we conjecture

PROPOSITION 5.1 The intension of a construct x in a closed set of constructs $\mathbb{C}$ is included in the full sense of x:

$$\text{If } x \in \mathbb{C}, \quad \text{then} \quad \mathcal{I}(x) \subseteq \mathcal{S}_{\mathbb{C}}(x).$$

Example Consider the predicates "triangular" ($\triangle$), "equiangular" (A), and "equilateral" (L), all of them referred to closed plane figures in Euclidean geometry (E). Since $A \neq L$, $\mathcal{I}(\triangle \;\&\; A) \neq \mathcal{I}(\triangle \;\&\; L)$. But, because triangle equiangularity implies triangle equilaterality and conversely, $\mathcal{S}_E(\triangle \;\&\; A) = \mathcal{S}_E(\triangle \;\&\; L)$. Moreover the full sense of either complex predicate includes not just A and L but also the whole lot of derived properties of equilateral triangles, which their intensions do not.

From the preceding it follows that, if a construct happens to be basic (i.e. undefined or assumed) in a given context, then its intension coincides with its full sense and also with its import:

PROPOSITION 5.2 The intension of a basic construct a in a closed set $\mathbb{C}$ of constructs equals the full sense of a:

$$\text{If } a \in \mathbb{C} \text{ is basic in } \mathbb{C}, \quad \text{then} \quad \mathcal{I}(a) = \mathcal{S}_{\mathbb{C}}(a) = \mathcal{I}mp_{\mathbb{C}}(a)$$

A change in the basic principles that determine the sense of a construct may alter the latter even if we keep calling it by the same name. As Hilbert explained to Frege (who disliked axiomatic definitions), "Each axiom contributes something to the definition [of the concept of interest] and, as new axioms are introduced, the concept is accordingly changed" (Hilbert, 1900). In short, meaning is contextual.

This concludes the study of the concepts of sense we started in Ch. 4. It may well happen that our exactifications fail to capture the reader's intuitions. One man's sense is another's nonsense. This is quite in order: no technical concept is supposed to satisfy everybody's presystematic ideas. (Recall the example illustrating Proposition 5.1.) If the proposed elucidations are found unacceptable for technical reasons, then surely better theories can be contrived. But once a theoretical explication is accepted, be it in science or in philosophy, it is one's intuitions that are expected to adjust to the theoretical concept – until a better exactification becomes available. (Cf. Bunge, 1962.)

5. CONCLUSION

There are two main views on sense. One is extensionalism, according to which constructs have an exterior, or extension, but no interior or sense. We have found this, the hollow construct view, unacceptable not only in relation to factual science but also to pure mathematics (Ch. 4, Sec. 1.2). The opposite view regards all constructs other than sets as having a content. But there are many differences of opinion concerning the nature of this content (Ch. 4, Sec. 1.1). These differences are manifested, in particular in the question of the relations between the sense of a whole and the sense of its parts. There are two extreme views on this matter: semantic atomism and semantic holism. Let us take a glimpse at them and locate our own view in this perspective.

Semantic atomism holds that "The sense of the whole is determined by the senses of its parts". It has been the most popular view among illuminist philosophers from Hobbes right down to Montague (1970) and Scott (1970). But no semantic atomist seems to have constructed a suitable theory containing formulas that determine the sense of a construct as a function of the sense of its components. In short, semantic atomism has remained at a programmatic stage. The opposite extreme, semantic holism, maintains that "The sense of every item is determined by the whole of knowledge". Its most eminent proponent in recent times has been Quine (1952). This view too is programmatic and moreover doomed to stay in this stage, because nobody can handle the sum total of human knowledge.

Our own semantic theory takes a *via media* and therefore cannot be as charming as either of the extremes. Indeed, on the one hand we have proposed definite formulas for the intension of a composite construct in terms of the intensions of its components (Ch. 4, Sec. 2). However, this analysis is not a term by term resolution and, moreover, it offers no means for determining the sense of a component. If asked how the latter is to be determined, we offer still another theory, according to which the sense of a construct can be determined provided the construct occupies a definite place in a conceptual system. Hence, to the extent to which our theory provides for the sense analysis of a whole, it implements a modest version of the atomistic program. And since the full sense of a part is shown to depend on its role in a whole, our theory satisfies the holistic injunction not to isolate. In short our semantics constitutes a merger of the best (others would say the worse) of both extremes. If accepted, it becomes understandable why each of the two extremes has its appeal – and why none of them got beyond the program stage.

At first blush our *via media*, by admitting that the sense of a (theoretical) construct is relative to the theory in which it occurs, and is thus liable to become a different construct if inserted in a different theory, would seem to encourage subjectivism. Perish the thought. Firstly, only the sense of a theoretical or systemic construct is determined by the whole theory in which it occurs. Extrasystematic constructs, such as the common observational statements, are not theory-dependent – but then their sense is uncertain. Secondly, it is not that "the meaning of a scientific construct is theory-laden", as the fashionable trend has it, but the other way around: theories (even logical theories) are meaning-laden. The meaning of any component of a theory is relative to the theory, i.e. it depends on the role it plays in the theory, but is not "theory-laden" – whatever this metaphor may mean. Thirdly, every authentic scientific theory, even if false, is objective – ergo so is every factual component of it. It is objective both semantically (by its reference to entities that are supposedly out there) and methodologically – for being publicly scrutable. On the other hand the attempts to defend the objectivity of science by anchoring it to an experiential rock bottom may easily lead back to subjectivism, as witnessed by operationism.

To sum up, we have proposed a contextual but not holistic theory of sense. The contextual nature of sense explains why one and the same symbol can be interpreted differently in different contexts and never fully outside some well delineated conceptual framework. But the matter of interpretation deserves another chapter. As a matter of fact we shall devote it the initial chapter of Part II of this work.

INDEX OF SUBJECTS

Analogy 103
Analytic 55–56. *See also* Tautology
Assumption, semantic 104–114
Axiom 149

Background of a theory 151–152
Boolean algebra 144, 151

Category, Aristotelian 131
  mistake 79
  semantic 13–14
Closure, semantical 65
Coextensiveness 134–135
Cointensiveness 125
Commensurability of theories, methodological 77–78
  referential 66–68, 77–78
Communication 8
Complexity, semantic 169
Concept 14–18
  factual 59
  formal 60
  modal 122–123
  pragmatic 121–122
Confirmation 140
  paradox of 79–80
Construct 13, 31, 43, 57, 88, 92
Content 158–166
  changes in 166
  empirical 161–163
Context 57, 143
  closed 143–145
  factual 60
  formal 60
Conventionalism 70–72, 160–161
Core sense 169
Coreference 57–58
Correspondence rule 25, 106. *See also* Denotation rule, Semantic assumption
Craig's interpolation theorem 66
  reduction 164

Data 70
Denotation 25, 42–43
  rule 25, 105–109
Designation 11, 21–25, 42
  function 23–25
  rule 25
Difference in gist 154
  intensional 130–133
Differentia specifica 130

Empiricism 113. *See also* Operationism, Phenomenalism, Positivism
Entailment 128–129, 145
Equivalence, logical 53, 130
  of representations 95
Evidence 44–45, 163
  relevant 79
Expression 10–11, 14, 24, 26
Extension 34–35, 49, 118–120, 130. *See also* Volume 2, Chapter 9, Sec. 1
Extensionalism 118–120

Family resemblance 133
Filter 155–156
Form, logical 115–116
Formalism, mathematical 104–105
Foundations of a theory 152

Gist 147, 149–154
  changes in 153–154
  extralogical 151–153
Grammar 11, 46
Grammaticalism 46

Holism, semantic 152, 171
Hypothesis 111

Ideal 145–146
Import 116–117, 134, 142, 156–165
  extralogical: see Content
Information, semantic 121, 135–138

  statistical 137–138
Intension 115–141, 170
Intensional context 121–122
Interpretation, factual 105–114. *See also* Volume 2, Chapter 6
  mathematical 105

Language 8–13, 18–20
  conceptual 23–26
Lattice 143–145, 155
Law statement 89, 94
Logic 4–5, 39, 64
  intensional 121

Magnitude 95–97
Materialism, conceptualist 32
Mathematics 4–5, 39, 120
Meaning 3, 6, 29, 45, 109, 172. *See also* Intension, Reference, Sense, and Volume 2, Chapter 7

GENERAL PREFACE TO THE *TREATISE*

This volume is part of a comprehensive *Treatise on Basic Philosophy*. The treatise encompasses what the author takes to be the nucleus of contemporary philosophy, namely semantics (theories of meaning and truth), epistemology (theories of knowledge), metaphysics (general theories of the world), and ethics (theories of value and of right action).

Social philosophy, political philosophy, legal philosophy, the philosophy of education, aesthetics, the philosophy of religion and other branches of philosophy have been excluded from the above *quadrivium* either because they have been absorbed by the sciences of man or because they may be regarded as applications of both fundamental philosophy and logic. Nor has logic been included in the *Treatise* although it is as much a part of philosophy as it is of mathematics. The reason for this exclusion is that logic has become a subject so technical that only mathematicians can hope to make original contributions to it. We have just borrowed whatever logic we use.

The philosophy expounded in the *Treatise* is systematic and, to some extent, also exact and scientific. That is, the philosophical theories formulated in these volumes are (*a*) formulated in certain exact (mathematical) languages and (*b*) hoped to be consistent with contemporary science.

Now a word of apology for attempting to build a system of basic philosophy. As we are supposed to live in the age of analysis, it may well be wondered whether there is any room left, except in the cemeteries of ideas, for philosophical syntheses. The author's opinion is that analysis, though necessary, is insufficient – except of course for destruction. The ultimate goal of theoretical research, be it in philosophy, science, or mathematics, is the construction of systems, i.e. theories. Moreover these theories should be articulated into systems rather than being disjoint, let alone mutually at odds.

Once we have got a system we may proceed to taking it apart. First the tree, then the sawdust. And having attained the sawdust stage we should move on to the next, namely the building of further systems. And this for three reasons: because the world itself is systemic, because no idea can become fully clear unless it is embedded in some system or other, and because sawdust philosophy is rather boring.

The author dedicates this work to his philosophy teacher

Kanenas T. Pota

in gratitude for his advice: "Do your own thing. Your reward will be doing it, your punishment having done it".

INDEX OF SUBJECTS 208

PREFACE TO *SEMANTICS II*

This is the second and last part of our work on semantics. The first part, titled *Sense and Reference*, constitutes volume 1 of the *Treatise*.

What follows presupposes an understanding of the slippery notions of sense and reference. Any theories elucidating these concepts will do for the purpose of tackling the present volume. But, of course, only the theories expounded in Part I will articulate cogently with those we are about to discuss. Nevertheless, the gist of Part I can be summarized in a few words.

Philosophical semantics is about constructs, in particular predicates and propositions. Every such object has both a sense and a reference. The full sense of a construct is the collection of its logical relatives. This collection is made up of two parts: the purport, or set of implicants, and the import, or set of implicates. For example, the purport of a defined concept is the set of concepts entering in its definition, and its import is the collection of concepts hanging from it. As to the referents of a predicate, they are the individuals occurring in its domain of definition. And the reference class of a statement is the union of the reference classes of all the predicates occurring in the proposition. Some constructs, notably those occurring in ordinary knowledge and in scientific theories, have a factual sense and a factual reference. The theories of sense and reference put forth in Part I allow one to calculate both the sense (in particular the factual sense) and the reference class (in particular the factual reference class) of any predicate and any statement. By this token they can help us solve certain tricky semantical problems posed by some of the most important scientific theories, the sense and reference of which are often the object of spirited debates. So much for a résumé of Part I.

The present volume starts with the problem of interpretation. Interpretation is construed as the assignment of constructs (e.g. predicates) to symbols. It can be purely mathematical, as when the dummy x is interpreted as an arbitrary natural number, or also factual, as when such a number is interpreted as the population of a town. Now, as we saw a while ago, predicates and propositions have both a sense and a reference – and nothing else as far as meaning is concerned. These, then, are taken to be the meaning components. That is, the meaning of a construct is defined as the ordered couple constituted by its sense and its reference class. Once the meaning of a proposition has been established we can proceed to finding out its truth value – provided it has one. If the proposition happens to be factual, i.e. to have factual referents, then it may be only partially true – if true at all. Hence we must clarify the concept of partial truth of fact. This we do by building a theory that combines features of both the correspondence and the coherence theories of truth. The remaining semantical notions, notably those of extension, vagueness, and definite description, are made to depend on the concepts of meaning and truth and are therefore treated towards the end of this work. The last chapter explores the relations between philosophical semantics and other branches of scholarship, in particular logic and metaphysics.

This volume, like its predecessor, has been conceived with a definite goal, namely that of producing a system of philosophical semantics capable of shedding some light on our knowledge of fact, whether ordinary of scientific. We leave the semantics of natural languages to linguists, psycholinguists and sociolinguists, and the semantics of logic and mathematics (i.e. model theory) to logicians and mathematicians. Our central concern has been, in other words, to clarify and systematize the notions of meaning and truth as they occur in relation to factual knowledge. For this reason our semantics borders on our epistemology.

SPECIAL SYMBOLS

C	Set of constructs (concepts, propositions, or theories)
$\mathbb{C}$	Context
$\mathscr{C}$	Content (extralogical import)
$\mathscr{C}n$	Consequence
$\mathscr{D}$	Designation
Δ	Denotation
$\hat{=}$	Representation
$\mathscr{E}$	Extension
$\mathscr{I}$	Intension
$\mathscr{I}mp$	Import (downward sense)
L	Logic
$\mathscr{L}$	Language
$\mathscr{M}$	Meaning
Ω	Universe of objects (of any kind)
$\mathbb{P}$	Family of predicates
$\mathscr{P}ur$	Purport (upward sense)
$\mathscr{R}$	Reference
S	Set of Statements (propositions)
$\mathscr{S}$	Sense
$\mathscr{S}ig$	Signification
T	Theory (hypothetico-deductive system)
$\mathscr{V}$	Truth value function

CHAPTER 6

INTERPRETATION

All of the symbols in a scientific theory are interpreted. They are interpreted as designating certain mathematical concepts, some of which are in turn interpreted as representing certain aspects of the world. Such a double interpretation must be shown as completely and explicitly as possible if the signification of the symbolism is to emerge clearly. But what is an interpretation, in particular a factual one? This is the central theme of the present chapter.

1. KINDS OF INTERPRETATION

Anything, from sign to gait, can be interpreted if one knows how to. Thus farmers interpret cloud shapes, physicians bodily appearances, and charlatans dreams. In all three cases observed facts are correlated to hypothesized ones and the latter are assumed to explain the former. This kind of interpretation, bearing on natural signs, may be called *epistemic*: actually it is a mode of explanation. The concern of semantics is with another kind of interpretation, one bearing either on signs or on constructs. Henceforth we shall adopt this acceptation of 'interpretation', which may be called *semiotic.*

Semiotic interpretation may be construed either as bearing on signs or as bearing on constructs. The interpretation of signs is a task for designation rules, while the interpretation of constructs is performed by semantic assumptions. Example of sign interpretation: '&' *designates* conjunction. Example of construct interpretation: $F(a, b)$ *represents* the strength of the interaction between a and b.

Whether bearing on signs or on constructs, interpretation is required whenever that which is interpreted is not definite enough. Interpretation goes from the less to the more definite or specific. For example, from an ambiguous sign like 'S' to a definite generic construct such as "set", from the latter to a specific construct like "the set of pairs", or from here to a factual item like the collection of married couples, or to an empirical item such as the collection of married couples counted by the census bureau. We distinguish then four different kinds of interpretation relations, that are exhibited and exemplified in Table 6.1.

TABLE 6.1

Semiotic interpretations

Kind of interpretation		Relata	Example
1 Designation	$\mathscr{D}$	Symbol→Construct	Function letter→Function
2 Mathematical	μ	Generic construct→Specific construct	Function→sin
3 Factual	ϕ	Specific construct→Factual item	$\sin \omega t$→pendulum elongation
4 Pragmatic	π	Specific construct→Empirical item	$\sin \omega t$→measured value of pendulum elongation

The first kind of interpretation, i.e., designation, occurs in every conceptual system: without designation rules a symbolism does not symbolize. Thus a page of the *Journal of Mathematical Psychology* may be regarded as a system of conventional signs (words and mathematical symbols) together with a set of interpretation conventions – mostly tacit but nevertheless operative. In other words, a conceptual system may be regarded as an *interpreted language*, i.e., a symbolism together with a collection of designation rules. An uninterpreted language, i.e., a well constructed system of artificial signs with no designata, would be as idle and unintelligible as a scientific manuscript after a total nuclear holocaust. The very notion of a totally uninterpreted language makes no sense except for purposes of analysis.

The most basic of all conceptual systems are of course the logical calculi: they are the most abstract in the sense that they are the least interpreted. Logical calculi are prime examples of *abstract theories*, i.e. of theories containing predicates with no fixed interpretation – hence making room for a variety of interpretations. But they are all interpreted languages in the sense that they contain a designation rule for every sign type. Thus a predicate letter like '*P*' is interpreted as an arbitrary predicate or attribute. The interpretation is limited to designation: the calculus is uninterpreted solely in the sense that it involves none of the kinds 2 to 4 listed in Table 6.1 above. Hence the calculus fails to characterize its individuals and to assign them definite properties: it deals with unspecified individuals and attributes. Ergo it contains no specific laws, i.e., laws satisfied by objects of a definite kind, such as earthquakes or revolutions. In short the predicate calculus, by being semantically noncommittal, is attached to no ontology. But it is not an empty symbolism either: its small case letters are interpreted as unspecified individuals, its capital letters as unspecified predicates, and so on.

The indicated interpretation of logical calculi in terms of constructs of a certain type is the usual or *standard* interpretation but not the only possible one. Logical calculi can be assigned alternative interpretations – but then they may cease to be logical theories, i.e., theories concerned with deductive inference. A well known *nonstandard* model of the propositional calculus is the one in terms of switches in an electric network. And Kolmogoroff's interpretation of the intuitionistic propositional calculus in terms of problems is a nonstandard model of that calculus. These examples are mentioned only as a reminder that logical calculi are abstract theories except for the designation rules (e.g., ⌜'p' designates a proposition⌝), which we do not always care to state explicitly.

2. MATHEMATICAL INTERPRETATION

2.1. *Abstract Theory*

The mathematical theories occurring in factual science, such as trigonometry and the infinitesimal calculus, come with a definite mathematical interpretation. In other words they are specific ("concrete") theories concerned with mathematical objects of a definite kind, such as plane triangles or real functions. Thus the formulas $\ulcorner \sin^2 x + \cos^2 x = 1 \urcorner$ and $\ulcorner d \sin x/\mathrm{d}x = \cos x \urcorner$ are uniquely interpreted, namely in the field of real numbers. The latter can be extended to the field of complex numbers, but this is yet another specific structure: it is just an example or model of a field.

By contrast to such fully interpreted theories, those in logic, abstract algebra and topology are calculi with no fixed sense over and above the one determined by their axioms. These calculi, or *abstract theories* as we prefer to call them, are sometimes called *languages* or even *uninterpreted languages*. But this name seems misleading. First because, unlike a language, a theory, no matter how abstract, contains definite assumptions (axioms). Second because these assumptions give the theory a definite if parsimonious sense: it may be called the *minimal sense* of any theory built upon the given abstract theory by interpreting or specifying some or all of its concepts. Such a further interpretation will turn the abstract theory into a "concrete" theory with a richer sense – and correspondingly a narrower extension. The consideration of an example will clarify these points.

Consider lattice theory L. This is an abstract or formal theory concerned with a roomy structure $\mathscr{L} = \langle S, \preccurlyeq, \wedge, \vee \rangle$ that fits a number of species of specific mathematical objects. Being thus unattached to any specific interpretation, lattice theory can espouse (and subsequently divorce) a number of alternative interpretations. These are interpretations of a mathematical theory within mathematics: they are *mathematical interpretations*. And these are superimposed on the designation rules that turn a symbolism into an abstract theory – in this case L. A few such additional (or mathematical) interpretations of L are listed in Table 6.2.

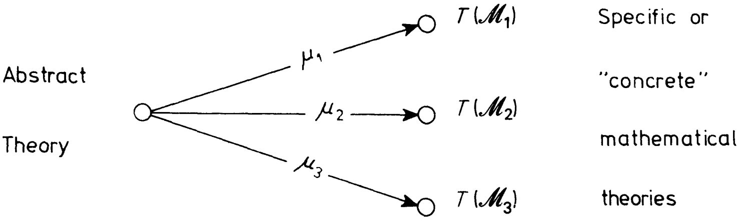
TABLE 6.2
Four mathematical interpretations of lattice theory

Primitives of L	Order interpretation	Class interpretation	Propositional interpretation	Arithmetic interpretation
Abstract set S	Abstract set S	A collection F of abstract sets	The set P of propositions	The set N of natural numbers
Partial order $\preccurlyeq$	Partial order $\preccurlyeq$	Set inclusion $\subseteq$	Entailment $\vdash$	Divisibility ⁒
Binary operation $\wedge$	Greatest lower bound	Set intersection $\cap$	Conjunction &	Greatest common divisor
Binary operation $\vee$	Least upper bound	Set union $\cup$	Disjunction $\vee$	Least common divisor

Table 6.2 illustrates the following important points.

(i) Mathematical interpretation is a construct-construct relation and, more particularly, an *intertheoretical* affair. This contrasts with the other three kinds of interpretation listed in Table 6.1.

(ii) Mathematical interpretation is a *one-many relation* between the set of abstract theories and the set of "concrete" (specific) theories:



(iii) Not all of the interpretations of an abstract theory are equally "concrete" or *specific*. For example, the order interpretation of L maps S and $\preccurlyeq$ onto themselves and specifies only $\wedge$ and $\vee$. Thus the referents remain nearly as indeterminate as before. The class interpretation of L is more "concrete" or familiar but not completely so: the domain F could in turn be interpreted by specifying the nature of the sets in F. Only the propositional and the arithmetic interpretations are full, i.e., not susceptible to any further specification – except of course instantiation, as when a definite proposition is picked out of the set P.

(iv) Every specific structure, such as $\mathscr{F} = \langle F, \subseteq, \cap, \cup \rangle$ or $\mathscr{P} = \langle P, \vdash, \&, \vee \rangle$, is a realization or *model* of the abstract structure $\mathscr{L} = \langle S, \preccurlyeq, \wedge, \vee \rangle$. That is, the new (specific) constructs satisfy the formulas of the abstract theory L. Equivalently: the formulas of the abstract theory are satisfied in any of its models.

(v) A specific structure, or model, may be regarded as the value of an interpretation function μ that maps abstract primitives into specific ones. Examples:

$$\mathscr{L} \overset{\mu_1}{\mapsto} \mathscr{F}, \qquad \mathscr{L} \overset{\mu_2}{\mapsto} \mathscr{P}.$$

Let us take a closer look at models – in the mathematical or model theoretic sense of the word not in any of the alternative senses. (For the various senses of 'model' see Bunge (1973a).)

2.2. *Model*

An axiomatized theory may be construed as describing the structure constituted by its specific basic or primitive concepts. Thus the general theory T of partial order may be regarded as the theory about the abstract relational structure $\mathscr{A}=\langle S, \preccurlyeq\rangle$, where S is an arbitrary set and $\preccurlyeq$ an ordering of S. Since neither S nor $\preccurlyeq$ is definable in T, they are primitives of T. And since they are mutually independent, as well as sufficient to develop T provided some logic has been presupposed, $\mathscr{A}$ is the primitive base of T. Equivalently: T is the theory of $\mathscr{A}$, or $T(\mathscr{A})$ for short.

Let us emphasize the abstract character of $\mathscr{A}$. The elements of S are utterly faceless, hence $\preccurlyeq$ itself is quite anonymous except for the axioms of T that determine the sense of $\preccurlyeq$ – i.e., the properties of reflexivity, antisymmetry, and transitivity. This, then, is the basic purport or gist of T – that S is a partially ordered set. (Recall Ch. 5, Sec. 3.3.) It would be nonsense to say that T is meaningless. The axioms of T provide the *minimal sense* of any theory obtained by assigning to S and $\preccurlyeq$ a specific interpretation i.e., by exemplifying both primitives of T.

Take now any of the specific mathematical theories resulting from assigning both S and $\preccurlyeq$ definite senses within mathematics. Consider, in particular, the propositional model $\mathscr{P}$ and the real number model $\mathscr{R}$ of the abstract structure $\mathscr{A}=\langle S, \preccurlyeq\rangle$:

(I_1) $\mu_1(S)=$The set P of propositions, $\mu_1(\preccurlyeq)=$The relation $\vdash$ of entailment,

(I_2) $\mu_2(S)=$The set R of real numbers, $\mu_2(\preccurlyeq)=$The smaller than or equal to relation $\leqslant$.

The outcome of each interpretation of the primitive of T is a specific relational structure or *model*:

$$\mathscr{M}_1=\mathscr{P}=\langle P, \vdash\rangle, \qquad \mathscr{M}_2=\mathscr{R}=\langle R, \leqslant\rangle.$$

These are models or realizations of the abstract structure $\mathscr{A}=\langle S, \preccurlyeq\rangle$. Since the axioms of the abstract theory $T(\mathscr{A})$ are satisfied under either interpretation, they are said to hold (or to be true) in the corresponding model. Upon adjoining either interpretation assumption (or semantic formula) to T, we get a "concrete" (specific) theory i.e. one concerned with a definite species of objects, such as propositions or real numbers. The object of such an interpreted theory being a model or specific structure, we may call the former the *theory of the model*, or $T(\mathscr{M})$ for short.

In our case we have

$T(\mathcal{M}_1)=T(\mathcal{P})=T(\mathcal{A})$ conjoined with the semantic assumptions I_1,
$T(\mathcal{M}_2)=T(\mathcal{R})=T(\mathcal{A})$ conjoined with the semantic assumptions I_2.

$\mathcal{M}_1$ and $\mathcal{M}_2$ above are but two members of an unlimited population of models of $\mathcal{A}$. And they are all *full models* in the sense that they are obtained by interpreting every constituent of the abstract primitive base $\mathcal{A}$. We might also have built a family of partial models resulting from a *partial interpretation* of $\mathcal{A}$. It would be the family of all the structures in which the nature of S but not the one of $\preccurlyeq$ is specified. (On the other hand it would be impossible to specify the order relation without at the same time fixing the nature of the elements of S.) In short, there are degrees of abstraction or, conversely, of semantic commitment. This notion is made more precise by

DEFINITION 6.1 Let $T(\mathcal{A})$ be an abstract theory with a primitive base $\mathcal{A}=\langle A_1, A_2, \ldots, A_n\rangle$ consisting of n nonlogical constants. Furthermore let $\mathcal{M}=\langle\mu(A_1), \mu(A_2), \ldots, \mu(A_n)\rangle$ be the value of an interpretation μ at $\mathcal{A}$. Finally, assume that μ does not effect a mere permutation (reshuffling) of the coordinates of $\mathcal{A}$. Then $\mathcal{M}$ is of *syntactic rank n*, *semantic rank* $m\leqslant n$ and *degree of abstraction* $\alpha=(n-m)/n=_{df} m$ of the interpreted primitives $\mu(A_i)$ differ from the corresponding abstract primitives A_i.

DEFINITION 6.2 $\mathcal{M}=\langle\mu(A_1), \mu(A_2), \ldots, \mu(A_n)\rangle$ is a *model* (or a *full model*) of $\mathcal{A}=_{df}$ the degree of abstraction of $\mathcal{M}$ is $\alpha=0$. On the other hand, if $0<\alpha<1$, $\mathcal{M}$ is a *partial model* of $\mathcal{A}$.

Instead of the degree of abstraction α we might have defined the *degree of interpretation* $\beta=1-\alpha=m/n$. This would have had the advantage that it would not have involved the ambiguous term 'abstraction', which we use in its semantic acceptation not in the epistemological one of remoteness from sense experience. The concept of degree of interpretation will reappear in the theory of factual interpretation (Sec. 3.4).

We close this subsection with a couple of historical notes. The idea of a partially interpreted calculus, usually credited to Carnap (1939), goes back to Boole and was used by Whitehead (1898, pp. 10–11) in his campaign for the independence of algebra with respect to arithmetic. And the notion of a partial model introduced by Definition 2 must not be taken for the concept of semimodel introduced by Kemeny (1956): a semimodel involves full interpretation and differs from a model in that it does not involve validity in some structure.

2.3. *Intensional Models and Extensional Models*

We distinguish two kinds of mathematical interpretation and consequently two sorts of model: extensional and intensional. Equivalently: a model can be characterized either extensionally or intensionally. (Recall that our use of 'intensional' is the traditional one not the one current in modal logic.) An *extensional interpretation* assigns to every predicate in the abstract theory its extension in some field. For example, a binary relation is interpreted as the set of ordered pairs that stand in the given relation. On the other hand an *intensional interpretation* maps the abstract primitives into more specific mathematical objects that need not be set theoretic objects. For example, in the class interpretation of lattice theory considered in Table 6.2, Sec. 2.1, the lattice operations (meet and join) are assigned the class intersection and the class union respectively, and these operations are in turn characterized by the axioms of the algebra of classes.

More precisely, let T be an abstract theory formalized to the extent that all of its specific primitives can be identified and arranged in a sequence

$$\mathscr{A}=\langle A_1, A_2, \dots, A_n, \dots\rangle.$$

A possible *intensional model* of $\mathscr{A}$ is a structure

$$\mathscr{M}(\mathscr{A})=\langle \mu(A_1), \mu(A_2), \dots, \mu(A_n), \dots\rangle,$$

the coordinates of which are definite mathematical objects with the same logical properties as their arguments in $\mathscr{A}$: an individual constant in $\mathscr{A}$ (e.g., the unit element in an algebra) is assigned an individual in $\mathscr{M}(\mathscr{A})$; a class in $\mathscr{A}$ is matched with a class in $\mathscr{M}(\mathscr{A})$; an m-ary relation in $\mathscr{A}$ is assigned an m-ary relation in $\mathscr{M}(\mathscr{A})$; a function in $\mathscr{A}$ is paired to a function in $\mathscr{M}(\mathscr{A})$, and so on. For example, in Table 6.2 we had the propositional interpretation of $\mathscr{L}=\langle S, \preccurlyeq, \wedge, \vee\rangle$, to which it assigned the model $\mathscr{P} = \langle P, \vdash, \&, \vee \rangle$. Only the first coordinate of this quadruple is a set.

On the other hand a possible *extensional model* of an abstract structure $\mathscr{A}$ is produced by (*a*) introducing a nonempty domain of individuals D (the domain of the model) and (*b*) interpreting every coordinate of $\mathscr{A}$ as either a member of D or a set of m-tuples of members of D. In particular, an individual constant of $\mathscr{A}$ is matched with a member of D, an abstract unary predicate in $\mathscr{A}$ is interpreted as a subset of D, and every abstract m-ary predicate of $\mathscr{A}$ is assigned a subset of D^m. Every coordinate of a model is now a mathematical object with a definite set theoretic status: see Figure 6.1. In particular, the image of an abstract predicate is the extension of the latter – not, as sometimes claimed, the meaning of the predicate.

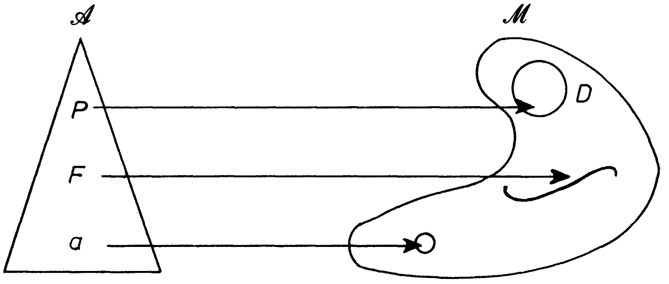


Fig. 6.1. An extensional interpretation maps the constituents of an abstract structure $\mathscr{A}$ into set theoretic objects built exclusively with the domain D of the model.

The peculiarities of the two kinds of model are exhibited in Table 6.3 overleaf.

2.4. *Insufficiency of Extensional Models*

The discipline that studies extensional models (in the sense of Sec. 2.3) is called *model theory*. This is a sizable and growing chapter of metamathematics and it may be regarded as covering most of the semantics of logic and mathematics. The concern of model theory is "the mutual relations between sentences for formalized theories and mathematical systems in which these sentences hold" (Tarski, 1954, p. 572). For example, model theory investigates the relations between abstract Boolean algebra and its models. In particular, model theory can characterize the whole lot of models of a given abstract structure and can study the morphisms between such models.

Model theory is not only concerned with models *per se* but is also interested in the *use* of models to solve certain syntactic problems about any mathematical theory, whether abstract or specific. Indeed, model theory is the most powerful tool available to investigate questions of consistency, concept independence, definability, independence of axioms, provability, categoricity, etc. On this count model theory is relevant not only to pure mathematics but also to the foundations of science and to exact philosophy.

TABLE 6.3

Intensional model and extensional model

Abstract primitive	Intensional object	Extensional object
Individual constant a	Individual $\mu(a)$	$\mu(a) \in D$
Unary predicate P	Attribute $\mu(P)$	$\mathscr{E}(P) \subseteq D$
m-ary predicate P^m	m-ary attribute $\mu(P^m)$	$\mathscr{E}(P^m) \subseteq D^m$
m-ary operation or function F^m	m-ary operation or function $\mu(F^m)$	$\mu(F^m): D^m \to D$

However, as conceived heretofore model theory is limited to extensional models and is therefore of restricted use even for purely mathematical purposes. Firstly, extensional models are not easy to come by: except in trivial cases sets are not given extensionally, i.e., by displaying their memberships, but are determined by some predicate or other. That is, normally a set is given by some law or rule which is not in turn resolvable in set theoretic terms. (Thus the fact that the *general* notion of a function can be partially elucidated as a set of ordered n-tuples does not entail that every *special* function can be so given. For example the logarithmic function is not given by a table of logarithms – the extensionalist ideal – but by certain formulas, such as $\ulcorner log(xy) = log\,x + log\,y \urcorner$, with $x, y \in R^+$.) In mathematics, just as in science, extensions are ultimately determined by senses. Secondly, even if it were possible to construct every model or example in purely set theoretic terms, intensional models could be dispensed with only provided we adopted the principle that coextensives are identical. But, as we say in Ch. 4, Sec. 1.2, this is a false dogma. It is particularly misleading with reference to factual science, where "descriptive interpretations" are essential (Carnap, 1958, p. 173). Therefore the claim (Suppes, 1961, 1967, 1969; Przelecki, 1969) that model theory can take care of the semantics of science is as unjustified as the identification of a model of an abstract structure ("formalized language") with "the real world" (Beth, 1962) or even with "a fragment of reality" (Przelecki, 1969).

Model theory does not tackle any of the problems peculiar to the semantics of factual science for the following reasons:

(i) The overwhelming majority of the mathematical theories used in factual science are not abstract but interpreted (within mathematics). Thus there is no way of reinterpreting a differential equation within mathematics: its degree of abstraction is nil. Now, model theory has little if anything to say about such theories – e.g., the theory of complex variables, the theory of integral equations, or differential geometry. Only abstract theories, such as group theory, or the general theory of topological spaces, pose model theoretic problems such as "Does this interpretation of the primitives yield a model?", "Are all the models of the given structure isomorphic to one another?", or "Can we prove a representation theorem for this theory?".

(ii) The models occurring in "intuitive" (nonformalized) mathematics and in science are mostly intensional models, i.e., they are "defined" by properties and laws rather than extensionally. On the other hand the models studied by model theory are extensional, hence incapable of discerning intensional differences unless the latter are accompanied by extensional differences. Applied mathematics and science cannot dismiss such differences, particularly since coextensive predicates may be characterized by different law statements, whence they must be counted as distinct.

(iii) As practised in formalized mathematics, which is the object of model theory, axiomatics involves *de*interpretation. For example, the abstract theory of natural numbers is formulated in such a way that the very concept of a natural number is not explicitly included in it, precisely in order to allow for alternative interpretations. A possible axiomatization of this abstract theory boils down to the following set of postulates:

A1 $x' \neq 0.$

A2 $x' = y' \Rightarrow x = y.$

A3 $(P0 \,\&\, (Px \Rightarrow Px')) \Rightarrow (y)\, Py.$

One recognizes here the kernel of the five Dedekind-Peano axioms. But the above formulas are satisfied in models other than the standard number theoretic one. In order to have the above postulates describe the essential properties of the natural numbers, suitable interpretation assumptions must be joined to them. Interpretation is thus external to formal axiomatics as opposed to the axiomatics found in "concrete" or "intuitive" mathematics and in science. (For an elucidation of the differences between formal axiomatics and *inhaltliche Axiomatik* see Hilbert-Bernays, 1968, I, Sec. 1.) In particular, scientific axiom systems must contain interpretation assumptions, as emphasized by Carnap (Carnap, 1939, 1958). Otherwise we would not know what the theory is about nor, consequently, how to apply and test it.

(iv) Because science concerns the external world, scientific theories must involve not only mathematical interpretations but also factual ones, i.e. construct-fact correspondences. These correspondences fall outside the scope of model theory, which is concerned with mapping structures into structures. The semantic assumptions in factual science correlate definite mathematical structures with real systems – and a real system is not a mathematical object. (The fashionable identification of models with possible worlds has suggested the view that the actual world is just a possible model. This new fangled version of the Platonic allegory of the cavern overlooks a couple of details. One is that, while a model is a harmless unpolluted construct, the world is not the work of a mathematician. Another is that, while a formula may or may not be satisfied in a model, the natural laws are inherent in the real world. A third is that, while every single model is fully characterized, no chunk of reality, however minute, is known exhaustively.) Furthermore the semantic assumptions in factual science are refutable hypotheses (Ch. 3). For example, improved accuracy in measurement showed that Yukawa's theory was not about μ-mesons, as originally conjectured, but about π-mesons. In contrast, the rules of assignment (of extensions) given by an extensional model may be regarded as holding analytically provided analyticity is construed in a permissive fashion (Kemeny, 1956).

In sum, model theory does not help us to elucidate the semantic peculiarities of factual science. The semantics of science takes off where model theory leaves: see Figure 6.2.

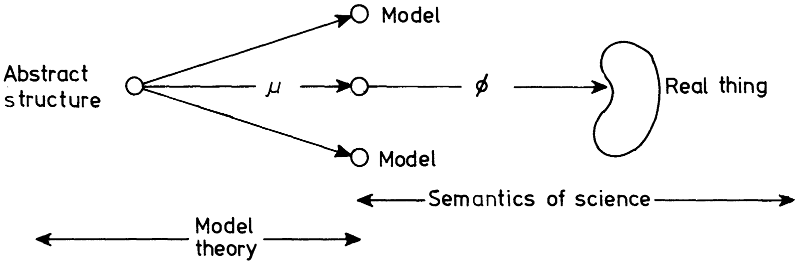

Fig. 6.2. From abstraction to reality through model (or conversely).

Let us now turn to the problem of factual interpretation – the map ϕ that model theory does not deal with.

3. FACTUAL INTERPRETATION

3.1. *The Need for Factual Interpretation in Science*

Every contemporary scientific theory worth the name has a mathematical formalism. This formalism consists of a set of mathematical theories the symbolism of which is interpreted by tacit or explicit designation rules pairing symbols to constructs. The overwhelming majority of such formalisms are not abstract theories but theories of models in the sense of Sec. 2.2. Probability theory and the theory of Hilbert spaces are theories of this kind and the two are components of the mathematical formalism of quantum mechanics. Whatever additional interpretation any such formalism be assigned, is nonmathematical – hence it cannot be described exclusively in mathematical terms. Thus a physical geometry will consist of a mathematical geometry together with semantic assumptions pairing constructs to things or properties of things.

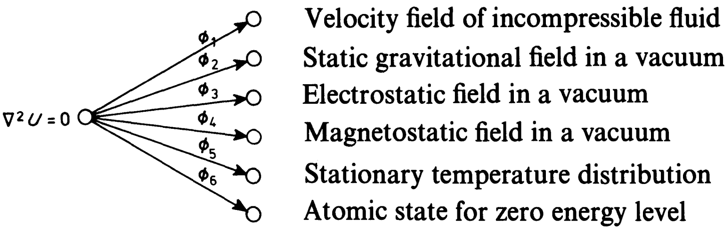
However, many mathematicians see no need for such additional interpretations. Thus a distinguished mathematical physicist postulates that the isotropic subspaces of R^n are light rays, whence ray optics is just the theory of such spaces (Jost, 1965, p. 18). Another distinguished mathematician proposes the following definition: "A lever is a system consisting of a plane π, a straight line ℓ in that plane, called a beam, a point O on that line called the fulcrum, etc." (Freudenthal, 1971, p. 316). Mind: in the two quotations certain mathematical objects are not said to *represent* certain physical objects but are *identified* with them. Finally an eminent philosopher-scientist has forcefully defended the slogan "To axiomatize a theory is to define a set-theoretical predicate", i.e., "one that can be defined within set theory in a completely formal way" (Suppes, 1967). If this is how scientific theories are to be reconstructed then it is obvious that (*a*) logic applies to physical objects such as dynamical systems: "as far as dynamical systems are concepts (a lever, a solar system) they allow for logical relations" (Freudenthal, 1971, p. 321); and (*b*) "there is no theoretical way of drawing a sharp distinction between a piece of pure mathematics and a piece of theoretical science" (Suppes, *op. cit.*). The view, held by all three authors, that a scientific theory consists of its mathematical formalism alone, may be regarded as an updated version of the Pythagorean philosophy and may be called *semantic formalism* – or *unsemantics* for short.

Most theoretical scientists are not semantic formalists: they hold with Einstein (1936) that a scientific theory has a content that overflows its mathematical formalism and thereby throws the theory at the mercy of facts. Suppes himself acts on this nonformalist conviction when expounding scientific theories. Thus he formulates his theoretical model of individual decision in the following fashion (Suppes, 1969, p. 148). "We shall call an ordered triple $\mathcal{S} = \langle S, C, D \rangle$ an *individual decision* situation when S and C are sets and D is a set of functions mapping S into C. The intended interpretation is:

S = set of states of nature,
C = set of consequences,
D = set of decisions or actions."

These interpretation assumptions are not included in the axiomatic definition of an individual decision situation but are juxtaposed to the latter: nevertheless they are not forgotten although they certainly are not set theoretic constructs.

The typical theoretical scientist will not say that a factual item f (thing, property, state, event, process) *is* a mathematical object m but rather that *m represents f*. He knows that one and the same mathematical object (set, function, space, equation, etc.) may be assumed to represent different factual items in different theories. For example, the Laplace equation occurs in at least the following capacities:



$\nabla^2 U = 0$
ϕ_1
ϕ_2
ϕ_3
ϕ_4
ϕ_5
ϕ_6
Velocity field of incompressible fluid
Static gravitational field in a vacuum
Electrostatic field in a vacuum
Magnetostatic field in a vacuum
Stationary temperature distribution
Atomic state for zero energy level

Since scientists meet the same functions and equations over and over again in different chapters and associated with different factual contents (senses and referents), they know that a scientific theory has a factual content which is not exhausted by its formalism. Most scientists realize that whatever can be read *out* of a mathematical formalism is what we have more or less unwittingly read *into* it. They differ only as to the nature of this content and the way it should be assigned. Thus while most scientists seem to favor a realist but sloppy semantics, those who do take pains to spell out the interpretation assumptions do it often in operationist terms. Only a few hold the magic view that a mathematical formalism yields its own interpretation (Everett, 1957; DeWitt, 1970). To help settle these problems let us analyze a couple of examples.

3.2. *How Interpretations are Assigned and What They Accomplish*

Let us exhibit three examples of factual interpretation with a view to finding out what it adds to the mathematical formalism.

Theory 1: Rat race

Primitives: S, Δ.

Axiom 1 Δ is a binary associative operation in the set S: i.e., for any $x, y, z \in S$, $(x\Delta y)\,\Delta z = x\Delta\,(y\Delta z)$.

Axiom 2 $\phi(S)$ = collection of rats.

Axiom 3 $\phi(\Delta)$ = joining a race, i.e., $\phi(x\Delta y) = x$ joins y (in this order) in a race to some goal.

The mathematical formalism boils down to Axiom 1, which states that

$\langle S, \Delta \rangle$ is a semigroup. The other two postulates are semantic assumptions. By virtue of the latter, the former becomes the law statement ϕ (A1) = ⌜First to enter race wins⌝ (or ⌜Late comers are eliminated⌝).

Without A2 and A3 no such "reading" (interpretation) of A1 would be explicit and unambiguous. The first semantic assumption identifies the referents of the theory as rats. The second stipulates that Δ represents race joining. Axiom 1 determines the mathematical sense of Δ, but the full sense of Δ is given by all three axioms.

Theory 2: Switching circuits

This theory contains half a dozen semantic assumptions defining an interpretation function ϕ that relates certain formulas to elements of circuitry of a kind. This function is a one to one mapping $\phi : B \to N$ from the set B of Boolean functions of a certain type onto the set N of two terminal series-parallel electrical networks. The domain of ϕ is a construct while its range is an aggregate of pieces of hardware: ϕ is a factual interpretation function. Given any Boolean form b in B, ϕ locates a possible network n in N such that $\phi(b) = n$, i.e. such that *b represents n*. And conversely: given a possible network n, its Boolean image will be $b = \phi^{-1}(n)$, where ϕ^{-1} is the inverse of ϕ. *Example*: Figure 6.3.

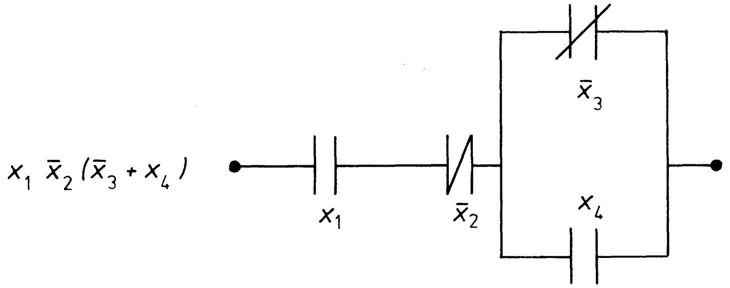


Fig. 6.3. A representation of switching circuits by Boolean forms.

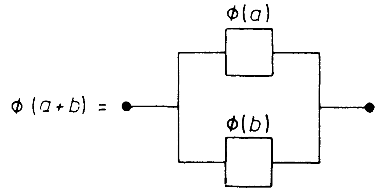
The specific semantic assumptions determining ϕ are (Harrison, 1965, p. 79)

A1 $\phi(0) = \circ$ (Equivalently: $0 \hat{=} \circ$)
A2 $\phi(1) = \circ\!\!-\!\!-\!\!-\!\!\circ$ (Equivalently: $1 \hat{=} \circ\!\!-\!\!-\!\!-\!\!\circ$)

A3 For any variable x_i, $\phi(x_i) =$ 
(Equivalently: $x_i \hat{=}$ a normally open contact)

A4 For any variable x_i, $\phi(\bar{x}_i =$ 
(Equivalently: $\bar{x}_i \hat{=}$ a normally closed contact)

A5 For any Boolean forms a, b in B:



(Equivalently: $a+b \hat{=}$ two terminal parallel circuit.)

A6 For any Boolean forms a, b in B:

(Equivalently: $ab \hat{=}$ two terminal series circuit.)

Here again the semantic assumptions determine both the reference class and the way the constructs represent some of the features of their referents.

Theory 3: Assembly theory

The preceding considerations apply not only to scientific theories but also to theories in scientific or mathematical metaphysics, such as assembly theory (Bunge, 1971b). This theory is concerned with the basic modes of assembly or composition of systems apart from their specific properties. It may be regarded as ring theory (a stalwart member of abstract algebra) together with the following semantic assumptions

A1 $\phi(S) =$ the set of all systems
A2 $\phi(0) =$ the null system
A3 $\phi(+) =$ system juxtaposition or joining
A4 $\phi(\cdot) =$ system interpenetration or superposition

By virtue of these semantic assumptions every formula in ring theory becomes a metaphysical statement. For example, for any x, y, z in S,

$\phi(x(y+z)=xy+xz)=$ The superposition of system x with the outcome of the juxtaposition of systems y and z equals the juxtaposition of the systems (x superposed to y) and (x superposed to z).

We now generalize the preceding considerations by defining a theoretical factual construct as a mathematical construct together with a factual interpretation map. More precisely, we adopt

DEFINITION 6.3 A construct c will be said to be a *theoretical factual construct* iff

(i) c belongs to a theory and

(ii) $c=\langle m, \phi\rangle$, where m is a mathematical construct and ϕ is an interpretation map such that $\phi(m)$ is a factual item (thing, property, or event) or a collection of factual items.

Example The ordered pair $\langle M, \phi\rangle$ is the concept of mass in particle mechanics iff $M: P \rightarrow R^+$ is an additive function and

(i) $\phi(P)=$ Particles,

(ii) $\phi(M(x))=$ Inertia of x for every $x \in P$,

(iii) M occurs in the equations of motion of particle mechanics multiplying the particle acceleration.

To conclude we collect the lessons learned from our analysis:

(i) The nonsemantic axiom(s) of a theory determine(s) the mathematical sense of its primitives;

(ii) the semantic axiom(s) determine(s) the referents and sketch(es) the full factual sense of the primitives and of the nonsemantical axiom(s);

(iii) the sense and reference of the derived constructs of a theory are determined by its axioms.

In sum, the sense and reference of a theory are determined jointly by all of its axioms. Equivalently: the significance of the symbolism ("language") of a theory is given by all of its axioms taken together.

3.3. *The Factual Interpretation Maps*

The first three examples discussed in the last subsection are extremely simple, hence atypical: they involved a single interpretation. In fact, in each of them the interpretation function ϕ mapped an abstract structure $\mathscr{A}$ into a factual domain $\mathscr{F}$. Thus in the first case $\mathscr{A}=\langle S, \Delta\rangle$, and $\mathscr{F}$

consisted of a collection of racing rats. There was no intermediary mathematical model such as, say, the ring of integers or Euclidean geometry. In brief, we had

$$\mathscr{A} \overset{\phi}{\mapsto} \mathscr{F}. \tag{1}$$

Moreover in the second case ϕ was no less than an isomorphism between the set B of constructs and the collection N of things. Besides, in this case as well as in the case of assembly theory ϕ was a morphism of addition and of multiplication. Such simplicity is exceptional in science.

In most scientific theories the domain of ϕ is not an abstract structure but a model of such. In other words, the mathematical formalism of the typical scientific theory is a *theory of a model.* And this theory is seldom found ready-made in a mathematical rack: the theory is usually built by enriching an interpreted mathematical theory (or rather a motley collection of fragments of interpreted mathematical theories) with some specific assumptions not found in mathematics. For example, a classical field theory is obtained by putting the following components together: (*a*) the theory of differentiable manifolds, (*b*) a set of specific formulas, chiefly the field equations, boundary conditions, and constraints, and (*c*) a set of semantic assumptions.

In these cases we have two successive and dovetailing interpretations: μ and ϕ, the former from an abstract structure $\mathscr{A}$ to a model $\mathscr{M}$, the latter from $\mathscr{M}$ to a factual domain $\mathscr{F}$:

$$\mathscr{A} \overset{\mu}{\mapsto} \mathscr{M}, \qquad \mathscr{M} \overset{\phi}{\mapsto} \mathscr{F}. \tag{2}$$

Hence, with a qualification to be mentioned shortly, we may regard the factual interpretation of an abstract structure as the composition of the two mappings, i.e. $\phi \circ \mu : \mathscr{A} \to \mathscr{F}$. (Bunge, 1972b.) It is true that the abstract structure is seldom if ever dug out when analyzing a typical scientific theory: one usually starts from a model. However, we do not get the full semantical picture unless we uncover that deeper layer.

In point of fact only a portion $\mathscr{M}_0$ of a mathematical model is usually assigned a factual interpretation. For example, not every vector decomposition, or series expansion, or integral representation, nor even every solution of a differential equation is always assigned a factual counterpart. A part of the mathematical formalism of a factual theory is usually either idle or plays a purely syntactical role. (For example, in Theory 3 of Sec. 3.2 the unit of the ring is assigned no special interpretation.) Consequently ϕ is normally a *partial* function from $\mathscr{M}$ to $\mathscr{F}$. Equivalently: ϕ is a total function on a *sub*set $\mathscr{M}_0$ of $\mathscr{M}$. We indicate this by writing

$$[\mathscr{M}]\overset{\phi}{\mapsto}\mathscr{F} \tag{3}$$

and drawing Figure 6.4.

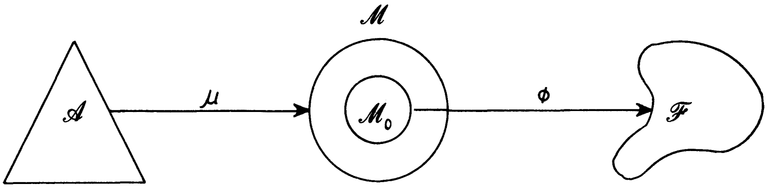


Fig. 6.4. Normally a factual interpretation ϕ maps only a part $\mathscr{M}_0$ of a model $\mathscr{M}$ of an abstract structure $\mathscr{A}$ into a factual domain $\mathscr{F}$.

In the case of the switching circuits theory discussed in Sec. 3.2 the interpretation map ϕ was one to one and consequently ϕ^{-1} had an inverse. That is, two constructs were the same (different) just in case their factual images were identical (different). We warned already that this is the exception rather than the rule: usually ϕ does not discern among equivalent systems. Actually this is so even in the case of the theory of switching circuits, which does not distinguish among circuits constructed with different materials and having different sizes as long as they are topologically equivalent. That is, ϕ is really a mapping of $\mathscr{M}_0 \subset \mathscr{M}$ into a *family of equivalence classes of concrete systems.* In other words, the range of ϕ is not a factual domain $\mathscr{F}$ but the quotient of $\mathscr{F}$ by an equivalence relation $\sim$, i.e. $\mathscr{F}/\sim$. This equivalence relation is defined in a tacit fashion by the very theory T in question, namely thus: Two factual items are *equivalent with respect to* T iff T does not discern between them, i.e. iff it represents them by the same constructs. In brief, instead of (3) we usually have

$$\phi : [\mathscr{M}] \to \mathscr{F}/\sim, \tag{4}$$

where $\mathscr{M}$ is a collection of mathematical models and $\mathscr{F}$ a set of factual domains.

In sum, we distinguish four different factual interpretation maps ϕ:

Abstract theory → Factual systems (1)
Theory of a model → Factual systems (2)
Part of a theory of a model → Factual systems (3)
Part of a theory of a model → Equivalence classes of factual systems. (4)

In either case we adopt the following

DEFINITION 6.4 If $\mathscr{M}$ is a mathematical model and ϕ a factual interpretation map, then the structure $\mathscr{M}_\phi = \langle \mathscr{M}, \phi \rangle$ is called a *factual model.*

DEFINITION 6.5 If $\mathscr{M}_\phi$ is a factual model, then a theory $T(\mathscr{M}_\phi)$ of such a model is called a *factual theory.*

The preceding elucidations suffice to settle certain much debated questions such as whether gravitation theory is reducible to geometry, as is often held with reference to Einstein's general relativity. If the semantic assumptions of the theory are not stated explicitly, then of course one has, strictly speaking, only a mathematical formalism not a factual theory. However, the context makes it usually clear what things (material systems and fields) the theory is about and which of the properties (e.g. gravitational interaction) it represents. That is, the formalism is treated as a full fledged factual theory. Moreover, and this is a strictly syntactic point, if gravitation theory were just a geometrical theory, then it would contain no formulas other than those of Riemannian geometry – but in fact it adds to the latter its own field equations and equations of motion.

3.4. *Factual Interpretation: Full and Partial*

We saw in the preceding subsection that the mathematical formalism of a theory is likely to contain components without representatives in the real world. For example, not every Fourier analysis will represent the spectral decomposition of a wave packet. Conversely, not every trait of a factual system is likely to be represented by any theory of it. Thus half of the wave-like solutions to Maxwell's field equations are usually discarded because they would have to be interpreted as representing waves coming from the future. (They are often called 'unphysical' or 'physically meaningless' solutions.) On the other hand the same equations fail to account for the photon structure of a light beam. Briefly: the theory has redundant constructs and also leaves some factual items dangling in the midst of reality. This is quite general: we may assume that no $\mathscr{M}$ is isomorphic with $\phi(\mathscr{M})=\mathscr{F}$ except perhaps in some limited respects. Usually $\mathscr{M}$ contains elements with no images in $\mathscr{F}$ and, conversely, $\mathscr{F}$ has elements not accounted for by $\mathscr{M}$. See Fig. 6.5.

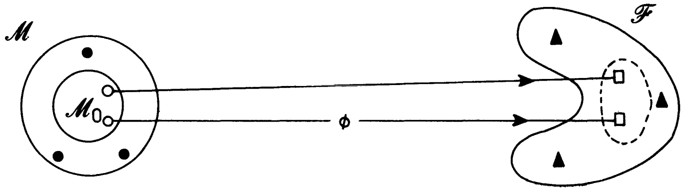

Fig. 6.5. Black dots = redundant constructs. Black triangles = orphan entities.

From a semantic point of view the best scientific theory referring to a given factual field is the one with the fewest black spots and leaving the fewest black triangles. This holds for the formulas (e.g., equations) and their constituents (e.g., parameters in the equations). Rich theories are likely to contain idle formulas but on the other hand are bound to contain few if any uninterpreted parameters, while shallow theories abound in such parameters. (A *fundamental theory* is often defined as containing no constants other than universal constants.) While a redundant formula can be isolated and immobilized, the factually uninterpreted parameters cannot be disposed of short of replacing the theory. Such parameters are of the essence of phenomenological (or black box) theories as well as of the hypotheses that cover the available data and little else. Since those parameters can be varied almost *ad libitum* to conform to the data, the corresponding theory is a docile data recipient with only a weak explanatory power (Bunge, 1963b, 1964, 1967a). The more detailed a "picture" of reality a theory supplies, the more heavily interpreted it is: the less specific, the less semantically committed.

The degree of semantical commitment of a scientific theory can be quantified with the help of the Definition 1, in Sec. 2.2, of abstraction degree. We presently adapt it to a factually interpreted model and a factually interpreted theory as characterized by Definitions 4 and 5 in Sec. 3.3:

DEFINITION 6.6 Let $\mathcal{M}=\langle M_1, M_2,..., M_n\rangle$ be a mathematical model of some abstract structure and let ϕ be a factual interpretation of $\mathcal{M}$. If $m \leqslant n$ of the interpreted concepts $\phi(M_i)$ for $1 \leqslant i \leqslant n$ differ from the corresponding mathematical primitives M_i, then the factual model $\mathcal{M}_\phi = \langle \mathcal{M}, \phi\rangle$ and any theory $T(\mathcal{M}_\phi)$ of it are said to possess *a degree of interpretation* $\beta = m/n$.

DEFINITION 6.7. Let $\mathcal{M}_\phi = \langle \mathcal{M}, \phi\rangle$ be a factual model and $T(\mathcal{M}_\phi)$ be a theory of $\mathcal{M}_\phi$. Then

(i) $\mathcal{M}_\phi$ and $T(\mathcal{M}_\phi)$ are said to be *fully interpreted* in factual terms iff $\beta = 1$.

(ii) $\mathcal{M}_\phi$ and $T(\mathcal{M}_\phi)$ are said to be *partially interpreted* in factual terms iff $0 < \beta < 1$.

Example 1 Probability theory is based on two primitives: the sample space S and the probability measure P. If neither is assigned a factual interpretation, $\beta = 0$ and the theory remains in pure mathematics. If the elements of S are interpreted as states of a system or as events of some kind, e.g. learning a certain task, then $\beta = \frac{1}{2}$. Most stochastic learning theories are of this kind, i.e. semantically half committed. Finally, if also P is interpreted, then $\beta = 1$. For example, if $s \in S$ is assigned an event of a certain kind, then $P(s)$, which is some number in the real number interval [0, 1], might be interpreted as the tendency or disposition for that event s to occur. This would complete the interpretation of the stochastic theory concerned – without of course ensuring its truth. (On the other hand identifying $P(s)$ with the relative frequency of s would not count as an interpretation of probability but as an estimate of probability values.)

Example 2 Let $\mathcal{M} = \langle S, F, G, k\rangle$ where S is a set, F and G real valued functions on S, and k a positive real. So far this is a specific structure or model. Now introduce an interpretation map ϕ such that

$$\phi(S) = \text{set of bodies}, \ \phi(F) = \text{mass}, \ \phi(G) = \text{volume}, \ \phi(k) = k.$$

We get a factual model $\langle \mathcal{M}, \phi \rangle$ with degree of interpretation $\beta = \frac{3}{4}$. And if a different map ϕ' is chosen, one that assigns to every coordinate in $\mathcal{M}$ a factual item, then β jumps to 1.

3.5. *Generic Partially Interpreted Theories*

A *generic factual theory* is one concerned with a genus rather than a species of factual items – e.g., with bodies, or organisms, or societies. When adjoined specific assumptions it can become a specific theory prepared to deal with certain traits of some species of systems – say fluids, or flat worms, or industrial societies. In short, the reference class of a generic theory in factual science is some genus or other – not necessarily a natural genus. And what it represents are some pervasive features of its referents.

There are two kinds of factual generic theory: fully interpreted and partially interpreted in factual terms. The giant classical theories of science, such as classical mechanics and the theory of evolution, are fully interpreted generic theories: they are concerned with whole families of species and all their basic concepts are assigned a factual interpretation. In addition to these theories there are generic factual theories with a low degree of interpretation. This lack of a firm semantical commitment makes them readily portable from one field of research to another. The first outstanding specimen of this kind of theory was Lagrangian dynamics, which started out as a chapter of mechanics, then spread over almost all of physics (cf. Bunge, 1957, 1967b) and has now found its way into the general theory of systems of any kind (White and Tauber, 1969). Newer members of the species are information theory, the mathematical theory of machines, and general network theory. All of these theories are factual in the sense that they refer to real systems though not to any definite species of such. And, far from representing specific properties, they represent only very general features. Consequently they are useful guides in either of the following situations: (*a*) absence of detailed knowledge of the system; (*b*) a detailed knowledge may be available but only certain outstanding features compatible with a number of possible mechanisms are of interest, and (*c*) a unified treatment of a number of research subjects is intended – for instance in order to bring out their common formal traits.

To get a feel of the semantic peculiarities of such generic semi-interpreted theories in factual science, as well as of the methodological problems they raise, we shall take a look at the Rashevsky-Turing theory of morphogenesis (Rosen, 1970, I, Ch. VII). This theory states, in a nutshell, that any initially homogeneous or amorphous system that reaches an unstable state may evolve towards a final state of inhomogeneity (e.g., polarity) under the action of slight external perturbations. The state variables of this theory are left factually uninterpreted. Only the independent variable is interpreted, namely as time. Moreover, the theory is kinetic rather than dynamic, in the sense that it assumes no specific forces or interactions responsible for the process: any force will do as long as it is compatible with the equations of change of state. In sum, the Rashevsky-Turing theory of morphogenesis is a morphological theory: a theory of the genesis of differentiation or form in nearly any complex system. It is richer than a black box theory in that it accounts for certain changes in the interior of the box, but is equally noncommittal regarding the nature of the components and their interactions.

A Rashevsky-Turing system is defined as any system satisfying the assumptions of the theory, whatever its actual physics and chemistry may be. In other words, the Rashevsky-Turing theory has a number of possible interpretations. It is not just that it concerns a whole class of systems – every general theory does. It concerns a family of classes, i.e. a genus. As soon as the state variables of the theory are specified, i.e. as soon as they are assumed to represent definite properties, interactions, etc., one species in the genus is singled out for reference. In short, upon interpreting the state variables of the theory, the family of species is restricted to a single species of morphogenetic systems.

This semantic difference between a partially interpreted and a fully interpreted theory is of importance for methodology. Since a generic morphogenesis theory specifies neither the substratum nor the forces acting in it, no definite predictions can be computed with the formulas of the theory. Hence such a theory is untestable in the usual way. Partially interpreted theories call for a revision of the conventional methodology of science. In fact such theories are tested vicariously, namely by testing some of the specific theories obtained upon specifying (interpreting) the state variables as definite properties of a system of a definite kind (Bunge, 1973a, Ch. 2).

3.6. *Principles of Factual Interpretation*

Any given mathematical construct may be assigned a number of different factual interpretations. Therefore there is often uncertainty, and occasionally spirited controversy, as to which interpretation is the best. Consequently it is desirable to have a battery of explicitly formulated criteria for an admissible factual interpretation – if not to facilitate the interpretation task at least to ease rational argument about it. We propose the following conditions that a sound interpretation of a mathematical construct in factual terms should satisfy: the interpretation should concern a reasonably safe mathematical construct; it should not originate inconsistencies; it should be strict, i.e. adjusted to the mathematical formalism; it should be literal not figurative; it should be factual rather than empirical; it should be full not partial; and it should aim at the truth. Let us spell out these conditions.

(i) *Factual interpretations should bear on mathematically sound formalisms.* If the mathematical skeleton is ambiguous or inconsistent, no amount of cunning interpretation will turn it into a reasonable factual theory. This seems self-evident, yet some highly refined scientific theories, such a quantum electrodynamics, fail to satisfy the condition: they contain ambiguous expressions (e.g., integrals whose value depend on the mode of computation) and inconsistencies (e.g., the electric charge, assumed to be finite when occurring in an equation of motion, turns out to be infinite in derived formulas). Hence the interpretation of such theories must be regarded as insecure. And instead of trying to save the sick formalism by a semantic *tour de force* one should try alternative formalisms. But before anyone attempts to bell this cat the dogma that quantum electrodynamics is perfect will have to be shaken.

(ii) *Factual interpretations should introduce no inconsistencies.* There is danger of inconsistency whenever a construct is assigned different factual correlates – i.e. if the theory contains more than one interpretation map. However, this is sometimes necessary and need not lead to any inconsistencies. For example, a neuropsychological theory may contain variables that are assigned both a neurological and a psychological interpretation. Thus in Grossberg's theory of learning networks every vertex function is interpreted both as a stimulus trace and as an average membrane potential (Grossberg, 1969). These happen to be mutually compatible interpretations of one and the same mathematical construct. On the other hand the standard formulations of quantum mechanics contain multiple interpretations that do lead to contradiction – as when the 'Δx' occurring in Heisenberg's inequalities is interpreted as both the average scatter of the *particle* position and the width of the *wave* packet, and perhaps also as the physicist's *uncertainty* concerning the exact particle position. (See Bunge, 1973b.)

(iii) *Factual interpretations should be strict not adventitious.* A factual interpretation should match the structure of the construct concerned: it should pour no more content than the construct can possibly hold. For example, if a hamiltonian contains only variables referring to a given system (e.g., a molecule) then it should not be taxed with representing both the system and an unspecified measuring device – let alone the experimenter's mind. In general, the value of a function should not be interpreted as concerning more referents than arguments. If it be assumed that a formula α concerns a certain fact f, then α should contain at least one variable x such that $\phi(x)=f$. Otherwise it must be concluded that the interpretation is adventitious: that it has no mathematical leg to stand on (Bunge, 1969).

(iv) *Factual interpretation should be literal not metaphorical.* In mathematics the concept of analogy can be elucidated in an exact way, namely as homomorphism, and can thus be kept under control. Outside mathematics analogy wears too many faces, all of them blurred and tinged by subjectivity: one man's similarity is another's dissimilarity. Metaphor can be a pragmatic asset: it may have heuristic value and may also be of some use in teaching but it can be terribly misleading precisely for being highly subjective. For this reason it does not belong in scientific theory – *pace* a rather fashionable view (Black, 1962; Hesse, 1965). The aim of a new scientific theory is not to win neophobic followers but to account for things with characteristics of their own – which traits the metaphor is bound to hide, as the gist of metaphor is to pass the new for old. A scientific theory must involve literal interpretations only – no *as ifs*. This need was first realized at the turn of the century when

Maxwell's electromagnetic theory was freed from any mechanical associations, and is now acutely felt in relation with quantum mechanics. Indeed the classical analogies of position and momentum, and particle and wave, though probably inevitable in the early stages, have introduced inconsistencies and have blocked the understanding of the theory as an original creation referring to *sui generis* things (Bunge, 1967c). In short: analogy belongs in the scaffolding not in the building. (Metaphor is dead but it won't lie down.)

(v) *Scientific theories should be interpreted by reference to facts not test procedures.* For example, acidity is indicated by, but not interpretable as, a color change in litmus paper; and physiological stress is not interpretable as organ enlargement as revealed by autopsy. If on the other hand an analysis of observation (or of measurement) is held to be the key to the factual interpretation of a theory, then (*a*) meaning is being mistaken for testability and (*b*) the scope of the theory is restricted to situations under experimental control. Which is what happens with the standard or Copenhagen interpretation of quantum mechanics. The result is not only confusion but also inconsistency, as exemplified by Bohr's thesis that the theory, though nonclassical, is based on classical physics (i.e., presupposes the latter) just because the end results of measurements are describable in classical terms. If operationism is given up then the quantum theories can be interpreted in their own revolutionary terms – as demanded, albeit timidly, by Wheeler (1957) and Everett (1957) – as well as in strictly objective terms (Bunge, 1967b).

(vi) *Factual interpretations should be global not spotty.* Not isolated formulas but whole formalisms should be assigned a factual interpretation if the risks of inconsistency and irrelevance are to be avoided. Taken in isolation any formula can be interpreted in a number of ways: taken together with other formulas of the same conceptual system, the number of interpretations is decreased because the number of conditions to be satisfied is increased. For example, Shannon's formula for the quantity of information (cf. Ch. 4, Sec. 3.2) looks like Boltzmann's formula for the entropy and is therefore often interpreted as the entropy of the system. However, this metaphoric interpretation is quite arbitrary, as the information theoretic "entropy" is not related to any thermodynamic function such as energy, temperature, pressure, or volume. Consequently it is not entitled to be called 'entropy' – nor is entropy entitled to pass for quantity of information. Just as mathematical interpretation is constrained by the requirement that it yield formulas satisfiable in some model, so factual interpretation should produce formulas reasonably true to fact – in particular it should ensue in statements representing laws. In other words, factual interpretation is not a matter of convention nor even one of mathematical validity: it depends upon the actual structure of the world. Which borders on the next condition.

(vii) *Factual interpretation should maximize truth.* The semantic assumptions of a scientific theory should contribute to producing a maximally true theory. As with the previous conditions, this one is easier legislated than lived up to. Since factual truth depends on both the mathematical formalism and the semantic assumptions, the goal of maximal truth can only be attained by a mutual adjustment of these two components. The test of correctness of semantic assumptions is of course the truth of the theory as a whole. But we can never check the entire theory and we should not expect it to be completely true. Hence even a strong confirmation of the theory provides no final assurance that the semantic assumptions are right. And if the tests are unfavorable then we may blame either the formalism or the semantic assumptions and attempt to reform either. Whatever the outcome of the tests we cannot be sure about the adequacy of the interpretation. We must take risks and be prepared to lose. In sum, interpretation is just as tentative as formalism – and both are prior to tests. By the same token interpretations can be changed in the interest of truth. If a theory fails to pass some tests for truth it need not be rejected *in toto*: some of it may be salvaged by partially modifying its formalism or its interpretation or both. In any case interpretation is prior to truth valuation and should maximize truth value.

This last condition leads us to the next point – the confusion between interpreting and stipulating truth conditions.

3.7. *Factual Interpretation and Truth*

Interpretation maps constructs either into further constructs (the case of μ) or into facts (the case of ϕ). In either case interpretation is prior to truth valuation: the latter depends upon the former. Thus consider the abstract formula $\ulcorner$For every x and z there is at least one y such that $x \circ y = z\urcorner$. Unless we interpret the individual variables and the operation we cannot even ask whether the formula holds. A formula in abstract mathematics holds or fails to hold *under some interpretation* (or in some model) or other. Of course we are chiefly interested in interpretations conducive to truth, so that an interpretation that fails to satisfy this condition will be given up. Likewise in factual science interpretation comes before truth valuation even though an unfavorable outcome of the latter may force us to reinterpret the given mathematical formalism. In sum, both in mathematics and in factual science *only interpreted formulas can be tested for truth*, and only such tests allow us to assign truth values. In a nutshell, the process looks like this:

Formulation → *Interpretation* → *Testing* → *Truth valuation.*

The same can be seen from another angle: interpretation and truth valuation are utterly different functions. Let us confine ourselves to factual interpretation ϕ and to the assignment $\mathcal{V}$ of degrees of truth of fact. (But similar considerations hold for mathematical interpretation and assignment of formal truth.) For one thing ϕ applies not only to full formulas but also to their nonlogical constituents, whereas $\mathcal{V}$ is a (partial) function on statements. For another, whereas the range of ϕ is a factual domain, the range of $\mathcal{V}$ is a set of truth values, e.g., 0 and 1. Consequently *to give the semantics of a scientific theory does not involve giving truth conditions*, let alone truth values: it only requires *specifying the interpretation map* ϕ.

However, according to a widespread view interpreting involves or even consists in giving truth conditions, perhaps even truth values. Thus Carnap: "By a *semantical system* (or interpreted system) we understand a system of rules, formulated in a metalanguage and referring to an object language, of such a kind that the rules determine a *truth-condition* for every sentence of the object language, i.e. a sufficient and necessary condition for its truth. In this way the sentences are *interpreted* by the rules, i.e. made understandable, because to understand a sentence, to know what is asserted by it, is the same as to know under what conditions it would be true. To formulate it in still another way: the rules determine the *meaning* or *sense* of the sentence" (Carnap, 1942, p. 23; see also p. 203). And, a quarter century later, Davidson (1967, p. 310): "to give truth conditions is a way of giving the meaning of a sentence".

This influential view is a version of the verification doctrine of meaning suggested by Frege and proposed by the operationists, Wittgenstein, and the Vienna Circle. It is so confusing that the reasons for rejecting it bear some hammering. First, although the doctrine looks plausible for the propositional calculus, where the sense of the connectives may be said to be given by their truth tables, the view fails for predicate logic. Here both the individual variables and the predicate variables have to be interpreted in a manner that is independent of truth, as shown in any standard logic textbook (e.g. Mendelson, 1963, pp. 49ff.; Shoenfield, 1967, pp. 61ff.; Suppes, 1957, pp. 64ff.). Second, before we set out to find out the truth value of a formula we must know what it "says" about what: fancy placing truth conditions on an uninterpreted formula. Third, truth depends upon interpretation, not the other way around. Thus $\ulcorner(\exists x)\, Gx\urcorner$ is true for $\phi(G)=$ Gipsy, and false for (or "under") $\phi(G)=$ Ghost. Fourth, except for idealist philosophers the assignment of degrees of factual truth is not a matter of semantics but of observation and scientific inference. Semantics cannot even devise truth conditions for scientific hypotheses and theories: this is a matter for methodology. Thus consider a theoretical statement of the form

$$t=\ulcorner P(s,u)=n\urcorner$$

evaluated in the light of a piece of empirical evidence in the form

$$e=\ulcorner\text{Average of measured values of } P(s,u)=n'\pm\varepsilon\urcorner,$$

where P is some property of a system s, n is the calculated value and n' the measured value (both in units u), while ε is the experimental error. Then a "truth condition" for t that is universally agreed on (without the assistance of the available semantical theories) is this:

$$t \textit{ is true relative to } e\textit{, to within } \varepsilon\textit{, iff } |n-n'|\leqslant\varepsilon.$$

The actual value of the experimental error ε will depend on the state of the experimental art: it is no business of semantics. (For the empirical assessment of truth values see Bunge, 1963a, pp. 127ff; and Bunge, 1967a, II, pp. 301ff.)

In short, interpretation and truth are related but not the way operationist semantics has it. Truth depends upon interpretation, which in turn should be subject to revision in the light of the tests for truth. A formula will hold or fail to hold (exactly or approximately), under a given interpretation, whereas alternative interpretations may render the formula meaningless or utterly false. This holds for mathematics as well as for science. So much for one of the worst muddles in the history of philosophy.

3.8. *Interpretation and Exactification*

Factual constructs come with different degrees of exactness and clarity. The most exact and clear of all are those belonging to a theory, i.e., the theoretical factual constructs. According to Def. 3 (Sec. 3.2) a construct c of this kind is a mathematical construct m together with a factual interpretation ϕ, i.e., $c = \langle m, \phi \rangle$. Consequently to *exactify* a factual construct consists in either revealing or assigning its formal component m. And to *elucidate* a factual construct consists in either revealing or assigning its semantic component ϕ. If we disclose the form or the content of a construct we engage in analysis; if we assign either of them we build or reconstruct a fragment of one of the theories housing the construct of interest.

In principle every *bona fide* scientific construct can be both exactified and elucidated, namely by either incorporating or expanding it into a theory or, if it belongs already to some theory, by analyzing or reconstructing the latter. Even initially obscure concepts can be exactified and elucidated. A good example is the one of disposition, tendency, propensity, or bent, which pervades both factual science and metaphysics. This intuitive notion can be analyzed into two distinct concepts: those of *causal propensity* and *chance propensity* (cf. Bunge, 1974b). An instance of the former is solubility: dissolution is an outcome of the mixing of the soluble substance with a proper solvent under suitable circumstances. Whenever these conditions are met dissolution occurs. Not so chance propensity, as exemplified by the emission of light by an atom or the learning of an item by an animal: even if the necessary conditions are met, the event occurs only with a certain probability – i.e., there seem to be no conditions both necessary and sufficient for the event to happen. Let us focus on this second concept of tendency, which is by far the more baffling and probably the most fundamental of the two.

The intuitive or pretheoretical concept of chance propensity is exactified by means of the mathematical concept of probability. And any specific concept of chance propensity is elucidated by incorporating it into a factual theory; for example, every concept of learning disposition or ability is elucidated by the corresponding stochastic learning theory. Exactification, though essential, is not sufficient to turn a specific concept of chance propensity into a semantically precise concept, because the mathematical theory of probability is not committed to any particular factual interpretation. We must specify also the interpretations of the arguments and values of the probability function. (Recall Example 1 in Sec. 3.4.) This may be done in the following way. Let the pretheoretical idea be that of the tendency or ability of a system σ of kind Σ to make a transition from an initial state A to a final state B. (For example, Σ could be a strain of albino rats, A the state of ignorance concerning the proper way to run a T maze, and B some stage in the learning process.) The explicans of that relatively obscure notion of ability is the ordered pair $\langle Pr(B \mid A), \phi \rangle$, where $Pr(B \mid A)$ is the conditional probability of B given A, and ϕ the interpretation map defined by the following value assignments:

$$\phi(\sigma) = \text{System of kind } \Sigma \tag{1}$$

$$\phi(A) = \text{Initial state of } \sigma \tag{2}$$

$$\phi(B) = \text{Final state of } \sigma \tag{3}$$

$$\phi(Pr(B \mid A)) = \text{Strength of the propensity for } \sigma \text{ to jump from } A \text{ to } B. \tag{4}$$

In other words, the coarse or presystematic idea of the tendency for σ to go from A to B is given a refined (exact and lucid) expression by the theoretical factual construct $\langle Pr(B \mid A), \phi \rangle$, which belongs to some theory concerning certain traits of the systems of kind Σ – a theory whose mathematical formalism includes some fragment of the mathematical theory of probability. While the latter is in charge of the *exactification* of the concept of chance propensity, the interpretation assumptions (1) to (4) provide an *elucidation* (or semantic clarification) of it. Let us insist that the interpretation assumptions are not part of the exactification procedure but external to it. If we were to regard them as belonging to the exactification process we would fall into a circle: we would be explaining propensity as propensity.

The preceding considerations solve one of the problems posed by the so-called propensity interpretation of probability championed by Popper (1959). The problem is to answer the charge that nothing is gained and much is lost by interpreting the clear concept of probability in terms of the obscure concept of propensity. Our answer is this: There is nothing wrong with adopting at the same time the propensity *interpretation* of probability, i.e.,

$$\phi(\text{Probability}) = \text{Propensity},$$

and the probability *exactification* of propensity, i.e.,

$$\varepsilon(\text{Propensity}) = \text{Probability},$$

as long as the two are not mixed up. Whereas interpretation assigns a factual content to a definite mathematical construct, exactification transforms an inexact construct into a definite mathematical object. Shorter: whereas exactification bears on presystematic concepts, interpretation enriches exact concepts.

Moreover just as the probability exactification of chance propensity is consistent with the propensity interpretation of probability, both are compatible with the *frequency estimate* (evaluation) of probability values. For example, in game theory the probability that a player chooses a given strategy may be interpreted as his propensity to adopt such a choice (cf. Rapoport, 1966); and this value can be estimated by observing the actual frequency of such an event. What is not possible is to give a *frequency interpretation* of probability. For one thing, probability and frequency are different functions: the latter is defined, for every sampling procedure, on a finite subset of the whole probability space; and the range of the frequency function is not the whole real interval [0, 1] but the collection of fractions in it. (Cf. Bunge, 1969.) Consequently if probabilities were *interpreted* as frequencies, the typical theorems of the calculus of probability, such as the laws of large numbers, could not even be stated, as they concern precisely *differences* between probabilities and frequencies. (For further criticisms of the frequency theories of probability see Fréchet (1939) and Suppes (1967, Ch. 3.)) Interpretation is a strictly conceptual operation not to be confused with numerical estimation, in particular measurement. Such a confusion amounts to mistaking semantics for pragmatics – something that deserves a separate section.

4. PRAGMATIC ASPECTS

4.1. *Pragmatic Interpretation*

School teachers find it effective to clarify mathematical and scientific ideas with reference to human operations. Thus $\ulcorner 3+2=5 \urcorner$ can be made clear and plausible by fingering, and Archimedes' law of the lever can be literally felt when riding a see-saw. These are examples of *pragmatic interpretation* or interpretation in terms of human actions. In Sec. 2 we mentioned some pragmatic interpretations of the propositional calculus. Table 6.4 exhibits pragmatic interpretations of a few typical formulas of the predicate calculus. The pattern is this: every construct in a set C is assigned one item in a set H of human actions. In short, $\pi: C \rightarrow H$. In other words, π is a rule or instruction for handling a construct with a definite means and a definite goal.

TABLE 6.4

Examples of pragmatic interpretation of typical formulas

Construct	Semantic interpretation	Pragmatic interpretation
Pa	The individual a has the property P.	Someone has proved or observed that a is a P.
$(\exists x)_U Px$	There is at least one object in U with the property P.	At least one object in the observed collection $T \subseteq U$ has been found or may be found to be a P.
$(x)_U Px$	All objects in U have the property P.	Every object in the observed collection $T \subseteq U$ has been found or may be found to be a P.
$A \vdash B$	A entails B.	B is provable from A.
$f(x)=y$	The f-ness of x equals y.	The result of determining (computing or measuring) f at x is (nearly) y.
$P_n(x)=0$	The nth degree polynomial P_n in x equals 0.	Find the values of x that annul the nth degree polynomial P_n in x.

There can be no quarrel with pragmatic interpretations when employed as didactic crutches – particularly if being reassured that the crutches will be dropped in due time. Nor should it be objected to translating formulas into instructions or commands for purposes of computer processing, lab checking, or action – particularly if the formulas are allowed to retain a content of their own independent of the way they are used or tested. What is inconvenient is to have to walk on crutches all life long; even worse, to be under the delusion of being a computer or of being chained to some measuring device. In other words, what is objectionable is to mistake a construct for a pragmatic interpretation of it. It is even worse to dignify this confusion with the name of a philosophy – say operationism, operative logic, or mathematical intuitionism. In short, while pragmatic interpretations are occasionally valid and useful (though always restricted to a minute subset of the collection of constructs), pragmatist semantics is untenable.

Most pragmatic interpretations are *adventitious* in the sense of Sec. 3.6. Indeed, in most cases they do not match the structure of the formula they bear on, as they refer to individuals (e.g., observers) and actions (e.g., measurements) not represented in the formula by any variables. For example, the orthodox interpretation of an eigenvalue α_k of a quantum-mechanical operator A_{op} reads: "α_k is a possible result of measuring the property represented by A_{op}". This interpretation is adventitious because neither A_{op} nor α_k (nor the corresponding eigenfunction) contain any variables capable of representing the measuring device (which one?) or the experimenter (who?). (Cf. Ch. 3, Sec. 4.3.)

If we were to outlaw all adventitious interpretations, few pragmatic interpretations would remain. As long as we are aware of the narrowness and arbitrariness that adventitious interpretation may land us on, we may afford to adopt a wider concept of interpretation validity. We propose the following conditions for regarding a pragmatic interpretation of a formula as *valid* (Bunge, 1969):

(i) There should exist a scientific theory containing the formula and assigning to it a semantic (mathematical or factual) interpretation. In other words, the formula to be interpreted (*a*) must be available to begin with and (*b*) must have a fairly definite content independent of the many ways it can be manipulated. (Imagine rushing to read a new scientific theory in operational terms before finding out what the sense and the reference of the theory are.)

(ii) Sufficient information, theoretical and empirical, must be at hand to justify as well as to carry out the operations called for or described by the pragmatic interpretation. If the construct on which the interpretation bears happens to represent an unobservable entity or property, as is so often the case with science, then additional hypotheses or theories linking the unobservable to observable items will be needed. (I.e., objectifiers or indicators will be needed, and these will usually rope in further theories.) Otherwise the proposing of a pragmatic interpretation would be a game like casting horoscopes or interpreting dreams. In other words valid pragmatic interpretation, even when adventitious, is a matter of law not convention: there should exist a lawful relation between the referent of the construct and the human action the rule prescribes. In sum, pragmatic interpretation should be grounded.

Pragmatic interpretation occurs in experimental science and in technology. The experimentalist may well read $\ulcorner y=f(x) \urcorner$ as "To infer y measure x" provided f is defined and the semantic interpretation tells him what these symbols stand for. Likewise the engineer may read the same formula as, say, "To get output y apply input x" – as long as the underlying theory supplies him with the sense and reference of the formula and provided experiment encourages him in taking the assumed functional relation as close enough to the truth. Pragmatic interpretations such as these are valid albeit adventitious: they rely on the formula concerned as well as on its semantic interpretation. Similarly with every other pragmatic interpretation: if valid it will rest on a previously assigned semantic interpretation. First get to know, then apply your knowledge.

There is no room for pragmatic interpretation in scientific theories. A theoretical formula refers to some concrete system (cell, society, or what have you) not to the way that very formula is to be tested or applied. Even the sciences of action, such as operations research and political science, regard their referents as objects. Consequently their formulas are first assigned a semantic interpretation, then they may be put to use as rules of procedure. We had to emphasize the dependence of pragmatic interpretation upon semantic interpretation because of the strong human tendency, called *anthropomorphism*, to read everything in terms of human feelings and actions. We must rid semantics of any association with such a tendency if we want it to account for the objectivity of science.

4.2. *The Interpretation Process*

Interpretations do not come out of the blue and, once proposed, they need not stay. Viewed historically, interpretation is a process. In some cases the formalism of a theory and its interpretation evolve hand in hand. In others the embryo is an intuitive idea in search of a formalism: this may have been the case with Newtonian mechanics, Maxwellian electrodynamics, and Einsteinian gravitation theory. Finally the converse process, namely the building of a formalism in search of an interpretation, can also happen: as a matter of fact this seems to have been the case, to a large extent, with quantum mechanics (Dirac, 1942; Heisenberg, 1955). Consequently there are no hard and fast rules for "discovering" the semantic assumptions of a scientific theory: some investigators proceed in one way, others differently. It is up to the psychology of science, not to semantics or even methodology, to discover what makes researchers tick, in particular what makes them guess that a given formula should be interpreted in a certain way.

Moreover no interpretation is likely to be final. Every theory in a process of growth suffers both mathematical and semantical adjustments. Even classical theories are still undergoing changes of both kinds (cf. Truesdell and Toupin, 1960). In particular the new interpretation may be at variance with the original intentions of the first theorist. The psychologist and the historian of science may wish to ask him what interpretation he had in mind but won't be able to discover all the possible unintended interpretations – if only because most of them will never occur to anyone. In any case the concept of intention, that occurs in the usual phrase 'intended interpretation', is a psychological one and therefore beyond the reach of semantics. Whether a particular outcome, semantic or other, was originally intended, is a psychological and historical problem. Therefore it is misleading to define interpretation as an *intended model* of a formalized language (Kemeny, 1956). For the same reason it is unsatisfactory to mention the *intended interpretation* of a formalism without stating it explicitly; and, once so stated, it is no longer intended. The semantic assumptions of a theory, whether they are the originally intended (or standard) ones or not, should be formulated as explicitly as the remaining assumptions if we are to have objectivity and the possibility of rational argument.

The need for arguing about interpretation matters is not always felt. It seems most acute in highly developed fields – but there it is often repressed. Every theoretical biologist knows that it is far easier to interpret the solution to a problem in mathematical biology than it is to formulate the problem. The opposite situation is the rule in physics, where it is far easier to formulate a problem and even to perform the computational tasks it calls for, than to find an adequate interpretation of the solution. Why this difference? In biology there are hardly any comprehensive theories supplying a general framework for the formulation of problems. Except in choice areas such as biophysics and genetics, nearly every problem has got to be treated separately, often leaning more heavily on physics or chemistry than on biology. Usually theories have to be built from scratch, sometimes inaugurating whole new branches of biology in the process. As a compensation the goal is more modest: the variables involved are fewer, they are often better understood and are frequently linked in simpler ways than the variables occurring in theoretical physics and chemistry. We can expect however that, as biology grows in depth, it will pose as many and as hard interpretation problems as physical theories do at present.

Regretfully, rational argument about the semantic assumptions of scientific theories is sometimes discouraged or even hushed up. Even complex theories like quantum mechanics and quantum electrodynamics, ridden as they are with unsettled interpretation problems, are often regarded as unproblematic and all discussion about their semantic assumption as a waste of time (Rosenfeld, 1961). There are several possible motives but not a single reason for adopting such a dogmatic and unhistoric stand. One is the longing for certainty. Another is the belief that foundations problems are settled by popular philosophical discourse rather than by digging out the axiomatic foundations of the theory concerned. A third possible cause is a faulty semantics of science, one holding that all that really counts in a scientific theory is its mathematical formalism. If this were true, then the producing of any new formula or any new set of numbers would be a valuable contribution to scientific knowledge, whereas the proposing of a more cogent interpretation of a theory would be insignificant. This attitude is widespread among scientists who must devote most of their time to solving difficult computation problems, e.g., with the help of perturbation theory. They take the basic equations for granted and consider themselves lucky if once in a blue moon they can find solutions in closed form – which are the ones best suited to interpretation. Since they have little time left to ponder over the interpretation of their very starting points, they have no patience with anyone's telling them that interpretation is always problematic, hence deserving of closer scrutiny. But of course the belief is mistaken. Since a theory in science is a formalism together with an interpretation, a change in the latter produces a new theory. Besides, some interpretations deserve being reformed because they are wrong. Hence disputes over interpretation matters are as important as arguments over mathematical points. What is true, and unfortunate, is that the standards of argumentation over semantical problems are so much lower than the standards of mathematical argument. It behooves the philosopher to upgrade those standards by building a semantical theory competent to deal with live science.

5. CONCLUDING REMARKS

In our view, since meaning is sense together with reference, a meaning assignment is an assignment of both sense and reference. Such an assignment involves an interpretation of the symbols concerned and eventually also an interpretation of the constructs designated by the symbols – as when the letter 'N' is first read as the cardinality of a set, then as the population of a group of organisms. However, we do not regard interpretation as meaning assignment. One reason for not identifying these two concepts is that, while interpretation may bear either on signs (e.g., predicate letters) or on constructs (e.g., functions), we construe meaning as a property of constructs only (see Ch. 7). Another reason is that not every interpretation assigns significance: some interpretations result in nonsignificant expressions. For example, if the predicate letter P in '5 is P' is interpreted as 'painful', a nonsignificant sentence results. Interpretation, though necessary, is insufficient to guarantee significance. Significance derives from meaning, which is in turn a conceptual matter.

Even assuming that we grasp the general concept of meaning we may not know how to go about assigning or finding out specific meanings. Placing the given construct (concept or proposition) in a given context (e.g., a theory) is surely necessary to that end since meaning is contextual, but may not suffice. Thus the axioms of an abstract theory, such as Boolean algebra, determine the (mathematical) sense of the theory but, fortunately, fail to specify any of the possible referents of the theory. In other words, the sets involved in the abstract theories are abstract: they consist of faceless individuals. It is only when adjoining an interpretation that definite individuals are characterized by the theory. And only semantic assumptions of the factual type indicate that such individuals are factual items. The semantic assumptions of a factual theory determine, *inter alia*, the reference class of the theory and thus contribute to sharpening its factual sense. In terms of the symbolism or language of a scientific theory: the axioms of such a theory (all the axioms) determine both the sense and the reference the symbolism points to. Or, as we shall say, they jointly determine the meaning of the factual theory. This, in a nutshell, is the theory of meaning to be developed in the next chapter.

CHAPTER 7

MEANING

We are now in a position to face the chief scandal of semantics. We shall start by distinguishing the significance of a sign from the meaning of the construct it designates. We shall then proceed to formulate and discuss our view that meaning is no more and no less than sense together with reference. If either component changes then a changed meaning, i.e., a different construct ensues. Since our previous investigations have shown us how to disclose sense and spot referents, we shall be in a position to compare meanings. In particular we shall be able to ascertain whether two given constructs have the same meanings so that their respective symbols will be synonymous. Finally we shall discuss some of the difficulties that have hampered the clarification of the meaning concept.

1. BABEL

Although the concept of meaning has been the subject of active inquiry since Socrates, and at the center of analytic philosophy for half a century, it is still far from clear. To be sure there have been heaps of brilliant meaning analyses and plenty of talk about the theory of meaning and the theory of reference, particularly about the virtues such theories ought to exhibit. But in fact no theory proper has been offered that does justice to the two aspects of meaning traditionally discerned, namely sense (or connotation) and reference (or denotation). And none of the existing theories of meaning, not even those proposed by philosophers of science, has been of any help whatever in performing a semantic analysis of a piece of live science or in teaching scientists to speak sensibly about the meaning of their own creations. No wonder many physicists still claim that the meaning (not just the worth) of a theoretical item is determined by observation procedures. No wonder chemists are fond of saying that each triplet of bases means (not just specifies or determines) a particular aminoacid. No wonder geneticists sometimes hold that mutations can produce meaningless sequences – rather than biologically dysfunctional proteins. In sum half a century of talk about meaning has been useless to scientists and has, if anything, increased confusion among philosophers. It has resulted in a Babel.

The views on meaning come in several degrees of formal sophistication but their gist can be conveyed in plain words. The most influential among the contemporary views are displayed schematically in the following list.

1 *Psychologism:* meaning is either thought or intention or understanding.
2 *Pragmatism:* meaning is usage.
3 *Operationism:* meaning is operation (computation or measurement).
4 *Verificationism:* meaning is truth condition.
5 *Epistemic view:* meaning is information.
6 *Nihilist view:* there are no meanings.
7 *Referential view:* meaning is the thing referred to.
8 *Intensional view:* meaning is either intension or content.
9 *Dualist view:* meaning has two dimensions – intension and extension.
10 *Synthetic view:* meaning is composed of sense and reference.

The first six views are characteristically modern. Psychologism is the oldest of them but was not made academically respectable until Brentano expounded it one century ago. It was espoused at one time by Russell (1919b). The second, linguistic pragmatism (and in particular dictionarism), was propounded by the later Wittgenstein. The third, operationism, may be traced back to Peirce and Dingler (1907) and has been in the air natural scientists have been breathing ever since. The fourth, verificationism, may be traced back to Frege and was one of the battle cries of the Vienna Circle. The fifth, informationism, was born in the 1950's. And the sixth, nihilism, is a cry of despair over the failure of all the previous opinions. We have criticized and rejected all six in Chs. 2, 4 and 5.

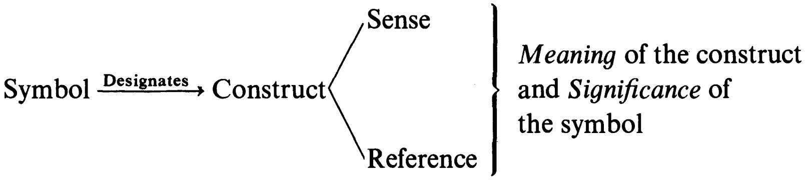
The remaining four views have much longer roots and are far sounder. The referential doctrine goes back to the medieval nominalists, particularly Ockham and Buridan, and their modern heirs, especially Hobbes. The intensionalist doctrine has been a constant component of idealism probably since Plato and was particularly vivid in Leibniz and Bolzano (1837). The dualist doctrine was sketched in the Port-Royal *Logique*

(1662) and was later revived, but also obscured, first by Frege (1891, 1892), then by Lewis (1944, 1951).

(We may as well list the weaknesses of Frege's influential doctrine of meaning in order to forestall any confusion between it and the next or synthetic view. To begin with, the great Frege did not employ a consistent terminology: for example, he often exchanged *Bedeutung* (our "reference") and *Bezeichnung* (designation). He did not distinguish clearly between reference and extension. He often construed *Sinn* (sense) in a psychologistic fashion, namely as the thought expressed by a sentence. He identified the *Bedeutung* of a statement with its truth value and ominously assigned truth conditions the job of determining senses. Finally Frege had no semantic theory to speak of: he never advanced beyond some unsystematic remarks – albeit often illuminating and always provocative. Frege's importance for semantics seems to lie in that (*a*) he stressed a number of distinctions – notably between symbol and construct, concept and extension, and sense and truth, and (*b*) he called the attention of others, notably Russell and Carnap, to semantic problems. For a very different evaluation see Dummett (1973, Ch. 19).)

Finally the tenth view – the synthetic doctrine – seems to have a medieval pedigree too. It was rescued from oblivion and popularized by J. S. Mill: his *System of Logic* (1843) was so influential that his distinction between the connotation and the denotation of a term has been incorporated into common speech. This view appealed to common sense and, since Mill was a champion of positivism, his revindication of connotation or sense, against the grain of nominalist referentialism, was above the suspicion of Platonism. Our own view is but an elaboration of Mill's and of Williams' (1937), which incorporated Mill's without its positivism. We have called it *synthetic* for the following reasons: (i) it applies not only to terms and other linguistic expressions but also (and primarily) to their conceptual designata; (ii) while it distinguishes sense from reference, it combines them into a single idea with a definite mathematical status – namely the sense-reference ordered pair; (iii) far from being a stray view it is an outcome of our theories of sense and of reference expounded in previous chapters. Let us peek at it before going into details.

To begin with we stipulate the kinds of object that can possess meaning. They are certain symbols and all constructs. In order to ward off confusion we shall call these two possibilities by different names: we shall say that (some) *symbols signify* and that (all) *constructs mean.* Furthermore we shall take meaning as primary and shall define it by its two components: sense and reference. And we shall construe signification, a property of certain signs, as the composition of designation and meaning. Graphically:



For example we shall say that the term ‘man’ designates the (or rather *a*) concept of man, the sense of which is given by anthropology, its reference class being the whole bunch of humans. These two constitute also the significance or vicarious meaning of the word ‘man’. On the other hand any sign that fails to designate a construct will be assigned an empty significance. For example a punctuation mark stands for no construct and is therefore devoid of significance. In sum if a sign is significant it is so vicariously, namely via some construct. This construal of ‘meaning’ avoids both nominalism and the variety of hylemorphism consisting in endowing mere marks with semantical properties. And it does not commit us to Platonism, for we do not adopt the ontological hypothesis that constructs have an independent being. Furthermore our view formalizes the opinion of those linguists who hold that a word has two semantic functions: one is to denote, the other is to encapsulate a whole system of generalizations and associations (Luria, 1961).

2. THE SYNTHETIC VIEW

2.1. *Meaning as Sense cum Reference*

In the previous section we agreed to regard meaning as a property of constructs (concepts, propositions, or theories). Now we propose to analyze the meaning of a construct as its sense together with its reference, as depicted in Figure 7.1 and exemplified in Table 7.1.

The stipulation that sense and reference are to be taken as the two components of meaning is literal not metaphorical. Calling $\mathscr{S}(c)$ the sense and $\mathscr{R}(c)$ the reference class of a construct c, our proposal can be symbolized as

$$\mathcal{M}(c) = \langle \mathcal{S}(c), \mathcal{R}(c) \rangle .$$

Now, as we saw in Chapters 4 and 5, $\mathcal{S}$ maps constructs into sets of constructs, i.e. $\mathcal{S}: C \rightarrow \mathcal{P}(C)$. And, according to Chapter 2, $\mathcal{R}$ maps constructs into sets of objects of any kind, i.e. $\mathcal{R}: C \rightarrow \mathcal{P}(\Omega)$, where $\mathcal{P}(\Omega)$ is

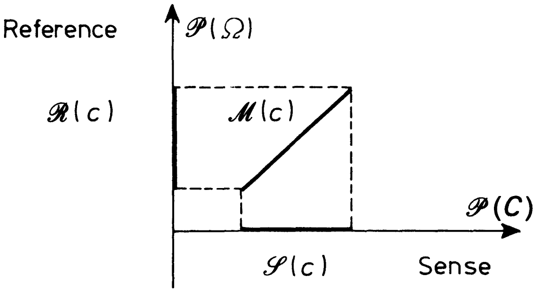


Fig. 7.1. Sense and reference as the components of meaning.

TABLE 7.1

The two components of meaning of the rat race theory in Chap. 6, Sec. 3.2

Construct	Meaning components	
	Sense	Reference
S	Set	Rats
Δ	Joining a rat race	Rats

the set of all subsets of the collection Ω of objects. The pairs $\langle \mathcal{S}(c), \mathcal{R}(c) \rangle$ define uniquely a third function

$$\mathcal{M}: C \rightarrow \mathcal{P}(C) \times \mathcal{P}(\Omega)$$

such that

$$p \circ \mathcal{M} = \mathcal{S} = \text{The first projection } (= \text{component}) \text{ of } \mathcal{M}$$
$$q \circ \mathcal{M} = \mathcal{R} = \text{The second projection } (= \text{component}) \text{ of } \mathcal{M}$$

That is, the two triangles in the following diagram commute:

$$\begin{tikzcd}
& & C \arrow[dll, "\mathscr{S}"'] \arrow[d, "\mathscr{M}"] \arrow[drr, "\mathscr{R}"] & & \\
\mathscr{P}(C) & & \mathscr{P}(C)\times\mathscr{P}(\Omega) \arrow[ll, "p"'] \arrow[rr, "q"] & & \mathscr{P}(\Omega)
\end{tikzcd}$$

In other words, we lay down the following

DEFINITION 7.1 Let Ω be the universe of objects and $C\subset\Omega$ the collection of constructs. Call $\mathscr{S}:C\rightarrow\mathscr{P}(C)$ the (full) sense and $\mathscr{R}:C\rightarrow\mathscr{P}(\Omega)$ the reference functions. Then the bijection $\mathscr{M}:C\rightarrow\mathscr{P}(C)\times\mathscr{P}(\Omega)$, such that $\mathscr{M}(c)=\langle\mathscr{S}(c),\mathscr{R}(c)\rangle$ for c in C, is called the *meaning function*, and its value $\mathscr{M}(c)$ at c is called the *meaning of c*.

Remark 1 Note that the full sense is involved in the preceding – i.e., the union of the purport and the import of the construct concerned (recall Ch. 5, Sec. 5). *Remark 2* This construal of meaning does not depent on the concept of truth, as both sense and reference are prior to any assignment of truth value. Both Lewis' (Lewis, 1944, 1951) and the author's (Bunge, 1967a) previous definitions as the intension-extension pair are unacceptable for this reason. (They are not identical because Lewis construes intensions in a referential fashion.) *Remark 3* On any extensionalist semantics theology is meaningful or meaningless depending on one's religious beliefs. According to our view theological statements can be perfectly meaningful in their own contexts, which determine both their sense and their reference. Belief and disbelief must rest on the assignment of extensions, not of sense or of reference. Thus while for a theist $\mathscr{E}$(Creator)$=\mathscr{R}$(Creator)$=\{$God$\}$, for an atheist $\mathscr{R}$(Creator)$=$ $=\{$God$\}$, but $\mathscr{E}$(Creator)$=\emptyset$. Consequently if anyone wished to argue for or against a particular religion he could not count on our semantics: he would have to resort to alternative means. In particular the disbeliever won't get away with the cheap assertion that theology is nonsense. (But he may succeed in showing that some theologies are contradictory, or that all of them lack positive empirical evidence.) On the other hand the claim that existentialism and Zen Buddhism make hardly any sense stands.

We can now give an exact answer to a question left over from the days of logical positivism, viz., Are tautologies meaningful? In Ch. 2, Sec. 3.3 we saw that a tautological construct refers to anything; if universal, like $\ulcorner(x)\,(Px \vee \neg Px)\urcorner$, it refers to the totality Ω of objects. And in Ch. 5, Sec. 4, we saw that the sense of a tautological construct in a context $\mathbb{C}=\langle S, \mathbb{P}, D\rangle$ with underlying logic L equals $S \cup L$. Consequently if t is any universal tautology in L,

$$\mathscr{M}_{\mathbb{C}}(t)=\langle S \cup L, \Omega\rangle .$$

If the context in question is strictly logical, i.e. if $S=L$, then t "says" whatever L "says", and this about any objects:

$$\mathscr{M}_{L}(t)=\langle L, \Omega\rangle .$$

But of course the extralogical meaning of t in L is $\langle\emptyset, \Omega\rangle$. I.e. within logic the tautologies "say" nothing extralogical about everything. And when associated with some extralogical body of knowledge they "say" everything the latter "says" because they get stuck to every bit of it. Hence logic cannot, by itself, teach us anything about the world even when we make it speak about the world: logic is not ontology. Whatever logic succeeds in teaching us about the world it does so by associating with extralogical contexts. In conclusion tautologies are meaningful even if they do not inform us about the world. (More in Bunge, 1974a.)

Consider now the whole meaning space, i.e. the totality of values of the meaning function $\mathscr{M}$. Take the set $\mathbb{P}$ of all predicates (alternatively propositions) concerning a fixed universe of discourse $D \subset \Omega$. Further, call $\mathscr{M}(\mathbb{P})$ the totality of meanings carried by the constructs in $\mathbb{P}$. The following operations can be defined in $\mathscr{M}(\mathbb{P})$: for any p and q in $\mathbb{P}$,

Meaning addition: $\mathscr{M}(p)+\mathscr{M}(q)=\langle\mathscr{S}(p) \cup \mathscr{S}(q), \mathscr{R}(p) \cup \mathscr{R}(q)\rangle$,

Meaning product: $\mathscr{M}(p) \dot{\times} \mathscr{M}(q)=\langle\mathscr{S}(p) \cap \mathscr{S}(q), \mathscr{R}(p) \cap \mathscr{R}(q)\rangle$,

Meaning complement: $-\mathscr{M}(p)=\langle\overline{\mathscr{S}(p)}, \overline{\mathscr{R}(p)}\rangle$.

Clearly the two binary operations are associative and commutative. Moreover meanings are idempotent: $\mathscr{M}(p)+\mathscr{M}(p)=\mathscr{M}(p)$ and similarly for the product. Also, multiplication distributes on both sides over addition:

$$\mathscr{M}(p) \dot{\times} (\mathscr{M}(q)+\mathscr{M}(r))=(\mathscr{M}(p) \dot{\times} \mathscr{M}(q))+(\mathscr{M}(p) \dot{\times} \mathscr{M}(r))$$
$$(\mathscr{M}(p)+\mathscr{M}(q)) \dot{\times} \mathscr{M}(r)=(\mathscr{M}(p) \dot{\times} \mathscr{M}(r))+(\mathscr{M}(q) \dot{\times} \mathscr{M}(r)).$$

Finally, by combining complement and product we build the null or least element $\square$ of $\mathscr{M}(\mathbb{P})$, whilst combining complement and addition yields the unit or last element ▯:

Null meaning: $\mathscr{M}(p)\dot{\times}(-\mathscr{M}(p))=\langle\mathscr{S}(p)\cap\overline{\mathscr{S}(p)}, \mathscr{R}(p)\cap\overline{\mathscr{R}(p)}\rangle=$
$=\langle\emptyset,\emptyset\rangle=\square.$

Universal meaning: $\mathscr{M}(p)+(-\mathscr{M}(p))=\langle\mathscr{S}(p)\cup\overline{\mathscr{S}(p)}, \mathscr{R}(p)\cup$
$\overline{\mathscr{R}(p)}\rangle=\langle\mathscr{P}(\mathbb{P}),\mathscr{P}(D)\rangle=\text{▯}.$

The set $\mathscr{M}(\mathbb{P})$ is not closed under addition and multiplication because, as we saw in Ch. 5, in general $\mathscr{S}(p)\cup\mathscr{S}(q)$ does not equal the sense of some compound of p and q. Only intensions behave this way. Hence if we restrict sense to intension the preceding considerations prove that the structure $\langle\mathscr{M}(\mathbb{P}), \square, \text{▯}, +, \dot{\times}, -\rangle$ is a ring of idempotents with unit and zero, i.e. a Boolean ring. We shall not pursue this line but shall instead analyze two notions of meaning relation.

DEFINITION 7.2 Let $p, q\in\mathbb{P}$ be either predicates or propositions with definite meanings. Then the meaning of p is *part* of ($\preccurlyeq$) the meaning of q iff the meaning of p does not add anything to that of q:

$$p\preccurlyeq q=_{df}\mathscr{M}(p)+\mathscr{M}(q)=\mathscr{M}(q).$$

DEFINITION 7.3 Let $p, q\in\mathbb{P}$ be either predicates or propositions with definite meanings. Then p and q are *semantically unrelated* ($\urcorner\!\llcorner$) iff the product of their meanings is nil:

$$p\urcorner\!\llcorner q=_{df}\mathscr{M}(p)\dot{\times}\mathscr{M}(q)=\square.$$

COROLLARY 7.1 Let $p, q\in\mathbb{P}$. Then

(i) If $p\preccurlyeq q$ then $\mathscr{S}(p)\subseteq\mathscr{S}(q)$ and $\mathscr{R}(p)\subseteq\mathscr{R}(q)$.

(ii) If $p\urcorner\!\llcorner q$ then $\mathscr{S}(p)\cap\mathscr{S}(q)=\emptyset$ and $\mathscr{R}(p)\cap\mathscr{R}(q)=\emptyset$.

Finally consider the whole lot $\mathscr{T}$ of theories with a common meaning core – e.g. the theories in mathematical linguistics. Because of the shared meaning the following sets will be nonempty for any two members T_i, T_k of $\mathscr{T}$:

$$T_i\sqcap T_k=\{s \mid T_i\vdash s \quad\text{and}\quad T_k\vdash s\}$$
$$T_i\sqcup T_k=\{s \mid T_i\vdash s \quad\text{or}\quad T_k\vdash s\}$$

(In the notation of Tarski (1956) the first set is $T_i\cdot T_k$, the second T_i+T_k.)

The former is the infimum (*glb*) and the latter the supremum (*lub*) of $\{T_i, T_k\}$. Hence we have proved

THEOREM 7.1 The structure $\mathscr{L} = \langle \mathscr{T}, \sqcap, \sqcup \rangle$, where $\mathscr{T}$ is the set of theories with a common core, is a lattice.

Let us now move on to matters of significance.

2.2. *Significance*

Let us begin by restricting our considerations to expressions belonging to a conceptual language $\mathscr{L}$ free from ambiguity. In this case the relation $\mathscr{D}$ of designation may be construed as a function from expressions Σ^{**} of $\mathscr{L}$ into constructs (see Ch. 1, Sec. 3.2). We stipulate that significance is a property that signs acquire when they happen to designate constructs – which is the case of numerals but not of musical notes. A sign of this kind signifies its significance, which is in turn the meaning of the construct it symbolizes. Briefly, signification (the function taking significances as values) is the composition of designation and meaning. In symbols: $\mathscr{S}ig = \mathscr{M} \circ \mathscr{D}$. More explicitly,

$$\begin{tikzcd}
\Sigma^{**} \arrow[rr, "\mathscr{S}ig"] \arrow[dr, "\mathscr{D}"'] & & \mathscr{P}(C) \times \mathscr{P}(\Omega) \\
& C \arrow[ur] &
\end{tikzcd}$$

In other words, we are proposing

DEFINITION 7.4 Let Σ^{**} be the set of expressions of a conceptual language $\mathscr{L}$, $\mathscr{D}: \Sigma^{**} \to C$ the designation function, and $\mathscr{M}: C \to \mathscr{P}(C) \times \mathscr{P}(\Omega)$ the meaning function. Then the composition $\mathscr{M} \circ \mathscr{D} = \mathscr{S}ig$ is called the *signification function* of $\mathscr{L}$ and its value $\mathscr{S}ig\,(s, \mathscr{L})$ for any s in $\mathscr{L}$ is called the *significance* of s in $\mathscr{L}$.

COROLLARY 7.2 The significance of a sign belonging to a conceptual language equals the meaning of the construct designated by the sign, i.e.

If $\mathcal{D}sc$ in $\mathcal{L}$, and $\mathcal{M}(c)=\langle\mathcal{S}(c), \mathcal{R}(c)\rangle$, then $\mathcal{S}ig(s, \mathcal{L})=\langle\mathcal{S}(c), \mathcal{R}(c)\rangle$.
Proof By Definitions 1 and 4.

The first component or projection $\mathcal{S}(c)$ of $\mathcal{S}ig(s, \mathcal{L})$ may be called the *vicarious sense* of s, and the second coordinate $\mathcal{R}(c)$ its *vicarious reference*. These names convey the idea that, although signs are physical objects and therefore devoid of conceptual properties, if they proxy for constructs they indirectly acquire a meaning. This vicarious meaning is their significance. All this is expressed succinctly and exactly in the following diagram.

$$\begin{tikzcd}
& \Sigma^{**} \arrow[d, "\mathcal{D}"] \arrow[ddl, "\text{Vicarious sense}"'] \arrow[ddr, "\text{Vicarious reference}"] & \\
& C \arrow[d, "\mathcal{M}"] \arrow[dl, "\mathcal{S}"'] \arrow[dr, "\mathcal{R}"] & \\
\mathcal{P}(C) & \mathcal{P}(C)\times\mathcal{P}(\Omega) \arrow[l] \arrow[r] & \mathcal{P}(\Omega)
\end{tikzcd}$$

Table 7.2 illustrates these concepts.

TABLE 7.2

The dual significance of signs: four examples

Sign	Vicarious sense	Vicarious referents
$\circ$	Concatenation	Unspecified individuals
$+$	Addition	Numbers
V	Velocity	Physical systems
U	Utility	Objects and persons

All the previous considerations hold for a language in which each sign represents just one construct. (The converse need not hold: one and the same construct may be represented by two or more signs.) The language dependence of the signification function is made explicit in the following conventions.

DEFINITION 7.5 A sign s is *significant* in a language $\mathcal{L}$ iff s designates a construct in $\mathcal{L}$.

DEFINITION 7.6 A sign s is *nonsignificant* (or *syncategorematic*) in a language $\mathscr{L}$ iff s designates no construct in $\mathscr{L}$.

An isolated individual variable letter such as 'x' and a stray individual predicate letter such as 'F' are nonsignificant precisely because they are stray, i.e. outside any theory that may assign them definite senses. As Frege (1912) warned, it won't do to say that they have variable meanings or even indeterminate meanings. But if a sign belongs to the symbolism of a definite theory then it signifies even though its vicarious reference be indeterminate – as is the case with an abstract theory. For, in this case, the sense of the symbol is determined by the axioms of the theory in question – and sense is sufficient for meaning.

The last two definitions are relevant to the one-sign-one construct languages. These are unusual: most actual languages are ridden with ambiguities, i.e. they do not possess a designation function but rather a designation relation. For example, in informal mathematical contexts the definite integral sign may designate any of a dozen or so concepts of integral: Cauchy, Riemann, Stieltjes, Lebesgue, Schwartz, etc. The precise significance of any expression involving the integral sign will depend then on the precise interpretation assigned this ambiguous sign. (So much so that some such expressions make no sense whatsoever under certain interpretations of the snake symbol. For example, the Riemann integral of the Dirac delta is as nonsignificant as '1/0'.) In other words in most cases a language, even a mathematical one, will be the result of superposing two or more different languages equipped with one designation function each. When significance questions arise, the expert starts by analyzing the given mixture. And then he may use our previous definitions.

Note finally that a sign designating a construct with nil sense is significant. On the other hand a sign such as 'spinning and inconsistent' is insignificant because "spinning" and "inconsistent", are defined on disjoint domains. (Likewise a zero velocity is a velocity, whereas hopes have no velocity because the velocity function is not defined for them.) By contrast 'round square' is significant because both "round" and "square" are defined on the same domain, i.e. the set of plane figures. This is what makes it possible to disprove the statement that there are figures both round and square. Incidentally, extensionalism cannot cope with this fact.

2.3. *Significance Assignment*

Unlike meaning, significance is *assigned* to its bearers rather than being inherent in them. By itself, i.e. apart from a more or less precise significance assignment, a sign is just a physical object. Hence it is mistaken to ask 'What does x signify?'. One should ask instead 'What significance has x been assigned in the language $\mathscr{L}$?'. Or, in pragmatic terms, 'What are we supposed to think of or do at the sight of x?'. In other words, it is up to us whether and if so what a sign is to signify. Not so with the constructs symbolized: even though we need not conceive of them as Platonic Ideas, they must be regarded as being born with some meaning – for otherwise they are nothing. In other words, whereas symbols are conventional and therefore substitutable, the constructs they symbolize are subject to law – logical, mathematical, or scientific. Consequently the disclosure of significance rests on knowledge rather than being the subject of some "language game".

If we wish to find out the standard significance of an ordinary language expression we look it up in a dictionary. But if the expression belongs to a mathematical language or to a scientific symbolism, then one must look it up in the respective theory. In either case we come up with the vicarious sense and the vicarious reference of the sign. The two go hand in hand even if one or the other happens to be somewhat hazy. Thus when elucidating the significance of an operation symbol such as '+' we must bring in the set or sets on which the operation (not the symbol) is "defined" – and the members of this set are precisely the referents of the operation (a construct). Similarly with the elucidation of the significance of scientific terms: here too the determination of the (vicarious) referents of a symbol is part of the assignment of its (vicarious) sense. In particular, a predicate symbol will signify a property of the (vicarious) referent of the symbol. Therefore it might be thought that there is no point in keeping sense and reference as distinct components of meaning. It might be surmised that reference is a function of sense. But this is not quite so: (i) an axiom set such as Peano's, precise though it is, does not characterize completely its objects or referents but fits a number of them; (ii) a scientific theory initially intended to represent things of a certain kind may turn out to refer to a different kind of object. And even if sense were to determine reference in an unambiguous way, this would not invalidate our Definitions 1 and 4, for surely an ordered couple remains such if its second coordinate is determined by the first one – as is the case with the pair $\langle x, y\rangle$, where $y=f(x)$.

Keeping sense and reference distinct has definite advantages. In the case of mathematics it allows us to elucidate the differences in meaning among the various realizations of a given abstract formalism, namely thus. Here we have as many meanings as interpretations (or as models). The first coordinate of each such meaning consists of a fixed sense determined by the abstract theory enriched with the semantic assumptions that determine the particular interpretation. And the second coordinate of the meaning value is the domain of individuals, which varies from interpretation to interpretation. What is common to all these is of course the sense of the abstract theory. And in the case of factual science the distinction between the two meaning components is a useful reminder that one and the same thing may be represented by a number of constructs. Here, unlike the case of mathematics, the second coordinate is held fixed: the thing referred to does not change with the point of view. But in both cases we have to do with meaning differences. We shall come back to this problem in Sec. 3.3.

In mathematics and in science the assignment as well as the analysis of significance start with the rules of designation that match symbols with constructs. The second and most important step is to characterize the construct itself – and this is a matter of theory not of rule. The characterization ("definition") is often incomplete: sometimes because we want to leave room for ulterior specification, at other times because we do not know any better. The former is the case with abstract mathematics: a full specification of both sense and reference, i.e. a "definition" of the theory of a particular model, will destroy the leeway typical of abstract mathematics. In the case of science even if we wanted to effect a complete characterization we could not get it. Any characterization of the factual sense of a scientific construct is bound to be incomplete because it includes semantic assumptions that "point" to the referents without any further assistance from mathematics. When mentioning a specific domain of individuals, such as the real numbers, the mathematician can fall back on the specific theory or theories that "define" those individuals. Not so the scientist: he does not construct the referents of his theories but finds them or hopes to find them, hence he cannot fall back on other constructs.

The best he can do is to set up a mathematical formalism and conjoin it with semantic assumptions interpreting the basic concepts as so many factual items. The latter are at best described, at worst just mentioned. Whence the unavoidable meaning indeterminacy of factual theories.

2.4. *Degrees of Significance Definiteness*

There are degrees of significance definiteness corresponding to the degrees of meaning determinacy. We may distinguish the following degrees:

(i) *Low*

(*a*) Sense: definite but minimal. Reference: arbitrary except for the very general conditions set by the postulates determining the sense. Example: any abstract theory.

(*b*) Sense: not fully specified. Reference: definite. Example: any body of factual knowledge that does not contain full blown theories.

(ii) *Medium*

(*a*) Sense: minimal enriched with interpretations of some of the basic constructs. Reference: either definite or arbitrary, depending on whether or not the basic sets are specified. Example: any partial model in the sense of Ch. 6, Sec. 2.2, Definition 2.

(*b*) Sense: specified by a theory formulated in an intuitive or heuristic way. Reference: definite. Example: almost any theory in factual science.

(iii) *Large*

(*a*) Sense: nearly full. Reference: definite. Example: any theory in intuitive or nonformalized mathematics.

(*b*) Sense: specified by an axiomatic theory containing factual semantic assumptions. Reference: definite but large (genus not species of things). Example: any generic factual theory formulated axiomatically.

(iv) *Maximal*

(*a*) Sense: total. Reference: definite. Example: any fully axiomatized theory of a particular model.

(*b*) No instances in factual science.

We can now state the necessary and sufficient condition of significance. It is no more and no less than this: For a sign to be *significant* it must designate a construct (Def. 5). And for a construct to have a *reasonably definite meaning*, i.e. for being reasonably definite itself, the construct must belong to a reasonably well organized body of knowledge. Optimal meaning definiteness is attained only in a theory proper. (But maximal, i.e., full meaning is achieved only in mathematics.) While the profile of a construct can often be sketched in a satisfactory manner with more modest means, only incorporation into a theory takes automatic care of the syntax and, to some extent, of the semantics of a construct. For example mechanics will denounce 'The mass of that car is 3' as ill formed, for this expression fails to specify the mass unit. And it will expose 'Vorticity is noble' as a mongrel or semantically ill constructed expression, hence just as nonsignificant as the former expression. On the other hand ordinary language analysis has precious little to say about either except that they are grammatically sound. (Category mistakes are conceptual not linguistic: recall Ch. 2, Sec. 5.1.)

Finally a warning: We are not claiming that a construct is meaningless if it belongs to no theory, but only (i) that a construct has no *clear cut* meaning but in the midst of a theory, (ii) that a construct may *change* its meaning (i.e. it may become a different construct) if transplanted to a different theory, and (iii) that a *theoretical* construct exists only in a theory. All three aspects are illustrated in the following example. Even if different theories of social change start out with the same dictionary definition of "revolution", e.g., as "a drastic and sudden change in the established social patterns", they may elucidate or refine it in different ways, thus ending up with *different concepts* of revolution. They do this by assuming different actors (or referents of "revolution") and by emphasizing different traits as well as different causes. Thus while one theory will claim that the protagonists of revolutions (the referents of "revolution") are institutions, another will assert that they are social classes and a third that they are individuals. And while one theory will focus on institutional changes another will emphasize changes in the social and economic structure while a third view will concentrate on changes in individual roles. Finally, while one theory will assume that revolutions occur when institutions outlive their usefulness, another will claim that they are the last straw in a class struggle, and a third doctrine will assert that they happen when the members of the ruling class become corrupt. Clearly, 'revolution' signifies different constructs in the various theories of revolution even though they all share the core meaning assigned by the dictionary. (In many cases there is no such core meaning constituted by the pretheoretical or intuitive construct.) Tell me the company a construct keeps and I will tell you what it is: recall Ch. 5, Sec. 4.

3. MEANING INVARIANCE AND CHANGE

3.1. *Synonymy*

Two signs will be said to be *semantically synonymous* just in case they have the same significance. And two symbols will be regarded as *pragmatically synonymous for a given user* if he employs them interchangeably or if, under the same circumstances, they evoke in him the same reactions. Pragmatic synonymy does not presuppose semantic synonymy: thus for many people 'psychiatrist' and 'psychoanalyst' are synonymous. And few of us are consistent in matters of pragmatic synonymy. If for no other reason, semantics cannot be based upon pragmatics. A second reason is that the determination of pragmatic synonymy calls for the observation of linguistic behavior, which is irrelevant to semantic synonymy: we do not circulate questionnaires in order to find out whether 'mass' and 'inertia' are semantically synonymous. We shall restrict our considerations to semantic synonymy.

Let us begin by restating our definition in more explicit terms:

DEFINITION 7.7 Two signs are said to be *synonymous* in a given language $\mathscr{L}$ iff they have the same significance in $\mathscr{L}$:

If s and s' are in $\mathscr{L}$, then $\mathscr{S}yn(s, s', \mathscr{L}) =_{df} \mathscr{S}ig(s, \mathscr{L}) = \mathscr{S}ig(s', \mathscr{L})$.

Example 'John loves Mary' and 'Mary is loved by John' are linguistically different but synonymous sentences: they are semantically identical – they express the same proposition.

COROLLARY 7.3 Synonyms designate the same constructs:

$$\mathscr{S}yn(s, s', \mathscr{L}) \text{ iff } \mathscr{D}\text{‘}s = \mathscr{D}\text{‘}s' \text{ in } \mathscr{L}.$$

COROLLARY 7.4 Synonyms have the same vicarious sense and the same vicarious reference:

$$\mathscr{D}sc \text{ and } \mathscr{D}s'c' \text{ in } \mathscr{L} \text{ and } \mathscr{S}yn(s, s', \mathscr{L}) \text{ iff } \mathscr{S}(c) = \mathscr{S}(c') \text{ and } \mathscr{R}(c) = \mathscr{R}(c').$$

Proofs The first corollary follows from Definitions 5 and 7. The second from Corollary 3 and the axiom for ordered pairs.

Remark 1 Corollary 4 looks pedantic but it is not, for we do not know that two signs do stand for the same construct, and are thus synonymous, unless we analyze their designata into sense and reference and prove, in a more or less rigorous way, that the senses and the referents are the same. A relatively frequent case is this: two different lines of reasoning within a theory come up with a function each. Further research shows that the two functions satisfy the same differential equation and are subject to the same initial or boundary conditions. This proves that the two functions are the same, or that they differ at most by a constant. *Remark 2* Logical equivalence is insufficient for synonymy. Not even equality may be enough: thus that two functions, f and g, share their values at a point a, i.e., $f(a)=g(a)$, does not entail that '$f(a)$' and '$g(a)$' are equisignificant or synonymous. Only identity guarantees synonymy. *Remark 3* If we demand that the definiendum and the definiens have the same meaning then we can accept only identities as qualified to define, since only an identity assures us that the two sides are just different names for one and the same object. Consequences: (*a*) equivalence is not the proper form of a definition, and (*b*) the intuitive asymmetry between definiendum (*LHS*) and definiens (*RHS*) is lost in the object language: it may be regarded as a metatheoretical or as a pragmatic trait. More in Ch. 10, Sec. 2.2.

As with synonyms so with antonyms:

DEFINITION 7.8 Two signs are *antonymous* in a given language $\mathscr{L}$ iff each designates the negate of the other's designatum:

If s and s' are in $\mathscr{L}$, and $\mathscr{D}sc$ and $\mathscr{D}s'c'$, then $\mathscr{A}nt\,(s, s', \mathscr{L}) =_{df} c' = \neg c$.

Remark By the double negation theorem of ordinary logic, $\mathscr{A}nt$ proves to be a symmetrical relation. If intuitionistic logic were adopted this would be lost unless the antonymy relation were redefined. Because we find no use for intuitionistic logic in science, we won't bother with this problem.

Synonymy and antonymy are just two bands of the entire spectrum of significance relations. Both $\mathscr{S}yn$ and $\mathscr{A}nt$ come in degrees: there is weak synonymy as well as weak antonymy. Thus 'set' and 'class' are weakly synonymous, and 'war' and 'truce' weakly antonymous. The following definitions elucidate the concept of likeness of significance.

DEFINITION 7.9 If s and s' are signs designating the constructs c and c' respectively, then s and s' are *partially synonymous* (or they exhibit a *likeness of significance*) iff the intersection of the senses of c and c' is not nil: $\mathcal{S}(c) \cap \mathcal{S}(c') \neq \emptyset$.

Example 'Hemisphere' in geography does not mean the same as in anatomy, but the senses of the two constructs concerned are close even though their referents (Earth and brain) are different.

DEFINITION 7.10 If s, s' and s'' are signs designating the constructs c', c' and c'' respectively, then the *likeness in significance* between s and s' is *closer* than the likeness in significance between s and s'' iff $\mathcal{S}(c) \cap \mathcal{S}(c') \supset \mathcal{S}(c) \cap \mathcal{S}(c'')$.

The preceding elucidations of the notions of equality and likeness of meaning should meet Quine's objection to propositions, namely that "If there were propositions, they would induce a certain relation of synonymy or equivalence between sentences themselves: those sentences would be equivalent that expressed the same propositions" (Quine, 1970b, p. 3, also 1960, Ch. VI). Well, don't they?

Our treatment of meaning relations, while at variance with the lexical view of semantics (Katz and Fodor, 1963), is in agreement with the view (Bar-Hillel, 1970) that such relations are logical relations. And our definition of synonymy confirms the view that the identity of the sets of implicants and implicates (i.e. sense) is necessary but insufficient for synonymy (Attfield and Durrant, 1973).

3.2. *Meaning Invariance*

The relation $\mathcal{S}yn$ of synonymy introduced by Def. 7 (Sec. 3.1) is an equivalence relation. Hence it defines the equivalence classes constituted by synonymous signs. In other words, for any language $\mathcal{L}$, if s is in $\mathcal{L}$,

$$[s]_{\mathcal{L}} = \{t \in \mathcal{L} \mid \mathcal{S}yn\,(s, t, \mathcal{L})\}$$

is the set of all the synonyms of s in $\mathcal{L}$. Every one of these equivalence classes corresponds to a single construct.

Take now the totality of equivalence classes under $\mathcal{S}yn$, i.e. the quotient set $\Sigma^{**}/\mathcal{S}yn$. This is the linguistic representative of all the constructs expressible in $\mathcal{L}$. Even if the designation function $\mathcal{D}$ is many-one, as we have assumed, we now have a one-one function $\mathcal{D}^*$ that matches distinct elements of $\Sigma^{**}/\mathscr{S}yn$ to distinct members of the set C of constructs expressible by $\mathscr{L}$. This isomorphism $\mathscr{D}^*: \Sigma^{**}/\mathscr{S}yn \to C$ may be called the *regular designation function*.

Let us pull the various items together. We start with the many-one function (surjection) $\mathscr{D}: \Sigma^{**} \to C$. Then we define the equivalence relation $\mathscr{S}yn$ in Σ^{**}. This relation determines the projection $p: \Sigma^{**} \to \Sigma^{**}/\mathscr{S}yn$ that assigns to every symbol the class of its semantic equivalents. Next we map the range of p onto C. Finally we compose p with $\mathscr{D}^*$. The outcome is $\mathscr{D}^* \circ p = \mathscr{D}$ as pictured by the diagram

$$\begin{tikzcd}
\Sigma^{**} \arrow[rr, "\mathscr{D}"] \arrow[dr, "p"'] & & C \\
& \Sigma^{**}/\mathscr{S}yn \arrow[ur, "\mathscr{D}^*"'] &
\end{tikzcd}$$

Now pick all the sentences of $\mathscr{L}$. Next group them into classes of synonyms, i.e., equisignificant sentences. Finally allow $\mathscr{L}$ to range over the set of all possible languages. That is, build the family of equivalence classes of sentences under the relation of equisignificance:

$\{[s]_{\mathscr{L}} \mid s \text{ is a sentence of } \mathscr{L} \;\&\; \mathscr{L} \text{ is a conceptual language}\}$. A nominalist might wish to identify this family of equisignificant sentences with what we call a *proposition* (or statement). But he cannot do this because he has no independent criterion of significance. In other words, the above cannot be treated as *defining* "proposition" because the latter concept is involved in the formation of the equivalence classes $[s]_{\mathscr{L}}$. Indeed, as we saw in Sec. 3.1, we do not know whether two sentences in mathematics or in science are synonymous unless we can show that they designate the same construct. Still, the above does clarify the idea that a proposition is that which remains invariant under all faithful sentence to sentence translations, as suggested by Russell (1940).

The translation concept can be elucidated in the following way. Consider the set $S_{\mathscr{L}}$ of all the sentences of a language $\mathscr{L}$ and the homologous collection $S_{\mathscr{L}'}$ for another language $\mathscr{L}'$. Even if these two sets are disjoint and structurally different, there may exist a one many relation

τ from $S_{\mathscr{L}}$ to $S_{\mathscr{L}'}$ that preserves significance. If such a relation exists we say that τ is a translation of $\mathscr{L}$ into $\mathscr{L}'$. More explicitly, we have

DEFINITION 7.11 Let $\mathscr{L}$ and $\mathscr{L}'$ be two conceptual languages and let τ be a one many relation from the set of sentences $S_{\mathscr{L}}$ to the set of sentences $S_{\mathscr{L}'}$. Then τ is said to be an *exact pointwise translation* of $\mathscr{L}$ into $\mathscr{L}'$ iff

$$\mathscr{S}\!\mathit{ig}(\tau\text{‘}s) = \mathscr{S}\!\mathit{ig}(s) \quad \text{for every} \quad s \in S_{\mathscr{L}},$$

where $\tau\text{‘}s \in S_{\mathscr{L}'}$ is a translation of s into $\mathscr{L}'$.

This concept of translation is useful in mathematics, where it can be strengthened to that of a function (Wang, 1951). But it is hardly applicable to natural languages, where not all sentences are independently meaningful. Here whole clusters of sentences must be paired off if significance is to be preserved. In other words, in the case of natural languages we must give up the ideal of pointwise translation and settle instead for global translation. However, this need not force us to adopt Quine's doctrine of the inevitable indeterminacy of translation: it only suggests supplementing Definition 11 with the following elucidation of the notion of global translation:

DEFINITION 7.12 Let $S_{\mathscr{L}}$ and $S_{\mathscr{L}'}$ be the sets of all sentences of languages $\mathscr{L}$ and $\mathscr{L}'$ respectively, and call $\mathscr{P}(S_{\mathscr{L}})$ and $\mathscr{P}(S_{\mathscr{L}'})$ their corresponding power sets. Then τ is an *exact global translation* of $\mathscr{L}$ into $\mathscr{L}'$ iff τ is a relation from $\mathscr{P}(S_{\mathscr{L}})$ to $\mathscr{P}(S_{\mathscr{L}'})$ such that

$$\mathscr{S}\!\mathit{ig}(\tau\text{‘}u) = \mathscr{S}\!\mathit{ig}(u) \quad \text{for every} \quad u \in \mathscr{P}(S_{\mathscr{L}})$$

where $\tau\text{‘}u \in \mathscr{P}(S_{\mathscr{L}'})$ is a translation of the set of u of sentences of $S_{\mathscr{L}}$ into $\mathscr{L}'$.

In sum, our concept of synonymy has allowed us to define two concepts of translation: pointwise and global. These concepts are strictly semantic as it should be: translation is concerned with meaning not with structure. (For the opposite view and a purely syntactic definition of translation see Svenonius (1973).) Surely perfect translations, even if global, are hard to come by. But, since they are desirable, the above definitions, far from being idle, may perform a regulative function. Thus it would be desirable to regularize the grammars and vocabularies of some of the natural languages so as to render them perfectly translatable into one another. Once this linguistic reform were implemented machine translation should offer no obstacles.

The concept of translation is relevant to linguistics, the foundations of mathematics, and the foundations of science – where it occurs with reference to equivalent theories utilizing different mathematical "languages". (For the use of theories as languages for further theories, see Ch. 1, Sec. 2.3.) However in factual science one is much more interested in different theories, whether or not they are couched in the same mathematical "languages". And, unlike translation, the passage from one theory to another may involve meaning changes. This matter deserves a separate subsection.

3.3. *Meaning Change*

If meaning is *sensus cum referens* then a change in meaning is a change in either sense or reference or both. And either change, when stripped of its pragmatic aspects, consists of a *difference* in sense and/or reference. Since both sense and reference have been constructed as sets, it is natural to define the difference in either as a symmetric (or Boolean) difference. It is equally natural to define difference in meaning as the pair ⟨difference in sense, difference in reference⟩. More precisely we have

DEFINITION 7.13 Let c and c' be constructs. Then

(i) The *difference in sense* between c and c' is $\delta_{\mathcal{S}}(c, c') = \mathcal{S}(c)\,\Delta\mathcal{S}(c')$;

(ii) the *difference in reference* between c and c' is $\delta_{\mathcal{R}}(c, c') = \mathcal{R}(c)\,\Delta\mathcal{R}(c')$;

(iii) the *difference in meaning* between c and c' is $\delta_{\mathcal{M}}(c, c') = \langle\delta_{\mathcal{S}}(c, c'), \delta_{\mathcal{R}}(c, c')\rangle$.

The least interesting case is the one in which the meaning "distance" between two constructs is maximal:

COROLLARY 7.5 Let c and c' be semantically unrelated constructs, i.e. such that both $\mathcal{S}(c) \cap \mathcal{S}(c') = \emptyset$ and $\mathcal{R}(c) \cap \mathcal{R}(c') = \emptyset$, which amounts to $\mathcal{M}(c) \times \mathcal{M}(c') = \langle\emptyset, \emptyset\rangle = \Box$. Then

$$\delta_{\mathcal{M}}(c, c') = \langle\mathcal{S}(c) \cup \mathcal{S}(c'), \mathcal{R}(c) \cup \mathcal{R}(c')\rangle.$$

The next case is far more interesting, as it concerns constructs with comparable senses:

COROLLARY 7.6 Let c and c' be two constructs such that the sense of c' contains the sense of c and such that they are coreferential. In brief, assume $\mathcal{S}(c')=\mathcal{S}(c)\cup\Delta\mathcal{S}$, with $\Delta\mathcal{S}\neq\emptyset$ and $\mathcal{S}(c)\cap\Delta\mathcal{S}=\emptyset$, and $\mathcal{R}(c)\cap\cap\mathcal{R}(c')\neq\emptyset$. Then

$$\delta_{\mathcal{M}}(c, c')=\langle\Delta\mathcal{S}, \Delta\mathcal{R}\rangle.$$

Example 1

$c=$ Partially ordered set $\langle A, \preccurlyeq\rangle$
$c'=$ Semilattice $\langle A', \preccurlyeq, \wedge\rangle$
$\mathcal{S}(c)=$ Axioms and theorems for posets, $\mathcal{R}(c)=A$
$\mathcal{S}(c')=\mathcal{S}(c)\cup$ Axioms and theorems containing $\wedge$, $\mathcal{R}(c')=A'\subseteq A$
$\delta_{\mathcal{M}}(c, c')=\langle$Axioms and theorems containing $\wedge$, $A-A'\rangle$.

Example 2

$c=$ Celestial mechanics (CM)
$c'=$ Lunar theory (L)
$\mathcal{S}(c)=$ Axioms and theorems of CM, $\mathcal{R}(c)=$ All celestial bodies
$\mathcal{S}(c')=\mathcal{S}(c)\cup$ Hypotheses concerning the Moon only, $\mathcal{R}(c')=\{$Moon$\}$
$\delta_{\mathcal{M}}(c, c')=\langle$Hypotheses concerning the Moon only, All celestial bodies except the Moon$\rangle$.

Whether or not our concept of meaning change elucidates the intuitive ideas put forth by Hanson, Kuhn, Toulmin and Feyerabend, and tossed so vehemently by so many philosophers, is hard to say. The preceding elucidations are offered as a semantic framework within which historical examples can be profitably discussed. Of course one may get inspiration for a theory of meaning by studying case histories: but such a study does not constitute an analysis of meaning, let alone a theory of meaning. Without a previous agreement on what 'meaning' signifies, i.e., unless a definite theory of meaning (and meaning change) is shared, if only for the sake of argument, the latter is bound to be chaotic, hence sterile. (For an example of such a dialogue among the deaf see the Minnesota discussion on correspondence rules, in Radner and Winokur (1971). For criteria for meaning changes see Kleiner (1971).)

The study of actual changes in significance belongs to pragmatics, historical linguistics, and the history of ideas. From this viewpoint every sign has a certain flexibility, also called *open texture* (Waismann, 1955). Thus "solid" has been redefined a number of times and will presumably be the object of further elucidations as the theories of solids evolve. It is only within the symbolism of a given theory that signs are nearly nonporous. Nevertheless the various significances assigned a scientific term in the course of its history often do have a solid core – namely the intersection of all its various significances. This core is not the "essence" of the sign: it may well consist of certain external characteristics. And it is often minute.

4. FACTUAL AND EMPIRICAL MEANINGS

4.1. *Definitions*

To elucidate the notion of factual meaning we blend the results of Ch. 2, Sec. 4.1 concerning factual reference with those of Ch. 5, Sec. 3.3 about factual sense. We thus get a specialization of Def. 1 in Sec. 2.1:

DEFINITION 7.14 Let c be a construct with a factual sense $\mathcal{S}_F(c)$ and a factual reference $\mathcal{R}_F(c)$. Then the *factual meaning* of c is defined as

$$\mathcal{M}_F(c) = \langle \mathcal{S}_F(c), \mathcal{R}_F(c) \rangle.$$

Example 1 c = Electrodynamics, or e for short.

$$\mathcal{M}_F(e) = \langle \{\text{Law statements, meaning assumptions, etc., of } e\}, \text{Electromagnetic fields} \cup \text{Bodies} \rangle.$$

Example 2 c = Mind concept, or m for short.

$$\mathcal{M}_F(m) = \langle \ulcorner \text{The internal activity of the brain} \urcorner, \text{Higher animals} \rangle.$$

Factual meaning should not be mistaken for empirical meaning. A construct may be said to have an empirical meaning just in case it refers at least partially to human experiences of some kind – e.g. perceiving, thinking, or doing. Thus while ⌜There are neutrinos⌝ is factually meaningful (and even true), it is empirically meaningless, for we have no experience of neutrinos. If a construct is empirically meaningful then it is factually meaningful – but not conversely. This principle of our semantics matches the metaphysical assumption that experience is a proper part of reality – namely the one involving experients. Both principles are of course at the center of a realist philosophy, of which more in Ch. 10, Sec. 3.3.

The difference between the factual and the empirical can be rendered slightly more precise by introducing the following conventions.

DEFINITION 7.15 A predicate $P: A \times B \times \ldots \times N \to S$, where S is a set of statements, is called *factual* iff at least one of the cartesian factors of the set on which P is defined represents a domain of factual items.

DEFINITION 7.16 A factual predicate $P: A \times B \times \ldots \times N \to S$ is called *empirical* iff at least one of the cartesian factors of the set on which P is defined is a set of sentient organisms.

DEFINITION 7.17 A predicate that is factual but not empirical is called *strictly factual* or *objective*.

Example Whereas "temperature" is strictly factual or objective, "hot" is empirical for having been defined on the set of ordered pairs thing-sentient being.

The rest is obvious. A statement is factual iff it contains at least one factual predicate, empirical iff it contains at least one empirical predicate, and strictly factual iff it contains factual but not empirical predicates. Similarly for sets of statements, in particular for theories.

Warning: Scientists sometimes call 'meaningless' what is actually meaningful but either uninteresting or false. For example, the runaway solutions of the equations of motion of classical electrodynamics are sometimes said to be 'physically meaningless'. As a matter of fact they are meaningful: they represent the motion of a self-accelerated point charge. Only, they are false. Moral: Dig out the concepts underneath the words.

4.2. *The Search for Factual Meaning*

When a scientific theory attains axiomatic maturity, the basic constructs determine the meanings of all others. This state of refinement is of course an outcome of a process of concept and theory formation that is anything but rule directed. In the preaxiomatic stages, i.e., in all theoretical domains save foundations research, the search for meaning is, like the search for hypotheses and theories, a guessing-trial-correction zigzagging. Even if the mathematical ideas are clear, their factual sense and occasionally even their referents are all too often imprecise at this stage. In sum, the semantics of a factual theory, i.e., its sense and reference, emerges gradually. It grows as a result of (i) solving more and more problems in the theory, (ii) enhancing the organization of the theory, (iii) relating the theory to other theories, and (iv) analyzing and evaluating the key constructs of the theory.

A typical situation in the search for the factual meaning of a theoretical construct is this:

(i) formulating a problem in the context of a given theory (very often an ill organized one);

(ii) detaching the mathematical component of the problem – i.e. formulating a problem in mathematics;

(iii) solving the mathematical problem;

(iv) wondering about the factual meaning of the solution.

This last task can be very hard, particularly in the preaxiomatic stages. Even if all the constructs occurring in the formulation of the problem have clear cut meanings, the solution may be quite unperspicuous: we may be able to "read" every symbol in it without however "making sense" out of the whole. For what we really are after is not a term by term interpretation: what we want to find out is what the solution *represents* – i.e. what aspects (e.g. properties) of the system it symbolizes and what facts (e.g. events), if any, it models. This is why J. C. Maxwell claimed that v^2, the square of a particle velocity, "has no distinct physical meaning", nor does mv^2, where m represents the particle mass (Maxwell, 1871). Actually the compound construct "mv^2" is perfectly meaningful in our large sense of 'meaning', since it is built out of individually meaningful constructs in a formally correct way. The trouble with it is not that it is meaningless but that it fails to *represent a definite property* of the system concerned. On the other hand v and mv do represent a property each and so does $\frac{1}{2}mv^2$. Why should the factor $\frac{1}{2}$ make such a huge semantic difference? Because it is $\frac{1}{2}mv^2$, not mv^2, that figures as an independent term (an addend) in a *law* statement of particle mechanics, i.e. in a theorem that is supposed to represent a natural pattern. In short, although both "mv^2" and "$\frac{1}{2}mv^2$" have definite senses and the same referent, the former is attributed no "distinct physical meaning" in the sense that it represents no particular property of the system concerned – and this in turn because it plays no role in any law statement.

The occurrence of a construct as an identifiable component in a law statement (e.g., as an addend) is then a good clue as to its factual meaning. No less and no more. Indeed, one and the same "quantity" (magnitude) can often be decomposed in different ways and these differences are only mathematically meaningful. Moreover, even if a construct occurs as a separate component in a law statement, we may fail to "read" it without further ado and so may have to resort to other procedures. For example, in a field theory a construct such as $\nabla \cdot V$, where V is a vector field, may not be "identified" or "recognized", i.e. assigned a "distinct physical meaning" right away. We may first have to integrate $\nabla \cdot V$ over a space region: by Gauss' theorem the outcome will be the flux of V across the boundary of that region, and this derived quantity may represent a property of the system. But even this may be insufficient: we may have to look for additional clues. A very fruitful one is dimensional analysis. Thus if the dimension of a magnitude X is LT^{-1} we may suspect that X represents the velocity of something. But then it may not.

Very often a theoretical construct with a perfectly definite referent has no manifest factual meaning – or, if preferred, its meaning is hidden. This is particularly the case with what may be called the *source magnitudes*. These are functions with definite reference classes and definite senses but representing no definite property of their referents although they generate a number of representing functions. Examples: (*a*) the various potential functions, whose gradients represent forces; (*b*) the partition function in statistical mechanics which, by mathematical manipulation, yields a number of representing functions; (*c*) the wave function and the statistical operator in the quantum theories. As long as a source function furnishes functions representing one property each we should tolerate, nay encourage them and defend them from the attacks of the operationist, who has no use for them because they are not directly measurable.

Gradually and somehow or other, both the mathematical formalism and its factual meaning mature to the point that the theory becomes ripe for axiomatization. In particular, the semantic assumptions can be stated explicitly and so contribute, alongside the remaining assumptions, to delineating the factual meaning of the theory. Once the theory has been given an axiomatic formulation everything should run smoother than before. For in a well organized theory everything flows from the axiom top: both theorems and meanings. In principle the meaning of a defined construct will be found by analyzing its definition and the meaning of a theorem will be found by analyzing its component constructs as well as the premises that entail it. In principle but not necessarily in practice: axiomatization eases proofs and interpretations and makes them more precise but not mechanical.

4.3. *Shape and Role of Meaning Assumptions*

There is no consensus on how to handle the factual meaning of scientific constructs. Every scientist proceeds in his own way, though often influenced by some philosophical school. Here follow in quick succession the main current views on the matter – or rather sketches of them.

(i) *Formalism and conventionalism.* No meaning assumptions are called for because scientific constructs have no factual meaning: they are just pieces in a mathematical machinery. A scientific theory is identical to its mathematical formalism. *Criticism* Any mathematical formalism may be assigned alternative interpretations: a factual construct is a mathematical construct together with a factual interpretation (Ch. 6, Sec. 3).

(ii) *The semantic miracle view.* Meanings take care of themselves: every formalism generates its own interpretation. Hence no meaning assumptions are needed. *Criticism* Same as for (i). The reason some formalisms seem to be necessarily associated with certain interpretations is just habit. A scientific specialist is so used to handling certain form-content pairs that it may not occur to him that the same form may be paired to an altogether different content.

(iii) *The meaning-lies-in-the-name view.* All we need to turn a mathematical formalism into a scientific theory is to add designation rules, such as ⌜The parameter t is called time⌝. *Criticism* While designation rules are necessary ingredients of the semantics of a scientific theory, they are insufficient. Names are conventional, meaning assumptions are not: the latter are testable, hence capable of being overthrown. Thus although we still use the electric current concept we no longer assume that it represents the rate of flow of the electric fluid. If we claim that a theory represents certain things then we must state clearly what in the theory represents what in the world.

(iv) *Classical empiricism.* Meanings are assigned by ostensive definitions or rules, such as "That is blue". *Criticism* First, an ostensive rule may be a subject for pragmatics but not for semantics: unless accompanied by suitable gestures it is devoid of (pragmatic) meaning. Second, unfortunately for toddlers, the most interesting constructs in science and even in ordinary knowledge are non-ostensive.

(v) *Operationism.* Meanings are assigned by specifying modes of observation, measurement, or action in general. For example, the concept of a thermodynamic state must be specified by describing a method of preparation of states (Carathéodory, 1924; Giles, 1964). *Criticism* First, most of the referents of a scientific theory are beyond the reach of the experimentalist – if only because they are possibles rather than actuals. Hence if a thermodynamic state must be the outcome of a human act then most physical systems are in no state at all. Second, this view is dangerously near subjectivism, which has no need for empirical procedures. Indeed, once a thermodynamic state has been made to depend on man, why not on mind alone? This step has actually been taken: it has been claimed that "a state is a state of mind induced by the available knowledge of preparation" (Burton, 1968). Third, the whole of operationism rests on a confusion between reference and evidence (Feigl, 1958; Bunge, 1967a, 1973a, 1973b).

(vi) *Mellowed operationism.* A theoretical term is significant to the extent to which it is related, in the body of a theory, to some observational sentence of the theory (Carnap, 1956). More precisely, "A theoretical term t is significant if there is an assumption A involving t such that from A and additional assumptions involving other theoretical terms that have already been recognized as significant it is possible to derive with the help of the postulates and the rules of correspondence an observation sentence that cannot be derived without the assumption *A*" (Carnap, 1963a, p. 80). *Criticism* First, most scientific theories contain no observational constructs. Strictly speaking *all* the constructs in a scientific theory are theoretical and often devoid of empirical (yet not of factual) meaning. Hence the theoretical/observational dichotomy is not applicable to scientific theories. Second, as suggested by Carnap himself, testable statements can only be had with external help – namely by roping in assumptions belonging to other theories as well as empirical evidence. (For details see Bunge (1967a) and (1970a).) Even so, this will render the theory empirically testable but not empirically meaningful.

(vii) *Realism.* Factual theories have a factual meaning. And factual meanings are determined jointly by all the assumptions of the theory – in particular, though not exclusively, by the semantic assumptions. Since the latter bear on the basic concepts, they belong in the axiomatic foundations of the theory. Every semantic assumption indicates the referent(s) of the construct and suggests what it represents. For example, a conditional probability value $P_n(b \mid a)$ can be made to represent the tendency of the *n*th system of a certain kind to jump from state *a* to state *b*. It makes no difference to the semantics of a theory whether the referents are perceptible and the traits that are being represented by the theory are directly observable or must be reached with the help of further theories: observability is relevant to testability not to meaning. In other words, the semantic assumptions in a scientific theory relate constructs to things and some of their traits: anything that relates constructs to empirical operations, such as preparation or measurement, may qualify as a *testability condition* but certainly not as a meaning assumption. *Criticism* None that I can think of.

Every one of these policies has its advocates and all of them but classical empiricism (ostensivism) are practised nowadays by scientists. Yet popularity is not the seal of truth: just because most scientists either do not care to formulate any explicit meaning assumptions or because they propose operationist interpretations, does not prove that those policies are right. A semantic policy, just as any other policy, must be judged by its success in achieving the goals it sets itself as well as by its success in surviving criticism. If judged in this dual way, the most popular semantic policies prove to be utter failures. The first three because they do not even attempt to pinpoint the peculiarities of factual theories *vis-à-vis* their mathematical formalisms. And the two varieties of operationism are flops as well because the semantic assumptions they recommend are too narrow: they are linked to particular laboratory techniques, hence closed to possible alternatives. And most of the time they are phony, as they stipulate impossible measurements. Try measuring a lagrangian density, or a partition function, or a state function.

The failure of the various attempts to specify the meanings of theoretical concepts by reducing, or at least linking them to observational concepts, has produced a mood of despondency among philosophers of science. Thus Putnam came to the conclusion that the very *problem* of interpreting theoretical terms "does not exist" (Putnam, 1962) and Hempel thinks now that the problem was "misconceived" (Hempel, 1970). Nevertheless the problem won't lie down: the theoretical scientist faces it every day when pondering over the possible factual meanings of his mathematical formulas. Moreover the scientist tries to solve his semantic problems in more of less naive ways, without the benefit of a full fledged semantic theory. No doubt he would fare better if, instead of being told that he should worry no more because he has really no problem at all, he were offered a definite semantic theory.

The failure of empiricist semantics does not entail the impossibility of every kind of semantics. It just suggests looking elsewhere for a solution to the genuine and difficult problem of specifying (or rather sketching) the meaning of theoretical concepts (or the significance of theoretical terms). An alternative to empiricism is realism, the only semantic policy that has emerged unscathed from the fifty years' war over the soul of scientific constructs. True, realism is not often practised in an explicit manner, i.e., by laying down the rules of denotation and the semantic assumptions that delineate the meanings of the undefined concepts of a scientific theory. But then (*a*) impopularity is not the seal of falsity, (*b*) few theoreticians care to render all their assumptions explicit, and (*c*) positivist semantics, even after having been repudiated by its propounders, still enjoys a considerable prestige among scientists. It behooves the philosopher to illumine the path by showing in particular cases how to interpret theoretical concepts in terms of facts.

We close with a warning. A semantic assumption occurring in an axiom system could rightly be called a *meaning postulate*. Unfortunately this expression was preempted by Carnap (1952), who employed it in a different sense. Consider the two standard examples of a "meaning postulate", first of all

⌜For every *x*, *x* is a bachelor iff *x* is a male and *x* is not married.⌝ (1)

This is a construct-construct relation that does not intend to say what "bachelor" refers to and represents but rather how it is related in extension to both "male" and "married". It seems to be an ordinary dictionary definition. In any case it is supposed to be a priori, hence empirically unassailable. The second standard example of a "meaning postulate" is

⌜For every *x*, if *x* is a bachelor then *x* is not married.⌝ (2)

This might be taken as a "law" of ordinary knowledge or as a linguistic fact or, finally, as a deductive consequence of the convention (1). In neither case is it an empirically refutable semantic assumption or axiom in our sense. Nor is it a postulate in the sense of 'axiom' (Carnap, 1952). Whatever it is, a Carnapian "meaning postulate" does not contribute to the sense of a scientific term, hence it takes no part in the axiomatic reconstruction of a scientific theory, whence it need not concern us.

5. MEANING ET ALIA

5.1. *Meaning and Testability*

We have elaborated the common sense or realist view of factual meaningfulness. According to this view a statement is factually meaningful only if it refers to, and the more so if it represents, a factual item – a thing, a state of affairs, or an event. The referent need not be actual and the representation, if there is any, need not be true: the statement may well concern the past or the future, and it may be utterly false or even impossible to test. Any narrower criterion of factual meaningfulness runs the risk of disowning the most interesting scientific speculations.

This commonsensical view was also the one Carnap held before he came under the influence of Wittgenstein: "The meaning of a statement lies in the fact that it expresses a (conceivable, not necessarily existing) state of affairs" (Carnap (1928) in Carnap, 1967, p. 325). Eventually

Carnap and the other members of the Vienna Circle succumbed to Wittgenstein's verifiability doctrine of meaning, according to which the meaning of a sentence consists in the way it can be verified – i.e. in its truth conditions. (Cf. Schlick, 1932/33.) If a sentence belongs to empirical science, the truth conditions must describe procedures of empirical test. Whence *Meaning = Testability*. And because only observational statements are empirically testable, *Meaning = Observability*. Put negatively: Whatever sentence is not verifiable by observation is empirically (= cognitively) meaningless.

This strict thesis was somewhat liberalized later on but without relinquishing the dependence of meaning on testability. The criterion that ultimately prevailed in the logical empiricist camp was this: A sentence is empirically (or cognitively) significant only if its sole extralogical constants are observational (e.g. 'sticky' and 'smelly') or if, conjoined with further sentences, it entails observational sentences (Carnap, 1956, 1963a; Rozeboom, 1962). In the latest version of this thesis testability need not be scientific hence objective: "I regard as meaningful for me whatever I can, in principle, confirm subjectively" (Carnap, 1963b, p. 882). Once again the subjectivist component of empiricism won out.

We criticized earlier the identification of meaning with testability (Ch. 4, Sec. 3.3). Suffice here to remark that false statements are as meaningful as true ones, and that all scientific theories contain incompletely testable or even wholly untestable statements: for example, quantum mechanics allows one to compute the velocity of an electron in an atom, which is an empirically inaccessible function. Let us undertake to state, even if in summary, the actual relations between meaning and testability.

It is a rule of scientific method to abstain from assigning truth values, except for the sake of argument, until after the relevant empirical evidence is at hand. In other words, testing is necessary for truth value: *Truth value ⇒ Testing*. In turn, a necessary condition for any actual tests is that the statement concerned be testable, i.e. that the theories and the empirical techniques of the day judge the statement to be susceptible of being confronted with facts, if not right now later on. In sum, *Testing ⇒ Testability*. Now, if a statement is susceptible to test then it is meaningful to begin with, i.e. it has a nonempty sense and a reference class – which may, alas, prove to be empty. Otherwise it would be impossible to devise a test for the statement. Briefly, meaningfulness, though insufficient for testability, is necessary for it: *Testability* ⇒ *Meaningfulness*. Finally if a statement is factually meaningful, i.e., if it has a factual sense and a factual reference (whether actual or possible), then it is well formed, i.e. syntactically meaningful in some formalism. (For a definition of the latter notion of meaningfulness see Tarski (1956), p. 284.) In short, *Meaningfulness* ⇒ *Well-formedness*.

In conclusion, the complete *logical* chain is

> *Truth value* ⇒ *Testing* ⇒ *Testability* ⇒ *Meaningfulness* ⇒ *Well-formedness*.

Consequently the *methodological* sequence is

> *Checking well-formedness* → *Assigning or analyzing meaning* → → *Judging testability and devising tests* → *Actual testing* → *Assigning truth value.*

5.2. *Meaning and Use*

At about the same time as Carnap was working out the *Tractatus*' view on meaning, Wittgenstein was busy demolishing it and attempting to sketch a pragmatist philosophy of language. On this view language is only a social activity and the meaning of an expression consists in its use. In turn, uses are established by custom as recorded by the (Oxford) dictionary – not by any theoretical analysis. As one of the disciples put it, "To give the meaning of an expression (in the sense in which I am using the word) is to give *general directions* for its use in making true or false assertions" (Strawson, 1950). Therefore "Ultimately a meaning-statement (a statement as to what a linguistic expression means) is to be tested by determining what people do in their employment of the expression in question" (Alston, 1968, p. 145).

What the second Wittgenstein and his apostles were interested in was, of course, the notion of *pragmatic meaning*. This concept can be exemplified but has so far escaped theoretical elucidation. (Only the notion of pragmatic synonymy has been elucidated – not by the Wittgensteinians but by Carnap (1939) and Naess (1956).) In any case it is different from the concept of semantic meaning and no possible substitute for the latter. The same "general directions" for manipulating a bunch of symbols are consistent with alternative significations assigned to those symbols. For this reason linguistic pragmatism cannot explain why two quantum physicists, while disagreeing on the significance of the symbols they use, can arrive at the same formulas. While linguistic pragmatism is incompetent to tackle semantic meaning, it can be effective in misleading philosophers into thinking that meanings can only be discovered by listening to (ordinary) talk rather than by uncovering sense and reference. Surely field observations can disclose pragmatic meanings – provided they are conducted with the methodological apparatus of the linguist. It is linguists not philosophers who are equipped to carry out linguistic investigations. Philosophers should philosophize about linguistics among other things – not language.

5.3. *Meaning and Understanding*

The significance of a sign and the meaning of the construct it designates must not be mistaken for the mental process of understanding either. Meanings are supposed to be objective whereas the experience of thinking of them is, like any other experience, subjective. This distinction, which goes against the grain of empiricism, goes back to Bolzano, Lotze, Frege, and Meinong. It is consecrated by the distinction, emphasized in the Introduction to Volume 1, between philosophical semantics and the psychology of cognition and language, which is a branch of factual science.

The distinction between meaning and the understanding of meaning is correct provided meanings are not reified or turned into Platonic Ideas. With meanings as with their carriers, i.e., constructs, we may adopt a fictionalist stand: we may *pretend* that they exist – without however assuming that they have an *autonomous* existence. No rational beings, no constructs; no constructs, no meanings. We have no use for the idealist thesis that there are concepts and propositions in themselves, i.e. apart from thinking beings. But if we wish to build a *theory* of constructs that brushes aside the particular ways and circumstances in which constructs are being thought, then obviously we must abstract from such ways and circumstances. Such a theory cannot possibly enter into conflict with any psychological theory concerning the understanding (or the misunderstanding) of a meaning, since it will not pose the question.

Although the concepts of meaning and of understanding belong to different fields of research, they are related, namely thus: *If anything* *is understandable then maybe it is meaningful.* ('Maybe' because any claim to intelligibility is of uncertain value.) Practical consequence: The clearer and more orderly the presentation of a body of knowledge the better the chances of understanding it. It does not follow that axiomatics is the ideal didactical wrapping. It does follow that a judicious combination of axiomatics with intuitive remarks and a statement of motivations is the best one can do to *facilitate correct understanding.* (See Bunge, 1973b, Ch. 8, Sec. 6.)

Not surprisingly, recent work in psycholinguistics and in artificial intelligence bears out our thesis that isolated sentences are nonsignificant, hence unintelligible. In fact to understand a sentence a person (or a computer) must know the language the sentence belongs to, must be able to do some reasoning, and must have some substantive information (Winograd, 1972).

A last question: Can computers grasp any meanings? The short answer is: No, because they handle physical signals not constructs. It is the programmer who assigns to these signals definite constructs, hence the meanings of the latter: he does this when setting up or using his programming code. In particular when he reads (interprets) the computer output – or, for that matter, when he reads anything. Unlike its programmer, the computer does not have to and cannot possibly interpret anything. So much so that a computer is incapable of making interpretation errors: only rational beings can make semantic mistakes. Computers are used not because they replace minds but because they simulate some aspects of the human mind. Only a living brain can have a whole mind of its own. And only some brains pose new conceptual problems, invent theories, and evaluate the latter. For a computer to understand a sign (e.g. a sentence) consists in associating it to the correct state (of the machine) to produce a final output (or machine state) according to a definite rule included in the program. No understanding of meaning is involved in this purely physical operation.

5.4. *Factual Meaning and Covariance*

Place words like 'here' and time words like 'now' do not have the same significance for everyone: they are subject-dependent or egocentric. Similarly space and time coordinate values are local not universal. Hence a statement such as ⌜Particle p is at place x at time t⌝, even if true relative to some reference frame, is not universally true, i.e., true in, or relative to, every possible reference frame. (But if we know how the given frame is related to some other frame then we can translate the statement into another statement that will hold in, or relative to, the new reference frame. The Galilei and the Lorentz transformation formulas are two such translation devices. Recall Ch. 3, Sec. 2.3).

In other words, position and time values are not *invariant* under every coordinate transformation. (On the other hand electric charge and transition probability values are invariant.) And statements involving position and time coordinates are not always *covariant* (or form invariant) under certain coordinate transformations. In either case, what is at stake is the permanence, or lack of it, under changes in the mode of representing or mapping facts in spacetime: invariance (or noninvariance) in the case of properties, covariance (or absence of it) in the case of law statements. For example, a Galilei covariant formula holds in every Galilei frame, i.e. it is covariant under the group of Galilei transformations. This is the case with Newton's basic equations of motion, not however with their solutions: the latter are frame-dependent – but at least we know how to translate them into statements that are true in, or relative to, alternative frames. But Newton's equations are not covariant under different coordinate transformations such as Lorentz'.

It is tempting to conclude that only invariant properties and covariant equations have a factual or objective meaning, all others being endowed with a subjective meaning if any. Thus Weyl (1919, p. 129) held that a relation between points in spacetime has an objective meaning (*objektive Bedeutung*) just in case it is invariant under Galilei's transformations. But then Galilei's law of falling bodies, a special solution of Newton's equations of motion, would be devoid of objective meaning because it is frame-dependent (not covariant). This is an abuse of the word 'meaning'. What is really at stake is *truth* not meaning: A statement involving spatial or temporal concepts (e.g., spacetime coordinates) and making explicit reference to some frame can be fully meaningful without being *universally true*, i.e., true in (relative to) every possible frame.

But what is invariant (or else covariant) under a certain transformation group may cease to be so under a different group. Thus while the relation of simultaneity is Galilei invariant, hence absolute in Newtonian physics, it is assumed to be frame-dependent, hence relative, in relativistic physics. In the latter context, therefore, a statement of the form ⌜Events *a* and *b* are simultaneous⌝ is regarded as being ill formed unless the context makes it clear which reference frame has been adopted. Relative to a certain frame f it may be that the two events are simultaneous, but then they may fail to be simultaneous relative to an alternative frame f'. Consequently the corresponding statements will not be universally true but instead locally so. In obvious symbols: while $\ulcorner S(a, b, f)\urcorner$ may be true, hence meaningful, $\ulcorner S(a, b, f')\urcorner$ may be false, hence meaningful as well. On the other hand Weyl inferred that simultaneity has no objective meaning (Weyl, *op. cit.*, p. 146). Which, in addition to being a semantic mistake, contradicts his earlier statement that Galilei invariants are meaningful.

Hilbert went even further by demanding the covariance of all statements, basic and derived, theoretical and experimental, under the most general coordinate transformations, i.e., those occurring in general relativity. In fact he stated that "a proposition that is not invariant under every arbitrary transformation of the coordinate system must be regarded as *physically meaningless*" (Hilbert, 1924, p. 274). Equivalently: "a proposition is invariant and has therefore a physical meaning if it holds for every arbitrary coordinate system" (Hilbert, *op. cit.*, p. 278). As with the cases of Galilei and Lorentz invariance discussed a while ago, what is actually involved is a criterion of universal (or frame-independent, hence observer-free) *truth* not one of factual *meaning.*

Hilbert, and Weyl before him, may have been using the term 'meaning' in a colloquial sense for, taken literally, their sentences concerning objective meaning are meaningless. In any case they should not be construed as formal definitions of "meaning" as covariance. (See however Suppes, 1967.) If they were so construed then almost every physical statement would have to be ruled out as meaningless. Only the *basic* physical law statements, such as the variational principles and their immediate consequences, can be required to be covariant with respect to certain transformation groups: their solutions *must* be frame dependent (relative) if they are ever to be subjected to experimental tests, for test devices are in the habit of being attached to some frame or other and of yielding results that are seldom the same for every other frame (Bunge, 1961a, 1967b).

Examples like the following have been offered in support of the claim that covariance (of some kind) is required for objective meaningfulness. ⌜The car is at rest⌝ is not an invariant (or frame independent) statement, for the same car is really moving relative to almost every reference frame other than our planet. That statement is an instance of an incomplete or ill formed statement. The complete, well formed statement is ⌜The car is at rest in (or relative to) the ground⌝ (or the ferry or whatever may be the case). The latter statement is unobjectionable: it is meaningful and perhaps even true. But it is not generally covariant: it holds (is true) relative to one frame only. To disqualify ⌜The car is at rest⌝ we do not need a requirement as severe as general or even Lorentz or even Galilei covariance. Our criterion of meaningfulness in Sec. 2.3 will suffice, for the predicate "is at rest" does not belong to any body of contemporary factual knowledge: the concept of velocity, in particular zero velocity, involves the one of reference frame. Indeed, the velocity function is a certain function on the set of ordered triples: physical system p – reference frame f – velocity unit u. Hence while ⌜$V(p, f, u)=0$⌝ is well formed and meaningful, ⌜$V(p)=0$⌝ is not. This simple solution to the problem squares with actual scientific practice. And it is far more economical than replacing ordinary logic by some system of three valued logic (true, false, and meaningless) in order to accommodate freaks like ⌜$V(p)=0$⌝ or ⌜The mass of c equals 5⌝, as has actually been suggested (Suppes, 1959, 1965, 1967). As emphasized in Sec. 2.3, scientific constructs are not to be judged, let alone tampered with, in isolation from the theories they belong to, for the simple reason that only such theories exhibit their form and content. In particular scientific theory, not philosophy, is competent to determine whether or not (*a*) a given formula in scientific discourse is well formed and meaningful and (*b*) a given magnitude (or physical quantity) is frame independent or unit free or both (Bunge, 1971a).

In conclusion, invariance and covariance have nothing to do with meaningfulness, nor even with objectivity. Most of the known, meaningful, and even partially true formulas of physics are not generally covariant. Covariance, then, is not necessary for meaningfulness. Nor is it sufficient, as it is possible to propose any number of formulas that are covariant with respect to certain transformations but are devoid of factual meaning. Consequently covariance does not define meaningfulness. On the other hand covariance is necessary (though insufficient) for frame independent (hence observer free) truth, a condition only a few basic law statements satisfy. (See Bunge (1959b) and (1967b).)

6. CONCLUDING REMARKS

Our view on meaning and significance combines sense with reference. Thus a term such as 'electron' signifies both "the lightest material unit of electric charge" and any concrete instance of this predicate. It therefore consecrates and systematizes the ambiguity of the word 'meaning' in ordinary languages – without however conflating the two meaning components.

In our semantics there is no separate theory of meaning. But for the meaning calculus sketched in Sec. 2.1, our theses on meaning are mostly definitions and they make sense only against the background of the theories of sense and reference expounded in Part 1. Once the latter are assumed our definitions of meaning, meaning change, significance, synonymy, and their kin, look natural and even trivial. In point of fact our definition of meaning as sense together with reference cannot compete in boldness with any of its rivals: that meaning is verifiability, or truth condition, or use, or understanding, or information, or general covariance, or what not. We are proposing the cowardly view that meaning is just meaning.

So far we have been concerned with that which makes a construct what it is – namely its sense and its reference. Change either and a different construct will emerge. Not so truth and extension: these bear on fully meaningful constructs of certain kinds and, if factual, they are determined *ab extrinseco* rather than by analysis. In particular, whereas every factual statement is born with a sense and a reference, it is assigned no truth value until after having been tested for truth (Sec. 5.1). Moreover every truth value assignment is corrigible in this case: the same factual statement may now be assigned a truth value, now another. This is why we could not tackle the problem of truth before. But now the moment of truth has come.

CHAPTER 8

TRUTH

Logicians and mathematicians may be envied (or perhaps pitied) for needing a single concept of truth, namely that of formal truth. And they must be commended for having subjected it to a rigorous theory, namely Tarski's, now incorporated into model theory. Moreover, since in this theory the concept of (formal) truth is derivative (definable in terms of satisfaction in a model), formal scientists need not regard it as basic. Besides, this concept of truth raises no questions of confrontation with any factual facts: in logic and mathematics checking and proving are purely conceptual operations.

Factual scientists and the semanticists of factual science do not have it so easy. They have to contend with a radically different concept of truth, as suggested by the typical statement ⌜Theory T is an approximately true representation of factual domain F (or a good approximation in view of the evidence concerning F)⌝. What is at stake here is the concept of *partial truth of fact*, which – in contrast to that of complete formal truth – does not occur in the semantics of formal science. In matters of fact there is not only factual reference but also, and consequently, adequacy or inadequacy with respect to fact. Moreover such adequacy or inadequacy is rarely complete: unlike logical truth and logical falsity, factual truth and factual falsity are not polar opposites but contraries since, though incompatible, they are not exhaustive. This is sometimes not realized because science employs ordinary logic, hence seems to espouse a two valued theory of truth. But logic is the theory of deduction not the theory of truth. It is perfectly possible to process logically a set of statements that are neither fully true nor completely false: this is what science does. Hence we need a theory of partial truth of fact consistent with ordinary logic. In the present chapter we shall explore a chromatic (many valued) theory of truth matching with black-and-white logic.

1. KINDS OF TRUTH

1.1. *Truth Bearers*

Granting that "truth" makes sense at least in some contexts, the very first questions we must try to answer are: (i) what kind of objects are the bearers of truth and (ii) what kind of object is truth itself. There is of course a number of views on this matter. All of them agree that sentences are involved in these questions and that sentences are physical objects (strings of sounds or written marks) belonging to some language or other. But the various views assign sentences different roles in relation to truth. Table 8.1 exhibits the main traits of the principal views. (We have not included the "no truth" view of truth, set forth by Ramsey (1931), for being so glaringly at odds with the practice of testing for truth.)

The first view, naive idealism, is entrenched in the Western modes of speech and thinking. It seems right in holding truth to be a property of propositions (as distinct from judgments and sentences), wrong in regarding propositions as eternal objects which man can only "discover". But at least this phantasy of the autonomously existing propositions is sometimes heuristically fertile. Thus a mathematician may claim that a theorem that has not yet been formulated, let alone proved, is true – and he may set out to "discovering it". The obvious criticism is that nonexisting objects have no properties. Just as my unborn great-grandson is neither here nor there, so unthought formulas are in no theory (except potentially) and a fortiori they are neither true nor false. Moreover, existing statements that have not yet been proved are conjectures that should be assigned no truth values except for the sake of argument. Likewise a factual hypothesis cannot be said to have been true (or false) from all eternity, even before it was formulated. We can assign it a truth value only after having subjected it to tests – and even so the assignment may be provisional. But the proposition must have been stated to begin with.

In conclusion we reject naive idealism. We retain however the idea that constructs, e.g. propositions, are distinct from both thoughts and sentences, and that they can be true or false. But instead of assuming that there are propositions in themselves we assume that, to exist, propositions must be thought or uttered (or written) by some rational being in some language or other. And rather than claiming that truth and

TABLE 8.1

Main views on the nature of truth and its bearers

View	Sentences	Propositions	Truth
Naive idealism, e.g., Platonic "realism".	Express some propositions (the known ones).	Timeless objects existing by themselves	Intrinsic property of propositions. These are T or F whether we know it or not.
Neoidealism, e.g. Frege and the early Russell.	Express all propositions.	The meanings of sentences.	The object denoted by a true sentence.
Naive materialism, e.g. nominalism.	Physical objects with a factual reference and a truth value.	There are none.	Property of sentences in relation to their denotata.
Conceptualist materialism.	Express all propositions. Devoid of semantic properties except vicariously, i.e., via propositions.	Indispensable fictions – equivalence classes of certain thoughts.	Assignable to some propositions on the strength of others. Factual truth: relative, partial and ephemerous.

falsity are inborn, we assume that they can be attributed (in some degree) – as well as withdrawn. But we shall not elaborate on these psychological presuppositions: we shall take them for granted.

The second view, neoidealism, shares with Platonism the belief that there are constructs in themselves. But, unlike Platonism, it is muddled and even inconsistent. First truth and falsity are predicated of sentences (or of propositions, according to the way the ambiguous German *Satz* is translated). Next they are made into separate Platonic entities, *das Wahre* and *das Falsche.* Worse, truth value is equated with the referent, or nominatum, or designatum (*Bedeutung*) of the sentence (Frege, 1892). Thus the *Bedeutung* of ⌜Chimpanzees are clever⌝ will be said to be the same as that of $\ulcorner 2^2 = 4 \urcorner$, namely The Truth. This is not only a confusion but it renders the concept of reference unnecessary, as it makes all true sentences have the same "referent" (*Bedeutung*) regardless of their genuine referents. Frege could obviously afford to make a couple of mistakes. (Another mistake of his was to oppose the type of axiomatics initiated by Peano and Hilbert as well as the correlative notions of definition by postulates and conditional definition.) Unfortunately Frege's muddle has been taken seriously by some of the best logicians and philosophers of our time, such as Carnap (1947), Church (1951), Kemeny (1956) and Ajdukiewicz (1967b). (On the other hand Russell overcame this confusion.) We shall do well to keep clear from this muddle while retaining instead the distinction (made by Bolzano, Frege, Russell and Carnap) between sign and construct as well as Frege's notion of sense (*Sinn*) – which, unfortunately, he did not elaborate on. (Recall Ch. 4.)

The third view, naive (or vulgar) materialism, is best represented by Buridan, Hobbes, Hilbert, Tarski, and Quine. Like naive idealism it is simple, clear, consistent – and mistaken. A sentence, *qua* string of sounds or ink marks, is an object for physical science (e.g., acoustics or chemistry). A physical object becomes a linguistic object the minute it is regarded as a medium for expressing something. As the astronauts have discovered, in an uninhabited world there are no more sentences than there are propositions: at most there may be inscriptions – the bones of dead sentences. Further, sentences can be well formed or ill formed. If the former then they may but need not express any propositions. Thus 'Aleph zero took a bath' is a sentence that stands for no proposition: this is why it is devoid of significance. (If sentences were assigned truth values then, to make room for nonsignificant or nonsensical sentences, we should adopt some system of three valued logic – which, to say the least, would be unpractical.) Finally a metaphysical point: to attribute to strings of marks or sounds any semantic properties, such as meaning and truth, is to indulge in hylemorphism *à la* Plato or Husserl. Following Leibniz (1703) we assume then that propositions, not sentences, are the direct bearers of truth: sentences can only be vicariously true.

We are thus left with the fourth view, conceptualist materialism – a sort of materialist version of conventionalism. It can be summarized as follows. Propositions are a kind of construct and as such they are useful fictions: we do not claim that they exist by themselves but only that it is often convenient (for example in mathematics but not in metaphysics) to feign or pretend that they do. We do not assert that the Pythagorean theorem exists anywhere except in the world of phantasy called 'mathematics', a world that will go down with the last mathematician. And we do not pretend that unknown propositions exist but find it advantageous to proceed *as if* all the logical consequences of a proposition, both the few known ones and the infinitely many unknown ones, did exist in some conceptual context. (After all this is what the most fervent nominalist does when he equates an axiomatizable theory with the set of consequences of the axioms of the theory.) In this way we keep the heuristic and metatheoretical advantages of Platonism, which allows us to handle infinite sets of statements, only a tiny fraction of which will ever be formulated, even less justified. But we avoid the weird metaphysical hypothesis that every possible proposition actually exists in a ghostly Realm of Ideas.

Our view can be clarified by contrasting it to the prevailing doctrine of truth, namely Platonism. To a Platonist such as Frege every proposition exists from all eternity and has a truth value even if we do not know which one. This is one reason for defining a proposition as anything that is either true or false. In our semantics propositions are not so defined: they are characterized instead together with predicates, namely thus: a predicate is a function from objects of some kind to propositions. (Cf. Ch. 1, Sec. 1.3.) Once we have formed a proposition we may *find out* its meaning and *assign* it a truth value. Meanings are discovered by investigating both the reference and the context (e.g. theory) in which the propositions dwell. In any case propositions are born with a fixed meaning. There is no such thing as a meaningless proposition (in contrast to a sentence devoid of significance). True, it often takes a lot of work to discover the full meaning of a proposition: it requires displaying the full context and the logical relations in it.

On the other hand propositions are not born with a truth value: this one is assigned, if at all, once the proposition has been formulated. There are propositions that have not yet been assigned a truth value, e.g. because we have been unable to prove (or disprove) them or confirm (or infirm) them empirically. Surely, if p happens to be a theorem entailed by premises which have already been evaluated, then we *discover* the truth value of p by proving p. But not all propositions are provable. Axioms are not, nor are data. And if a proposition is not provable then there is no truth value to be discovered. If p is not a theorem then either we assign p a truth value (on some ground or just for the sake of argument) or we don't. If we do, our assignment may be criticized and exchanged for another: we shall say that the truth value of p in the light of evidence e (empirical or theoretical) is v, only to point out that a different body e' of evidence might suggest a different truth value v'. And if we refrain from assigning p a truth value, e.g. for want of means or of interest, then p remains a proposition though one without a truth value. Which ruins the Platonic conception of propositions.

1.2. *Truth Values: Acquired*

Being constructs, propositions are *designated* (or expressed) by linguistic objects of a certain category, namely sentences. And, being constructs, propositions *have* a sense and a reference – the latter either actual or hypothetical. In addition to having a sense and a reference, some (actually most) propositions *can be assigned* a truth value. And a few such potentially true or false propositions are *actually assigned* a definite truth value – a value that need not be unalterable. To put it negatively: Not every proposition can be assigned a truth value, nor is every truth value assignment final.

To be more explicit, the following kinds of proposition are assigned no truth value at least within certain contexts:

(i) the propositions that are not decidable in (with the sole resources of) a given theory have no truth value in this theory;

(ii) the propositions containing empty descriptions, such as "the perfect man", are neither true nor false – unless they assert or deny the existence of their imaginary referents;

(iii) the statements that are formulated, but are neither postulated nor proved nor confirmed nor made plausible, have no definite truth values. For example, ⌜$p \vee \neg p$⌝ in intuitionistic logic, and ⌜There are black holes⌝ in current astrophysics and cosmology.

Since not every statement can be assigned a truth value we shall construe the truth value assignment (function) $\mathscr{V}$ as a *partial* function, i.e. as a function on a proper subset S_D of the set S of all statements. (I.e., we adopt the truth value gap view.) We shall characterize $\mathscr{V}$ in Sec. 3. But before doing so we must discriminate among the various kinds of truth, for different kinds call for different value assignment procedures.

Figure 8.1 summarizes our views so far.

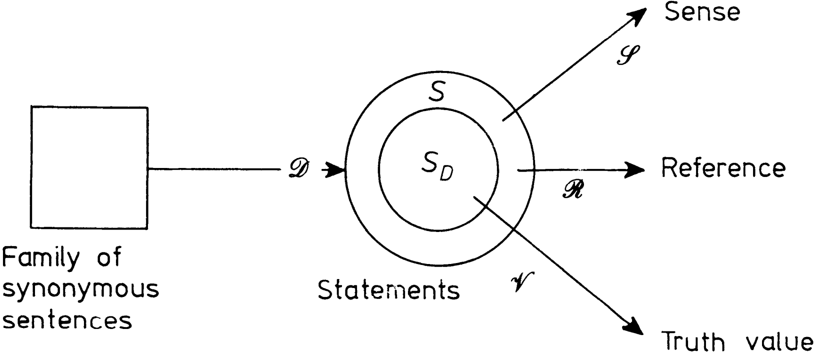

Fig. 8.1. Every set of synonymous sentences designates a statement in S. Every statement has a sense and a reference. Some statements are assigned a truth value.

1.3. *Quadruple Truth*

Consider the statements in Table 8.2, every one of which may be regarded as being true in its own context.

It would be nice if all these statements were true in the same manner, i.e., if a single concept of truth were applicable to them all. If this were the case then either the coherence or the correspondence doctrine might be able to span the whole set of statements. And if the former were the case, i.e., if every true statement were a *vérité de raison*, then model theory might suffice. That is, the semantics of mathematics would account not only for statements such as ⌜Formula ϕ is true in model M⌝ but also for propositions like ⌜The cost of living is rising steadily⌝. Unfortunately model theory does not help us with the second one nor with any statement in factual science, for the latter contains only fully interpreted formulas whereas model theory applies only if alternative interpretations (in mathematical structures – not with reference to the world) are possible. (Cf. Ch. 6, Sec. 2.) In particular, model theory is competent to handle formulas that hold under every interpretation of the variables involved – i.e. in all models. (These are the tautologies.) In sum model theory, which formalizes and systematizes the coherence view of truth, is not universal: it does not even apply to the whole of mathematics.

TABLE 8.2

Four kinds of truth: logical, mathematical, factual, and philosophical

Kind	Example
1 *Logical*	For any statement p, $\neg(p \mathbin{\&} \neg p)$
2a Abstract	In a Boolean algebra, for any element x, $x \wedge \bar{x} = 0$
Mathematical	
2b "Concrete"	In an algebra of sets, for any set S, $S \cap \bar{S} = \emptyset$
3a Theoretical	Let p_0 be the probability of allele A in the first generation and μ the mutation rate from allele A to allele a. Then the probability of the old allele A in the nth generation is $p_n = p_0(1-\mu)^n$
Factual	
3b Empirical	Almost all the individuals in the 100th generation of the bacillus X were observed to be mutants in the trait Y that had been observed in the fraction p_0 of the original population
4a Semantical	Meaning precedes truth
Philosophical	
4b Metaphysical	Every thing changes

On the other hand the correspondence theory of truth leaves us in the lurch with regard to logic and mathematics, which need not fit any facts in order to be valid. And it is unlikely that a third view could apply to all kinds of truth; at any rate no such all-encompassing theory seems to have been proposed. We had better recognize that the word 'truth' designates at least four different concepts, every one of which must be characterized in its own way: logical truth, mathematical truth, factual truth, and philosophical truth. Table 8.3 exhibits some of the salient peculiarities of mathematical truth and of factual truth. We shall take a

TABLE 8.3

Characteristics of three kinds of truth

Mathematical		Factual (e.g., biological)
Abstract (e.g., lattice theoretical)	"Concrete" (e.g., number theoretical)	
No formula has a truth value by itself, independent of an interpretation.	Most formulas have a truth value. Only the undecidable propositions lack a truth value (in the system in question).	Many formulas are assigned a truth value.
A relation between uninterpreted formulas and definite conceptual structures (models)	A relation between assumption and consequence.	A relation between statements and their referents.
Definable in terms of satisfaction (e.g., x satisfies ϕ in M) or of proof. Hence dispensable.	Definable in terms of provability in the case of syntactically complete theories. Hence dispensable in this case.	Not definable but characterizable. Indispensable.
Holds in a whole category of structures, e.g., the category of groups.	Holds only in a limited context, i.e., the theory of a model.	Holds only for a limited domain.
Can be total.	Can be total. Exception: approximation theory.	Can be total only in simple cases. Most theoretical factual statements are only partially true.
No decision procedure in most cases.	Usually decidable by proof or by counterexample.	No decision procedure. Only specific criteria for estimating truth values.
Truth valuation a purely rational procedure: experimenting infrequent and only heuristically valuable. Hence truth value independent of the world.		Truth valuation based partly on observation. Hence truth value contingent upon the world.

closer look at the former in Sec. 2.1, whereas the *vérités de fait* will be examined in Sec. 2.2.

2. TRUTH OF REASON AND TRUTH OF FACT

2.1. *Truth of Reason*

A truth of reason is, of course, one that can be established by reason alone. A number of kinds of truth of reason have been distinguished, among them the following.

(i) *Dictionary truth* or *veritas ex vi terminorum* – e.g., a nominal definition.

(ii) *Truth by request* or postulation – e.g., a postulate in a mathematical theory.

(iii) *Truth by proof or deduction* – e.g., a theorem in a mathematical theory.

(iv) *Logical truth* or *veritas ex vi formarum* or tautology – e.g., any valid formula in a given system of logic.

(v) *Truth by exemplification* or satisfaction in a model.

The first two hardly deserve to be classed among truths: dictionary "truths" are mere conventions; and mathematical postulates are proposed because they summarize theories not because they are assumed to be true in themselves. (If abstract they may be true in or relative to some model, if "concrete" they generate truths by deduction.) The third, truth by deduction, is another case of abuse of the word 'truth': if its peculiarity is that it is deducible from a set of assumptions then the concept of truth is redundant here. Only the last two concepts of truth are legitimate, namely those of true under all interpretations (logical truth) and true under some interpretations (mathematical truth). They are the object of model theory (Tarski, 1954–55; Robinson, 1963; Bell and Slomson, 1969; Chang and Keisler, 1973). We shall presently take a look at the model theoretic concept of truth – but only to better clarify, by way of contrast, the notion of factual truth.

Consider the formula $\phi = \ulcorner x^2 + x = 0 \urcorner$. This semiabstract formula is *satisfied* by the number -1, i.e. it becomes a *true* formula when x is interpreted as -1. Equivalently: the valuation $x := -1$ satisfies ϕ or produces a true statement. Also: ϕ is *satisfiable* in the structure $\mathscr{Z} = \langle Z, +, -, 0\rangle$, where Z is the set of integers. But the very same formula is also satisfied by the negative of any unit matrix I. Equivalently: ϕ is *satisfiable* in the ring $\mathscr{M}$ of square matrices. And so on and so forth. In symbols:

$$\models_{\mathscr{Z}} \phi(-1), \qquad \models_{\mathscr{M}} \phi(-I), \quad \text{etc.}$$

The notion of satisfaction can be extended to a set of formulas. For example, all of the axioms of the abstract theory of groups are satisfied by, or hold for, the integers. A proof that the structure $\mathscr{Z} = \langle Z, +, -, 0\rangle$ is or exemplifies a group $\langle S, \circ, ', e\rangle$ consists in showing that the valuation (interpretation)

$$S := Z, \qquad \circ := +, \qquad ' := -, \qquad e := 0$$

satisfies the axioms of group theory taken jointly. In other words, these abstract formulas (open formulas), when assigned the above interpretation, become formulas recognized as true in a specific (often familiar) field – in this case elementary number theory. The validity of the latter goes unquestioned in the proof. What one shows is that one conceptual structure (the abstract one) fits another conceptual structure (a specific or "concrete" one) – a clear case of *truth as coherence.*

This model theoretic concept of truth as satisfaction in a model serves to define the concept $\vdash$ of deducibility, namely thus. The formula ⌜If x and y are in L, then $x \wedge y \preccurlyeq x \vee y$⌝ can be said to *follow* from the axioms of lattice theory because, in *every example* of a lattice, meets precede joins. On the other hand a special theorem for chains, such as ⌜For any x and y in L, $x \preccurlyeq y$ or $y \preccurlyeq x$⌝, does not follow from the axioms for L. In general: let A be an abstract axiom system and let ϕ be a formula containing only concepts occurring in A. Then $A \vdash \phi$ iff every model of A is a model of ϕ, i.e. $A \models \phi$. This relation between $\vdash$ and $\models$ is easily generalized to a whole set S of abstract formulas. Call $\mathscr{M}(S)$ the whole lot of structures in which the formulas in the set S are satisfiable. Then the theory of $\mathscr{M}(S)$ is the set $\mathscr{C}n(S)$ of logical consequences of S. The notion of truth by proof is thus reduced, in a sense, to that of truth by exemplification or truth in a model. That this does not eliminate the methodological differences in proof types and procedures is beside the point: semantics is not concerned with methodological problems.

We have recalled succinctly the model theoretic concept of truth only to bring out its differences with the concept of factual truth employed in factual science. The most outstanding differences are these:

(i) The objects said to be true in some (extensional) model, or under some interpretation, are *abstract formulas.* What satisfies or fails to satisfy an abstract formula is always some construct or other. Because snow is not a mathematical object, it makes no sense in mathematics to state that snow satisfies the semiabstract formula $\ulcorner x$ is white$\urcorner$. Nor does it make sense in the context of factual (ordinary or scientific) knowledge, unless we are willing to assign a semantic property to a material thing.

(ii) An abstract formula, or propositional function, if satisfiable, and a fortiori if valid, is so *in one or more models.* By contrast, a factual statement need have no mathematical status at all: think of $\ulcorner$There are many beautiful children$\urcorner$. Moreover a factual statement, if true (to some extent), is true *of* the world not *in* a model. It would be ludicrous to write, say,

$\models_W$ Maxwell's electromagnetic equations, where W is the world.

if only because the real world is not a mathematically defined structure (an extensional model *à la* Tarski). The fashionable interpretation of models (or else of model sets in the sense of Hintikka (1969)) as possible worlds serves just one useful purpose – that of dressing Leibniz's notion of logical truth in modern garb. (To wit: p is logically true iff p holds under every interpretation of the nonlogical constants occurring in p, i.e. if p is satisfiable in every model – intuitively, if it holds in all conceivable, or conceptually possible, worlds.) This pseudo-ontological interpretation of model theory elucidates neither the concept of truth of fact nor that of real possibility. The former if only because truths of fact are more often than not partial, whereas a model set is constituted by formulas that are totally true under some interpretation. As to possibility, not any old model set describes a possible state of affairs or a possible course of events ("world"); only a set of law statements can do that. (The statements are at best approximately true when the possibilities are actualized. As long as the events are merely possible the corresponding statements do not form a model set.) Moreover, the translation of 'model' into 'possible world' has misled some philosophers into believing that, since logical truths hold (are valid) in every "possible world" (model or alternatively model set), and since the actual world is possible, logical truths must hold of reality, so that logic constitutes the basic ontology (Scholz, 1941) rather than a metaphysically neutral discipline. (More in Bunge, 1974a.)

To conclude. The model theoretic concept of truth elucidates the previously imprecise *coherence* theory of truth – contrary to Tarski's intention that it should formalize the correspondence theory. It also elucidates the notion of truth by proof. Consequently that semantic concept is of importance to pure mathematics. But it is irrelevant to factual knowledge, where we have not only coherence (or the fitting of constructs to one another) but also external reference.

Tarski's semantic conception of truth, in its mature (model theoretic) shape, revolutionized metamathematics. Moreover it drew the attention of some philosophers to a long neglected (or rather repressed) yet central problem of philosophy. But at the same time it persuaded some of the very best among them (notably Carnap, Popper, and Quine) that there was nothing problematic left about truth of fact. Yet Tarski's theory did not even attempt to grapple with the latter – so much so that all the technical work in model theory, starting with Tarski's pioneer papers (1936, 1954, 1955), is exclusively concerned with theories in pure mathematics – moreover with "formalized languages", i.e. abstract theories. Only an idealist could take model theory to be applicable to factual knowledge as well – since for him the world is a realization of an abstract idea. Let us then part company with model theory and take a fresh look at factual truth. (We shall return to Tarski's theory of truth in Sec. 2.4.)

2.2. *Truth of Fact: The Synthetic View*

A factual statement is one involving at least one factual predicate (see Ch. 6, Sec. 4.1). And factual truth (or falsity) is predicable of a factual statement in relation to some domain of facts and irrespective of its mathematical status.

Since the coherence theory of truth is not concerned with factual reference, it would seem that we must turn to the correspondence view of truth. According to the latter a statement is true if it fits the facts. Unfortunately the nature of this fitting has never been clarified: most of the time it is left in the twilight of metaphor, occasionally it is explained as isomorphism. Let us brush metaphors aside: they constitute no theory. Nor does the isomorphism thesis constitute a theory. To begin with isomorphism can only be defined between mathematically well defined structures – and reality is no such structure. Secondly, even the intuitive notion of isomorphism fails us here as shown by the facts that (*a*) every scientific theory contains constructs with no real counterpart and serving at the most as computational devices, and (*b*) every piece of reality ends up by showing traits that had not been contemplated by any theory. If there is correspondence between theory and facts it must be global not point by point. But it is doubtful whether this global correspondence can suffice to characterize factual truth. Indeed, consider the following cases, every one of which constitutes a counterexample to the (unformulated) correspondence theory of truth:

(i) ⌜There are no ghosts⌝ is factually true precisely because there is no such thing as a ghost.

(ii) Continuum mechanics is nearly true of most bodies – which are known not to be continuous.

(iii) The predictions and retrodictions calculated on theories assumed to be true refer to possible facts.

The reason for the failure to take the correspondence doctrine of truth beyond the metaphor phase and to have it surmount the indicated difficulties is both simple and radical, namely this. Statements cannot be compared or confronted with facts. Statements can only be confronted with other statements, and facts with other facts only. The expression 'Confronting a proposition with a fact' should be taken as short for 'Confronting a judgment (=brain process) with another fact' or, simpler, 'Thinking of a fact'. What holds for confrontation holds for fitting. A statement does not fit facts the way clothes fit people: it can only "fit" another statement, or "agree" with it barring certain details. In any case semantics is not equipped to investigate the mental processes of confrontation and adaptation of ideas to facts: it can only handle the confrontation among statements.

The following kinds of *inter-statement confrontation* are of particular interest to factual science:

$t-t'$ theoretical statements *vs.* theoretical statements
$t-e$ theoretical statements *vs.* empirical statements
$e-e'$ empirical statements *vs.* empirical statements.

Examples.

$t-t'$ The probability of a radiative transition of an atom from one energy level to another, calculated in nonrelativistic quantum theory, *vs.* the same probability calculated in relativistic quantum theory.

$t-e$ The probability of a radiative transition of an atom from one energy level to another, calculated in some theory, *vs.* the intensity of the radiation of a collection of atoms of the same kind, measured with a given equipment and technique.

$e-e'$ The intensity of the total radiation of a collection of atoms measured with a certain equipment and technique, *vs.* the values of the same magnitude measured with a different equipment and technique.

Any two statements can be put side by side. But if the aim is to estimate truth values then only statements with a *common meaning* (not necessarily identical) should be paired. In other words, for two statements to compete they must share some of their sense and some of their referents. (See Figure 8.2.) Thus while it may be fruitful to compare the values of a reaction time obtained by different methods, it would be foolish to compare either with the international price of sugar.

Fig. 8.2. Confronting scientific statements. Condition: both the senses and the reference classes must have nonempty intersections. Warning: $\mathcal{S}(e)$ and $\mathcal{S}(e')$ are rather vague.

The common meaning condition is most readily satisfied when the two statements are either theoretical or empirical. Difficulties arise when one of them is theoretical and the other empirical. And if the latter happens to be experiential (a sense datum), rather than observational or experimental, then there may be no point in confronting it with a physical object statement. For example, ⌜I am feeling hot⌝ differs both in sense and in referent from ⌜The present air temperature is 40 °C⌝. Hence neither can refute the other. In general, sense data are of little use in science precisely for this reason. Before a datum can become an item of evidence it must be depersonalized. But this is not enough: the datum must also be couched in the language of the theory it is supposed to be confronted with. For example, pointer readings must be interpreted as values of magnitudes handled by some theory. And before the latter can be confronted with any data it must be adjoined to special assumptions relevant to the situation that is being handled, as well as subjected to certain purely mathematical operations such as integration or substitution of reference frame. In short, the raw data are not comparable to the pure theory: the former must be lifted up to a theoretical level which is in turn lower than the axiom level. All this is a matter for the special sciences as well as for the general methodology of science (see e.g. Bunge, 1967a, Ch. 15, and 1973b, Ch. 10). It is also a matter for methodology to decide the conditions under which two comparable statements *agree* with each other, perhaps to within the preassigned experimental error. (See the next section.)

What is of overriding interest to semantics is (*a*) that the theory-fact confrontation boils down to confronting two sets of *statements*, and (*b*) that a theoretical statement is declared to be true if it "agrees" with some other *statements* (some of them empirical and others theoretical). It would seem that the coherence theory of truth does hold for factual science after all. It does but only in part: although a factual theory is true just in case it "agrees" with another set of propositions, all the parties involved – those in the dock as well as those in the jury box – happen to have a factual reference. We arrive thus at a sort of synthesis of the coherence and the correspondence views of factual truth – whence the name *synthetic* view. The coherence consists in inter-propositional agreement, the correspondence in factual reference. And the correspondence or degree of adequacy is tested by coherence: the latter supplies the criterion of truth not a definition of it. (Cf. Rescher, 1973.)

Another, no less important feature of factual truth of interest to semantics is this: it is *partial* more often than total – i.e. it comes in degrees. Figure 8.3 illustrates this contention (not contended by scientists though

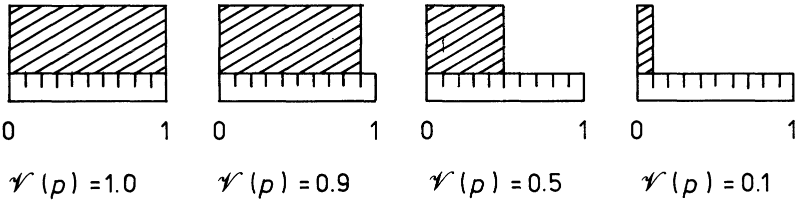

Fig. 8.3. Outcomes of a truth valuation of $p = \ulcorner$The box is 1 cm long$\urcorner$. (*a*) Complete truth; (*b*) approximate truth; (*c*) half truth; (*d*) near falsity.

brushed aside by logicians). The truth valuation function $\mathscr{V}$ occurring in the caption will be defined by Criterion 8.1 in Sec. 2.3. In the case of Figure 8.3 it is assumed that the ruler indicates its own actual length as well as that of the box. This hypothesis is the basis for assigning p a truth value.

2.3. *Truth Values: Conditional*

Although methodology is no substitute for semantics it may supply useful clues for investigating the semantics of science. In particular, if we wish to find out what factual truth is we shall find it useful to become acquainted with the way truth values are assigned in science. A very quick review will suffice for our purposes.

Whenever two statements, s and s', are confronted with a view to evaluating either of them, the following situations can arise:

(1) *Neither statement is taken for granted* (presupposed or assumed).

(*A*) *The two statements turn out to agree.* Unless there is a logical relation between them, both statements are assigned the same truth value: $\mathscr{V}(s) = \mathscr{V}(s')$. If s implies s' then $\mathscr{V}(s) \leqslant \mathscr{V}(s')$. In either case there is mutual confirmation but no independent assignment of truth values: for all we know the two statements could be equally false. (Moral: Confirmation, though necessary, is insufficient.)

(*B*) *The statements disagree.* They are assigned different truth values: $\mathscr{V}(s) \neq \mathscr{V}(s')$ – but we still do not know how much each is worth. (Moral: Refutation too is insufficient.)

Upshot: If neither of the two statements is assumed, at least provisionally, the other cannot be assigned a truth value either.

(2) *One of the statements, say s, is assumed* (unquestioned in the given investigation).

(A) *The two statements turn out to agree.* Both are assigned the same truth value, namely one or nearly so. Possible cases:
- (*a*) Both statements are theoretical. Theory confirms theory.
- (*b*) s is theoretical, s' experimental. Theory endorses experiment.
- (*c*) s is experimental, s' theoretical. Experiment supports theory.
- (*d*) Both statements are experimental. Experiment supports experiment.

(*B*) *The statements disagree.* The statement under examination is assigned a truth value below unity: $\mathscr{V}(s') < \mathscr{V}(s) = 1$. Possible cases:
- (*a*) Both statements are theoretical. Theory infirms theory.
- (*b*) s is theoretical, s' experimental. Theory indicts experiment.
- (*c*) s is experimental, s' theoretical. Experiment infirms theory.
- (*d*) Both statements are experimental. Experiment indicts experiment.

(*C*) *The statements agree in a certain region R but disagree in $\bar{R}$:* see Figure 8.4. The statement under examination is assigned a truth value dependent on the point x of the explored area: $\mathscr{V}(s', x) = 1 - \varepsilon(x)$, where $\varepsilon(x)$ is the discrepancy between s' and the base line s at the point x. Possible cases:
- (*a*) Both statements are theoretical. Theory confirms theory in region R, disconfirms it in region $\bar{R}$.
- (*b*) s is theoretical, s' experimental. Theory confirms experiment in region R, indicts it in $\bar{R}$.
- (*c*) s is experimental, s' theoretical. Experiment confirms theory in region R, infirms it in $\bar{R}$.

(*d*) Both statements are experimental. Experiment strengthens experiment in region R, weakens it in $\bar{R}$.

Upshot: If one of the two statements is assumed, if only provisionally, the truth value of the other can be estimated or at least bounded.

We conclude that factual truth values are *conditional* or *relative* not absolute. Hence strictly speaking we should always write '$\mathscr{V}(s' \mid s)$', read 'the truth value of s' given, or assuming, s', instead of '$\mathscr{V}(s')$'. And, since there are only relative factual truth values in science, there would be no point in trying to analyze $V(s' \mid s)$ into the absolute truth values $V(s')$ and $V(s)$ similarly to the way conditional probabilities are analyzable into absolute ones. Which suggests that truth values cannot be probabilities. (More on this in Sec. 5.1.)

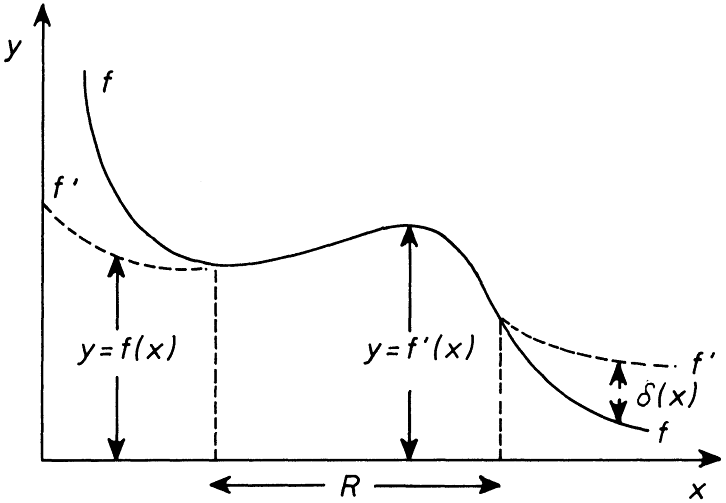

Fig. 8.4. A common situation in science: two statements, $s=(y=f(x))$ and $s'=(y=f'(x))$, agree in region R but disagree elsewhere. The relative discrepancy or error $\varepsilon(x)$ depends on the point x of the explored area and is proportional to the absolute discrepancy δ (x).

In general we shall not encumber our formulas with a symbol for the statement serving as a yardstick for the estimation of the truth value of another statement. But it will be convenient, nay indispensable, to indicate the baseline, in some way or other, whenever actual truth value assignments are made. A typical case in science is the evaluation, by alternative methods, of some magnitude M concerning an object b – for example the relative dilation of a metal bar. Suppose we have the following confrontation:

$$s = \ulcorner M(b) = m \urcorner \quad vs. \quad s' = \ulcorner M(b) = m' \urcorner,$$

where m and m' are rival numerical values obtained for the M-ness of b. (We are brushing aside, for being irrelevant to our purpose, the M-units as well as the experimental error.) The absolute value of the numerical discrepancy between the two statements is $|m' - m|$: this is the *error* made in accepting s' instead of s. If the error is small, then the truth value of s' will be close to that of s, i.e. near unity. But as the error increases the truth value of s' approaches zero. In general this error will depend on the referent b and its condition; hence the relative truth values themselves will exhibit this dependence.

The preceding considerations suggest the following

CRITERION 8.1 Let M and M' be two comparable functional representations of a given property of an object b, and let $s = \ulcorner M(b) = m \urcorner$ and $s' = \ulcorner M'(b) = m' \urcorner$ be estimates of M and M' respectively at b. Then the *relative truth value* of s' given (assuming) s equals

$$\mathscr{V}(s' \mid s) = 1 - \left| \frac{m - m'}{\mathrm{Max}\{m, m'\}} \right|$$

If the error is small, $\mathscr{V}(s' \mid s)$ comes close to 1; if the error is large, the truth value is near 0. *Example:* Let us compare the truth value of Boyle's law (B) relative to the law of Boyle and Mariotte (M), i.e., making the pretense that the latter is true. Since the statements are

$$M = \ulcorner p = aT/v \urcorner, \qquad B = \ulcorner p = b/v \urcorner,$$

we have

$$\mathscr{V}(B \mid M) = 1 - \frac{aT/v - b/v}{\mathrm{Max}\left\{\dfrac{aT}{v}, \dfrac{b}{v}\right\}} = 1 - \left| \frac{aT - b}{\mathrm{Max}\{aT, b\}} \right|.$$

Both for very low and very high absolute temperatures $\mathscr{V}(B \mid M)$ is near zero; it comes near unity for medium temperatures and certain gases. That truth values should depend on the kind of material and on the range of the physical variables involved may sound outrageous to both pure logicians and Platonists. But it is no news to a scientist, who is used to thinking of (factual) truth as holding to some extent *of*, or *with regard to*, definite external referents in definite conditions. This is precisely the peculiarity of factual truth: that it concerns facts. For this reason, as will be seen in the next subsection, the semanticist has no say in setting up truth conditions for factual statements.

Criterion 1 applies, in particular, to the comparisons of theoretical or calculated values with experimental values. In this case we have pairs of propositions such as these:

Theory $M(b)=m_t$, with m_t a knowable number

Experiment $M'(b)=m_e \pm \varepsilon_e$, with m_e and ε_e knowable numbers (m_e is the measured value and ε_e the random error characteristic of the particular run of measurements leading to m_e).

Unless the possible values of M are well spaced, the chances are that the theoretical value m_t and the central experimental value m_e differ from one another – and both from the real value. We need then definite criteria allowing us to make definite choices. One such criterion, actually used if not formulated explicitly in the sciences, is

CRITERION 8.2 Let m_t and m_e be a theoretical and an experimental estimate, respectively, of a magnitude M representing a property of a thing b. Then

(i) $\ulcorner M(b)=m_t \urcorner$ and $\ulcorner M(b)=m_e \urcorner$ are equivalent, to within the error ε_e, iff $|m_t - m_e| < \varepsilon_e$;

(ii) the "true" (or "real") value of M for b is close to m_t iff (*a*) m_t coincides with m_e to within ε_e (i.e. if (i) holds) and (*b*) $\varepsilon_e/m_e \ll 1$.

2.4. *Truth Conditions*

A truth condition (or criterion) for a set S of formulas is a metastatement stipulating the conditions under which the members of S are (fully) true. Example:

If x is a real number then $\ulcorner x^2 > x \urcorner$ is *true* iff $|x| > 1$ or, equivalently,

$\ulcorner x^2 > x \urcorner$ is *satisfied* by all real numbers x such that $|x| > 1$.

Tarski's theory of truth (Tarski, 1936), based on the concept of satisfaction, provides a general truth condition for all the *abstract* formulas of logic and mathematics and it has become part and parcel of model theory (see e.g. Hermes, 1963). Some philosophers believe that the same trick works for all statements, in particular for factual statements. (And it certainly should if, as Tarski and Quine hold, there is no radical difference between the factual and the formal nor, a fortiori, between the synthetic and the analytic.) Thus Carnap illustrates the theory by contriving a toy semantic system for an object language with 7 specific (extralogical) signs: the individual constants x_1, x_2 and x_3, the predicate letters P_1 and P_2, and the left and right parentheses (Carnap, 1942, pp. 22ff.). The atomic sentences are all of the form "$P_i(x_j)$" with $i = 1, 2$ and $j = 1, 2, 3$. There is one designation rule for every specific sign, in particular the following:

'x_1' designates Chicago.

'P_1' designates the property of being large.

The truth condition for the sentences of the microlanguage is

The sentence '$P_i(x_j)$' is true iff the designatum of x_j has the designatum of P_i.

An instance of this truth condition is, of course,

'$P_1(x_1)$' is true iff Chicago is large.

It would be nice if Tarski's theory of truth were a stretch theory fitting all kinds of statements, whether formal or factual. But it is not. First, in the body of factual knowledge there are no *uninterpreted* formulas, such as '$P_i(x_j)$', containing predicates with no fixed sense. Hence the possibility of having factual formulas satisfied in alternative models is not forthcoming – whence model theory is irrelevant to our concern.

Second, to say that Chicago *satisfies* the open formula $\ulcorner x$ is large$\urcorner$ involves assigning a nonphysical (namely a semantic) property to a physical entity – which is unacceptable to a non-Platonist. Things are the other way around: $\ulcorner x$ is large$\urcorner$ has the (semantic) property that, when the dummy x is replaced by a name for Chicago it becomes a true proposition.

Third, there is no *universal* truth condition for all of the (interpreted) formulas with a factual reference, from ⌜Chicago is large⌝ to the sophisticated equations of mathematical biophysics. There are at most regional truth conditions such as

> ⌜The city of x is large⌝ is *true* iff the population of x is over one million people.

In this simple case the truth condition proves to be a trivial convention of demography – one that is neither portable nor eternal nor stipulated by semantics. In other cases, *if* there are truth conditions they are more complex. And in any event they are laid down (and upset) by the competent discipline. It should be obvious why this is so: a factual truth condition depends on the specific meaning (sense and reference) of the corresponding statement as well as on the possible procedures for putting it to empirical tests. Consequently factual truth conditions cannot be cooked up by semantics.

Fourth, in factual science there are hardly any truth conditions having the neat form of biconditionals of the form: ⌜*A*⌝ *is true iff B*, a generalization of Tarski's principle: ⌜*A*⌝ *is true iff A*. The most we get in factual science are conditionals such as ⌜If the theory (or hypothesis) T is true then the effect e is observable⌝. (Or, equivalently, the corresponding counterfactual sentence 'If T were true then e would be observable.') But such conditionals work as clues for guessing at truth values not as criteria for assigning definite truth values. Indeed, the validation of the consequent e confirms the antecedent T without verifying it: in principle infinitely many alternative constructs T', T'',... might be substituted for T. It is only a whole lot of confirmations together with the compatibility of T with previously corroborated theories that allows one to (tentatively) assign (approximate) truth values to T. In sum, the normal situation in factual science is the lack of neat truth conditions and the presence of entire batteries of tests for (partial) truth (Bunge, 1967a, Vol. II, Ch. 15). And such assignments of degrees of truth are rarely final. (See Sec. 4.4.)

Fifth and lastly, since factual truth is rarely total, the truth conditions found in the usual treatments of mathematical logic are often inapplicable to it. A half truth such as ⌜Aristotle was a Chaldean philosopher⌝ fits neither of the standard truth conditions ⌜*A & B is true iff A is true and B is true*⌝, and ⌜*¬A is true iff A is not true*⌝. (Roughly, since one of the conjuncts is totally true and the other totally false, A & B is worth $\frac{1}{2}$ and so is its negate.) Hence logic, indispensable as it is for the control of inference, is utterly impotent to guide our assignment of factual truth values.

Instead of uniform and unchanging truth conditions, what we do meet in factual science are three kinds of conditions, all of them regional or subject matter dependent. We shall introduce them by way of example. Consider Galilei's law of falling bodies. There is, first, the *applicability condition* indicating the referents and the state they are in – for example a body immersed in a homogeneous gravitational field and in free fall in it. This condition occurs as the antecedent of the law statement: ⌜If a body falls freely in a constant gravitational field in vacuum, then G⌝, where $G = \ulcorner v(t) = gt + v_0 \urcorner$. The antecedent is not necessary for the truth of G but for its applicability or relevance: if the condition fails to hold the conditional is true but pointless. And the applicability criterion is *intra*theoretical: it owes nothing to test conditions. Rather on the contrary, testing presupposes that the applicability condition holds.

The second condition may be called an *ontological truth condition*, for it points to those referents that behave actually as indicated by the statement in question. In other words, the ontological truth condition for a statement is learned from experience and it exhibits the extension of the given formula. For example, the extension of G above is the collection of triples ⟨middle sized body, weak constant gravitational field, short time of fall⟩. This condition is *extra*theoretical and a posteriori. However, it is not theory free, for it sums up the outcome of tests conducted in the light of other (instrumental) theories and it evaluates the performance of the statement concerned in relation to (actual or possible) competitors.

A third and last metastatement of interest specifies the methodological conditions under which the given statement may be regarded as approximately true. It is, like the former, extratheoretical but, instead of specifying the kind of thing for which the statement holds (approximately), it concerns the particular empirical techniques employed in assaying it: this condition may therefore be called an *epistemic truth condition.* One such condition, in our example, would be this: ⌜G holds to within 1% for steel balls, in air, at sea level, and for distances of the order of 10 m, when tested with a sports chronometer and a commercial tape⌝.

All three conditions are special or subject matter dependent. Consequently they cannot be laid down by semantics. The semanticist may of course study them on condition that he leaves the methodological aspect to methodology and concentrates on the alethic aspect. But for this he needs a theory of degrees of factual truth, one elucidating the intuitive notion employed in factual science. We turn to one such theory.

3. DEGREES OF TRUTH

3.1. *The Problem and How to Fail to Solve It*

The notion of degree of truth, and the related notion of approximate truth, are employed everywhere in applied mathematics and in factual science. Examples: (*a*) most values of nonalgebraic functions, such as *log* and *sin*, are known only approximately; (*b*) all nontrivial measurement results are approximate; (*c*) all theoretical statements are, at best, good approximations – and we hope to be able to improve on them. Provided certain assumptions are made, i.e., provided some statements are taken to be wholly true, one can often estimate the goodness of the approximation, i.e., the deviation from the truth. In particular, one may compute (*a*) differences between values given by rival theories, (*b*) discrepancies between theoretical and empirical values, and (*c*) random errors of measurement. Mathematical statistics, by elucidating several concepts of error and computing their probabilities, helps us to estimate the deviation from the truth and, in this way, the degree of truth. On the other hand neither the theory of probability nor mathematical statistics have rules for assigning probabilities to either hypotheses or data: this assignment has always been a philosophers' game.

Since applied mathematics and factual science are shot through with the concept of approximate truth, it is a task for the semantics of science to elucidate this concept, i.e., to propose theories of degrees of truth matching scientific practice. There have been several attempts to do so. They fall into four main classes: (i) many valued logics (e.g. Moisil, 1972); (ii) the semantic interpretation of probability, i.e. the equating of probabilities and degrees of truth (e.g., Łukasiewicz, 1913; Reichenbach, 1949); (iii) Popper's theory of verisimilitude (Popper, 1963b), and (iv) the author's former theory of partial truth (Bunge, 1963a). None of these can be counted as successful, although the last may come close to providing a realistic explication of the concept of degree of truth, if only because it does not involve the mythical concept of probability of a statement.

Knowing why those attempts failed may help in avoiding similar mistakes. The reasons for those failures are, in a nutshell, the following. The systems of many valued logic may be mathematically interesting and they have exerted a liberating influence by showing that ordinary logic is neither logically necessary nor psychologically compelling. But none of them has attained the maturity needed to cope with actual deductive inference as practised in mathematics. None of them has ever been used in mathematics or in science, where ordinary logic is perfectly adequate. Moreover, none of them is likely to be used. First, because changing the logic in any one field of research would require changing it in all related fields: the revolution would have to spread all over mathematics and science in order to allow for contacts among theories. Second, it would be imprudent to relax the standards of criticism (Popper, 1970). Third, the main rationale for many valued logics is a mistake, namely the belief that logic should be a theory of truth. Logic must be regarded instead, in line with the Aristotelian tradition, as a theory of deduction not as a theory of truth. We should then be able to keep the calculi of ordinary logic even if we intend to adopt a many valued theory of truth. This policy will be implemented in the next subsection.

As to the probability theories of truth, they all rest on the mistaken assumption that there *are* ways of assigning probabilities to statements. In point of fact, whereas scientists often succeed in calculating and measuring probabilities of certain *facts*, e.g., events, no one has ever proposed a general procedure (other than arbitrary fiat or else betting) for assigning any probability values to *statements*. Mathematics would have nothing against it, for the set of statements qualifies as the support of a probability measure. But it so happens that there *are* no rules for assigning numerical values to such probabilities, as a consequence of which no one has ever succeeded in estimating the probability of any given factual statement. This difficulty alone disqualifies all the theories of truth degrees based on probability, whether they equate truth with probability or with some function of the latter. (More on this in Sec. 4.2.) On the other hand there are more or less definite rules for estimating relative degrees of truth, as we saw in Sec. 2.3.

Finally the author's previous theory of partial truth does not hinge on the concept of probability and it leaves ordinary logic intact. Besides, it incorporates the notion of discrepancy or error as it occurs in the theory of errors. However, it has some serious defects pointed out by the author himself (1963a) and by some readers. For one thing it overrates confirmation. For another its truth function is discontinuous. Thirdly, its multiplication theorem (or rather axiom) is so complicated that it is nearly impossible to compute by hand the truth value of a conjunction with a reasonable number of conjuncts. We shall presently expound an alternative theory of degrees of truth that shares the virtues but not the defects of the former theory.

The new theory to be presented is based explicitly on an *alethically neutral conception of logic* – one that can be attached to any number of alternative theories of truth. This construal of logic is nothing but an explicitation of Bolzano's remark that we should distinguish a proposition from the statement (actually a metastatement) that the proposition is true. Briefly, $p \neq \ulcorner \mathscr{V}(p) = 1 \urcorner$. One advantage of the neutral conception of (formal) logic is that it allows us to talk about partial truth and moreover to hitch any theory of partial truth to the calculi of ordinary logic. Scientists, though perhaps not formal logicians, will appreciate this advantage. A second advantage of this truth-free conception of logic is that it permits us to employ the dialectical method – in Parmenides' not in Hegel's sense. Indeed, the dialectical method, universally employed in mathematics and in science, consists roughly in exploring the consequences of an assumption *before* evaluating it and *in order to* evaluate it. To carry out this method we must assume that the propositions under examination obey the laws of logic whether or not they turn out to be true. The most we might need is the pretense that statements are true or false whether we know it or not. But we take this as a make-believe useful for heuristic purposes: we assume explicitly only that (some) statements *can be* assigned truth values, or rather truth degrees, not that they are born with an intrinsic and everlasting truth value.

Compare this formal or alethically neutral conception of logic with the alethic interpretations. Among these, the standard view is the model theoretic or referential one, which employs the notions of satisfaction and of (formal) truth, e.g., in setting up truth conditions such as truth tables. An alternative view that is receiving some attention these days is the so called substitution interpretation (Barcan Marcus, 1962). According to this view ‘$(\exists x)\, Px$’ should be interpreted as “Some substitution instance of Px is true” – and similarly for universal statements. Either view may be adequate for logic but, by the same token, it does not seem suitable for the applications of logic. For one thing they render the dialectical method inapplicable, insofar as they demand that every proposition be true or false from birth, whether we know it or not: i.e. it does not make room for tentative truth value assignments. For another, the alethic conceptions of logic employ a single concept of truth and moreover the one of total truth. If applied to factual science, where evidence is never complete and final, the alethic conceptions of logic may lead to the aberration of thinking that, precisely for those shortcomings, factual science need not abide by ordinary (classical) logic. (For a candid statement of this dangerous thesis see Birkhoff, 1961, Ch. XII.)

But enough of criticism: let us see how we can merge two valued logic with the idea that truth, unless it is formal, comes in any number of shades.

3.2. *Axioms*

Our theory of degrees of truth will treat complete truth and complete falsity as the two end points of a whole gamut of truth values, while retaining all the algebraic features of ordinary logic, for the latter is built into mathematics and science. In other words we shall (*a*) assume logic to be given in a purely syntactic fashion rather than with the help of (formal) truth values, and (*b*) join to it a valuation function $\mathscr{V}$ with values in a numerical interval, say the unit interval of the real line.

One way of implementing this programme is as follows. Consider the set S of all statements in a given field of inquiry, such as a scientific theory. Group all the statements in S that are logically equivalent to each other. That is, form the equivalence class $[s]$ of every statement s in S under the relation of logical equivalence: $[s]=\{s'\in S \mid \ulcorner s'\Leftrightarrow s\urcorner \text{ is a tautology}\}$. Call $[S]$ the set of all such equivalence classes, i.e. the quotient of S by the relation of tautological equivalence. It is well known that $[S]$ has the lattice structure. (This holds also for any extension of a given S but it need not hold for the union of arbitrary sets of statements, as they may be mutually incompatible. Thus the union of classical mechanics and quantum mechanics does not possess the lattice structure.) Moreover $[S]$ is a complete complemented and distributive lattice with null and unit elements – in short a Boolean algebra. The Boolean operations on the set $[S]$ of equivalence classes are defined in logical terms as follows: for any p, q, r in S,

$$\overline{[q]} = [p] \text{ iff } \ulcorner p \Leftrightarrow q \urcorner \text{ is a tautology}$$
$$[q] \cup [r] = [p] \text{ iff } \ulcorner p \Leftrightarrow q \vee r \urcorner \text{ is a tautology}$$
$$[q] \cap [r] = [p] \text{ iff } \ulcorner p \Leftrightarrow q \,\&\, r \urcorner \text{ is a tautology.}$$

Likewise the least element $\square$ and the last element ▯ of the Boolean algebra of the equivalence classes of statements are defined by

$$\square = \{p \in S \mid p \Leftrightarrow q \,\&\, \neg q \text{ and } q \in S\}$$
$$\text{▯} = \{p \in S \mid p \Leftrightarrow q \vee \neg q \text{ and } q \in S\}.$$

(It is true that the algebra of quantification is far more complicated than this. However we need not go into it if our purpose is restricted to computing the truth value of truth functional compounds in terms of the truth values of their components. Nor need we stop at the possible objection that the formulas of quantum mechanics fail to constitute a distributive lattice. This opinion is false: suffice it to recall that the quantum theories, just as any other scientific theories, involve only classical mathematics, which has classical logic in its bones. Cf. Bunge (1967b) and Fine (1968).)

We now assume that there is a real valued function $\mathscr{V}$, defined on a certain subset S_D of S, such that

$$\text{for every } p \text{ and } q \text{ in } S_D,\ \mathscr{V}(p \,\&\, q) + \mathscr{V}(p \vee q) = \mathscr{V}(p) + \mathscr{V}(q).$$

The statements in the complement $S - S_D$ have no truth value because none can be assigned to them. In this residual subset we find the statements in S that cannot be proved with the sole resources of S, as well as the statements containing empty descriptions, such as "The perfect man does not exist" and "The massless body is not affected by gravity". (See Ch. 9, Sec. 2.) In addition to the above conditions on the partial function $\mathscr{V}$ we shall postulate that $\mathscr{V}$ assigns contradictions the lowest truth value, namely 0, and tautologies the highest, namely 1. We shall also check whether our theory gives reasonable results in typical cases of scientific inference.

The foregoing is spelt out in an axiom disguised as

DEFINITION 8.1 The structure $\langle S, S_D, [S], \square, \text{▯}, \cup, \cap, {}^{-}, \mathscr{V}\rangle$, where S is a nonempty set, S_D a subset of S, $[S]$ the quotient of S by the relation $\Leftrightarrow$ of logical equivalence, $\square$ and ▯ distinguished elements of $[S]$, $\cup$ and $\cap$ binary operations on $[S]$, ${}^{-}$ a unary operation on $[S]$, and $\mathscr{V}$ a function on S_D, is called a *metric Boolean algebra of statements* iff

(i) the structure $\langle [S], \square, \boxed{\,}, \cup, \cap, {}^{-} \rangle$ is a Boolean algebra, i.e. a complemented and distributive lattice with null element $\square$ and universal element $\boxed{\,}$;

(ii) $\mathscr{V}$ is a real valued function on $S_D \subset S$ such that, for any elements p and q of S_D,

$$
\begin{aligned}
&(a)\ \mathscr{V}(p \,\&\, q) + \mathscr{V}(p \vee q) = \mathscr{V}(p) + \mathscr{V}(q);\\
&(b)\ \mathscr{V}(p) = 0 \quad \text{for all} \quad p \in \square;\\
&(c)\ \mathscr{V}(p) = 1 \quad \text{for all} \quad p \in \boxed{\,}.
\end{aligned}
$$

Condition (*a*) is common to all metric lattices or measure algebras. Conditions (*b*) and (*c*) determine the range of the values of $\mathscr{V}$. These three conditions are jointly necessary and sufficient to determine $\mathscr{V}$. However, they are not enough to compute the value of an arbitrary propositional compound from the values of its components. (In other words, condition (*a*) is not a full multiplication theorem.) However, we shall see in Sec. 3.4 that this partial indeterminacy is not a serious practical drawback.

Before going any further let us give two warnings. First, contrary to appearances, $\mathscr{V}$ is not a probability measure on S_D, if only because S_D is a set of individuals not a field of sets (a σ-algebra) – as it should if it were to qualify as a probability measure. More on this in Sec. 3.6 point ix. Second, we are dealing with closed bodies of knowledge rather than arbitrary sets of statements – let alone the totality of factual statements. The reason for the restriction is this. Every scientific theory, if consistent, is an ultrafilter (recall Ch. 5, Sec. 3.1). But not all scientific theories in use at a given time are mutually consistent. Hence their union does not constitute an ultrafilter. (Moreover: in general the union of two theories is not a theory.) In other words, Boolean algebra reigns within every theory but does not govern the totality of scientific propositions, not even in a given field of research.

3.3. *Topologies of S_D*

We shall presently show that S_D has two topologies of interest to semantics, given by so many metrics.

DEFINITION 8.2 The function $\delta_{-} : S_D \times S_D \to [0, 1]$ which assigns to each pair of propositions $p, q \in S_D$ a real number between 0 and 1, such that

$$\delta_{-}(p, q)=|\mathscr{V}(p)-\mathscr{V}(q)|,$$

is called the *horizontal distance*.

This name for δ_{-} is not metaphorical, for δ_{-} has in fact almost all the properties of a distance function, as shown by

THEOREM 8.1 The structure $\mathscr{M}_{-}=\langle S_D, \delta_{-}\rangle$ is a quasimetric space, i.e. the distance function δ_{-} satisfies the following axioms:

(i) $\delta_{-}(p, q)=\delta_{-}(q, p)$
(ii) $\delta_{-}(p, q)+\delta_{-}(q, r)\geqslant\delta_{-}(p, r)$
(iii) $\delta_{-}(p, q)=0$ iff $\mathscr{V}(p)=\mathscr{V}(q)$

for any p, q, and r in S_D.

The quasi metric δ_{-} defines a topology in the space S_D. An open ε-neighborhood of $p\in S_D$ is the set

$$U_\varepsilon(p)=\{q\in S_D \mid |\mathscr{V}(p)-\mathscr{V}(q)|<\varepsilon\} \quad \text{with} \quad 0\leqslant\varepsilon\leqslant 1.$$

This is the set of statements that are equivalent to the given statement to within the tolerance (error) ε. For example, the set of possible confirmers q of a hypothesis p is included in the ε-neighborhood of p. See Figure 8.5.

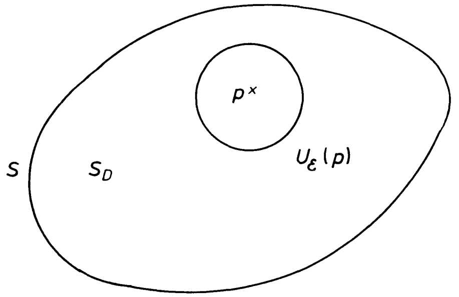

Fig. 8.5. An open neighborhood of $p\in S_D$. All the statements that agree with p to within ε are in $U_\varepsilon(p)$.

We can now formalize the notion of agreement between two statements, which we used in Sec. 2:

DEFINITION 8.3 For any given statement p in S_D and any preassigned real number $0\leqslant\varepsilon\leqslant 1$, the statement $q\in S_D$ *agrees with* p *to within* ε iff q is in the ε-neighborhood of p.

COROLLARY 8.2 Equivalent statements agree with one another.

Proof. By Theorem 2(iii), the distance between equivalent statements is nil.

Another equally natural topology is determined by a second distance function introduced by the following

DEFINITION 8.4 The function $\delta_{|}: S_D \times S_D \to [0, 1]$ which to each pair of propositions p, $q \in S_D$ assigns a real number lying between 0 and 1, such that

$$\delta_{|}(p, q) = |\mathscr{V}(p \vee q) - \mathscr{V}(p \,\&\, q)|,$$

is called the *vertical distance*. See Figure 8.6.

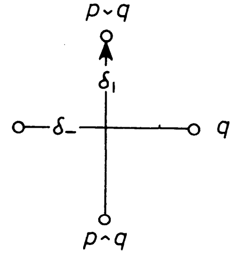

Fig. 8.6. Horizontal and vertical distances between propositions.

This other function deserves its name, as shown by

THEOREM 8.2 The structure $\mathscr{M} = \langle S_D, \delta_{|}\rangle$ is a quasimetric space.

This new metric defines a second topology in S_D. An open ε-neighborhood of $p \in S_D$ is now

$$U_\varepsilon(p) = \{q \in S_D \mid \delta_{|}(p, q) < \varepsilon\} \quad \text{with} \quad 0 \leqslant \varepsilon \leqslant 1.$$

The two truth spaces, $\langle S_D, \delta_{-}\rangle$ and $\langle S_D, \delta_{|}\rangle$, are separable (Hausdorff) because they are quasimetric. That is, for any two propositions p and q in S_D, there are open sets G and H in S_D such that p is in G and q is in H, and G and H are disjoint. Beyond their shared separability the two truth spaces are quite different, as shown by

THEOREM 8.3 The vertical distance between any two propositions is greater than or equal to their horizontal separation:

$$\text{If} \quad p, q \in S_D, \quad \text{then} \quad \delta_{|}(p, q) \geqslant \delta_{-}(p, q).$$

Consequently, any ε-neighborhood built with $\delta_{|}$ includes the corresponding set constructed with δ_{-}. Therefore the topology $T_{|}$ generated by $\delta_{|}$ is stronger than the topology T_{-} determined by δ_{-}. Because the vertical distance between a statement and its negate is maximal (i.e., $\delta_{|}(p, \neg p) = 1$), which is not the case with the horizontal distance, $T_{|}$ may be preferred to T_{-}. This is as far as we go in exploring the topologies for S_D determined by our truth valuation.

3.4. *Comparing Truth Values*

Let us now derive another few consequences from our assumptions. To this end we shall make free use of ordinary logic. And we shall bear in mind that stating a proposition is no indication of its truth value: the latter, if assigned at all, must be assigned by way of an extra metastatement such as, e.g., $\ulcorner \mathscr{V}(p) = \frac{1}{4}. \urcorner$

THEOREM 8.4 For any $p, q \in S_D$, $\mathscr{V}(p \vee q) \geqslant \mathscr{V}(p \,\&\, q)$.
Proof. By Definition 4 and Theorem 2.

THEOREM 8.5 For any $p \in S_D$, $\mathscr{V}(\neg p) = 1 - \mathscr{V}(p)$.
Proof. Set $q = \neg p$ in Definition 1.

THEOREM 8.6 The truth value of the antecedent of a wholly true conditional does not exceed the degree of truth of its consequent:
For any $p, q \in S_D$, if $\mathscr{V}(p \Rightarrow q) = 1$, then $\mathscr{V}(p) \leqslant V(q)$.
Proof. Set $\mathscr{V}(\neg p \vee q) = 1$ in Definition 1 and use Theorem 5 to obtain

$$\mathscr{V}(p) = \mathscr{V}(q) - \mathscr{V}(\neg p \,\&\, q) \leqslant \mathscr{V}(q).$$

COROLLARY 8.3 Equivalent statements in S_D have the same truth value:
For any $p, q \in S_D$, if $\mathscr{V}(p \Leftrightarrow q) = 1$, then $\mathscr{V}(p) = \mathscr{V}(q)$.
Proof. Trading p for q in Theorem 6 yields $\mathscr{V}(q) \leqslant \mathscr{V}(p)$ for the case $\mathscr{V}(q \Rightarrow p) = 1$. This, together with Theorem 6, entails the desired result.
Remark This corollary is not trivial because it is not restricted to formally true biconditionals.

THEOREM 8.7 For any $p, q \in S_D$, if $\mathscr{V}(p \Rightarrow q) = 1$, then

(i) $\mathscr{V}(p \,\&\, q) = \mathscr{V}(p)$
(ii) $\mathscr{V}(p \vee q) = \mathscr{V}(q)$

Proof. By logic,

$$q \Leftrightarrow q \,\&\, (\neg p \vee p) \Leftrightarrow (\neg p \,\&\, q) \vee (p \,\&\, q)$$
$$q \Leftrightarrow q \vee (\neg p \,\&\, p) \Leftrightarrow (\neg p \vee q) \,\&\, (p \vee q).$$

Taking $\neg p \,\&\, q$ and $p \,\&\, q$ as the variables in Definition 1 leads to (i). Similarly for (ii).

In the case of Theorem 7 the truth value of each statement depends on the degree of truth of the other: it is a case of *alethic dependence*. Alethic dependence subsumes *logical* dependence, which obtains when one of the statements entails the other. Let us now tackle the problem of alethic independence. To this end we shall introduce

DEFINITION 8.5 Let $p, q \in S_D$ with $\mathscr{V}(p) \neq 0$. Then the truth value of q relative to p is defined as

$$\mathscr{V}\left(\frac{q}{p}\right) = \frac{\mathscr{V}(p \,\&\, q)}{\mathscr{V}(p)}$$

(Caution: These are not the conditional truth values characterized in Sec. 2.3. In our view all truth values are conditional, i.e., presuppose some base line or other.)

If $\mathscr{V}(p \Rightarrow q) = 1$, Theorem 7 (i) and Definition 5 entail $\mathscr{V}\left(\frac{q}{p}\right) = 1$. In all other cases $\mathscr{V}\left(\frac{q}{p}\right) \neq 1$. Hence $\mathscr{V}\left(\frac{q}{p}\right) - \mathscr{V}(q)$ is a measure of the strength of alethic dependence. This suggests adopting the following

DEFINITION 8.6 Let $p, q \in S_D$ with $\mathscr{V}(q) \neq 0$. Then

(i) p is *alethically independent* of $q =_{df} \mathscr{V}\left(\frac{q}{p}\right) = \mathscr{V}(p)$.
(ii) p is *alethically dependent* upon q iff p is not alethically independent of q.

This relation of alethic independence is not symmetric but, whenever p is independent of q or conversely, the value of their conjunction is the same, namely the product of their degrees of truth. More explicitly, we have

THEOREM 8.8 If p and q are alethically independent statements in S_D, then

$$\mathscr{V}(p \,\&\, q)=\mathscr{V}(p)\cdot\mathscr{V}(q)$$

Proof. By Definitions 5 and 6.

COROLLARY 8.4 If p and q are alethically independent statements in S_D, then

$$\mathscr{V}(p \vee q)=\mathscr{V}(p)+\mathscr{V}(q)-\mathscr{V}(p)\cdot\mathscr{V}(q).$$

We now have all we need in practice: If p and q are alethically dependent we apply Theorem 8, otherwise we use Theorem 9. For purposes of reference we collect these results in the following chart:

p implies q	*p and q are alethically independent*
$\mathscr{V}(p \,\&\, q)=\mathscr{V}(p)$	$\mathscr{V}(p \,\&\, q)=\mathscr{V}(p)\cdot\mathscr{V}(q)$
$\mathscr{V}(p \vee q)=\mathscr{V}(q)$	$\mathscr{V}(p \vee q)=\mathscr{V}(p)+\mathscr{V}(q)-\mathscr{V}(p)\cdot\mathscr{V}(q).$

An obvious application of these results is the following

THEOREM 8.9 Let T be a scientific theory with n independent assumptions A_i. Then

(i) the degree of truth of the axiom basis equals the product of the partial degrees of truth:

$$\mathscr{V}\left(\bigwedge_{i=1}^{n} A_i\right)=\prod_{i=1}^{n}\mathscr{V}(A_i);$$

(ii) the degree of truth of an assumption conjoined with any of its logical consequences equals the former:

$$\text{If} \quad A_i \vdash t \quad \text{then} \quad \mathscr{V}(A_i \,\&\, t)=\mathscr{V}(A_i).$$

Proof. Part (i) follows from an obvious generalization of Theorem 8 to a conjunction of an arbitrary finite number of independent statements. Part (ii) is an application of Theorem 7 (i).

Since a well organized theory is constituted by a bunch of assumptions and all of their consequences, the preceding theorem justifies adopting the following convention concerning the degree of truth of a scientific theory.

DEFINITION 8.7 The *degree of truth of a scientific theory* equals the product of the truth values of its initial assumptions provided the latter are mutually independent.

This definition elucidates the notion of degree of truth of a theory without however allowing us to compute the degree of truth of any nontrivial theory in factual science. Such a numerical value must go uncomputed. All we can do is to estimate the truth value of a few logical consequences of the axioms conjoined with subsidiary assumptions and empirical data, and see whether the results confirm or infirm the premises, both theoretical and extratheoretical. In fact consider the following rather typical process. (For details see Bunge, 1967a, Ch. 15, and Bunge, 1973b, Ch. 10.)

Initial theoretical assumptions: A_1, A_2.
Additional premises: subsidiary hypothesis s and datum e.
Deduce a testable consequence t*:* $A_1, A_2, s, e \vdash t$.
Produce a new empirical datum e' relevant to t.
Contrast t *with* e'.
Estimate the truth value of t assuming e' to be true.
Infer whether the preceding step confirms or infirms the premises.

The attempt to go upstream and calculate the truth value of the initial assumptions on the basis of the degrees of truth of a few of their consequences conjoined with alien extra assumptions (such as s and e) is chimerical.

We close this subsection by defining some related concepts.

DEFINITION 8.8 Let $T = \langle S, \vdash \rangle$ and $T' = \langle S', \vdash \rangle$ be two theories with a common meaning core, i.e. such that $\mathcal{S}(T) \cap \mathcal{S}(T') \neq \emptyset$ and $\mathcal{R}(T) \cap \cap \mathcal{R}(T') \neq \emptyset$. Then T is *truer* than T' iff there is a 1:1 transformation f of S into S' such that, for every p in T, $\mathcal{V}(p) \geqslant \mathcal{V}(f(p))$.

DEFINITION 8.9 Let $T = \langle S, \vdash \rangle$ and $T' = \langle S', \vdash \rangle$ have a common meaning core. Then T and T' are *alethically equivalent* iff there is a truth preserving transformation $f: S \to S'$, i.e. one that, for every p in T, $\mathcal{V}(p) = = \mathcal{V}(f(p))$.

DEFINITION 8.10 Let T and T' be two alethically equivalent theories. Then T and T' are *semantically equivalent* iff they have the same sense and the same referents.

3.5. *Scientific Inference*

Let us now check whether our theory squares with usual procedures of scientific inference. To begin with the theory condones the scientist's common belief that factual propositions are more or less true rather than either wholly true or totally false. Moreover our theory gives quantitative precision to the idea of partial truth. In particular we have the following code.

Scientific vernacular	*Metascientific jargon*
p is *true*	$\mathcal{V}(p) \doteq 1$
p is *approximately true*	$0 \lll \mathcal{V}(p) < 1$
p is *true to within* $\varepsilon > 0$	$\mathcal{V}(p) = 1 - \varepsilon$
p is *partially true*	$\frac{1}{2} < \mathcal{V}(p) < 1$
p is *false to within* $\varepsilon > 0$	$\mathcal{V}(p) = \varepsilon$
p is *nearly false*	$0 < \mathcal{V}(p) \lll 1$
p is *false*	$\mathcal{V}(p) \doteq 0$
p is *truer than* q	$\mathcal{V}(p) > \mathcal{V}(q)$
p and q *agree to within* $\varepsilon > 0$	$\lvert\mathcal{V}(p) - \mathcal{V}(q)\rvert \leqslant \varepsilon$
p and q *disagree to within* $\varepsilon > 0$	$\lvert\mathcal{V}(p) - \mathcal{V}(q)\rvert \geqslant \varepsilon$,

where '$\doteq$' is a standard symbol for approximate equality, and ε the discrepancy introduced in Sec. 2.3.

Secondly, the theory contains the modus ponens and the modus tollens, which are the cornerstones of the theory and practice of deduction. In fact, if $\mathcal{V}(p \Rightarrow q) = 1$ and $\mathcal{V}(p) = 1$, then by Theorem 7(i) $\mathcal{V}(p \,\&\, q) = \mathcal{V}(p)$. Replacing these values in Definition 1 we get $\mathcal{V}(q) = 1$. Similarly for the modus tollens: setting $\mathcal{V}(q) = 0$ in Theorem 7(ii) yields $\mathcal{V}(p \vee q) = 0$, which substituted into Definition 1 entails $\mathcal{V}(p) = 0$. Similar results are obtained by substituting $\doteq$ for $=$, i.e. for the weakened inference patterns.

Suppose now a conditional is asserted tentatively and its consequent is tested for and found to be true (or false) to within a certain discrepancy ε, where $0 < \varepsilon \lll 1$. That is, we have

(i) *Confirmation*

Assumptions: $\mathscr{V}(p \Rightarrow q) = 1,\ \mathscr{V}(q) = 1 - \varepsilon$
Consequence: $\mathscr{V}(p) = 1 - \varepsilon - \mathscr{V}(\neg p \ \&\ q) \leqslant 1 - \varepsilon$

(ii) *Refutation*
Assumptions: $\mathscr{V}(p \Rightarrow q) = 1,\ \mathscr{V}(q) = \varepsilon$
Consequence: $\mathscr{V}(p) = \varepsilon - \mathscr{V}(\neg p \ \&\ q) \leqslant \varepsilon.$

In words: If q is confirmed, then p can be assigned an *upper bound* less than or at best equal to the value of q. And if q is refuted so is p. In short we retrieve what we knew all along, namely that, whereas confirmation is inconclusive, refutation is pretty clear cut – that is, if we restrict our considerations to pairs of statements.

The previous results hold only for *isolated* statements – the normal situation in inductive logic but an extremely artificial one in science. In live science hypotheses are assigned truth values in the light of both further hypotheses and whole bodies of empirical evidence; likewise the latter are estimated in the light of both further evidence and hypotheses –actually whole theories. When this circumstance is taken into account it becomes possible to obtain bounds other than those calculated above: i.e., confirmation may then be strengthened and refutation weakened – or conversely. In short, the whole body of relevant knowledge is summoned to pass judgment on every single hypothesis and every single datum. It is not that *das Wahre ist dans Ganze* (Hegel), but that the *recognition* of truth and of falsity calls for a whole battery of tests (Bunge, 1961c, 1967a, Vol. II, Ch. 15). The whole may be fully meaningful but, if factual, cannot be totally true.

Finally we note that our theory of truth is contiguous with the theory of scientific inference and, in particular, with the calculus of errors of observation. The latter is in charge of assigning the error or discrepancy ε a numerical value.

3.6. *Comments*

(i) The truth measure $\mathscr{V}$ is a continuous function. But this does not allow one to replace the tautology/nontautology dichotomy by a richer gamut of degrees of *logical* truth and falsity. This Aristotelian dichotomy is very basic: it is built into the very algebra of statements, which is a Boolean algebra with just two selected elements, □ and ▯. *This* is what we take "two valued" to mean in reference to ordinary logic – not that truth values other than 0 and 1 are disallowed. In order to introduce (in a purely syntactic fashion) degrees of analyticity intermediate between tautology and contradiction one would have to modify that algebraic structure – e.g., by increasing the number of distinguished elements of the statement set and characterizing them appropriately. However, it is doubtful that such a reform, though algebraically feasible, would be of interest to the logic of factual science. In any case the truth free formulation of logic we have adopted reminds one that logical truth and falsity, unlike factual truth and falsity, are structural or algebraic – something that the model theoretic presentation of logic tends to becloud. Logics are not truth calculi but entailment calculi.

(ii) The above mentioned continuity of the valuation function $\mathscr{V}$ allows one to consider arbitrarily close approximations to either complete truth or total falsity. A typical example is afforded by any series expansion. When expanding a function as a convergent series and adding up only the first n terms, one makes the error $R_n = |S - S_n|$, where S is the exact but perhaps unknown sum of the series while S_n is the known or knowable sum of its first n terms. As more terms are added the remainder R_n decreases and the truth value of the approximation increases accordingly. Indeed, one may set $\mathscr{V}(S_n \mid S) = |1 - R_n/S|$.

(iii) Our theory enables one to elucidate the intuitive notion of the "asymptotic approaching-to total truth" – sometimes also expressed, misleadingly enough, as "the gradual advance from relative truth to absolute truth". One way of exactifying this notion is, following Reichenbach (1949), to apply the standard notion of convergence of a sequence to a sequence $\langle p_n \mid n \in N \rangle$ of propositions all with the same form and referent – e.g., the successive outcomes of measurements of the electron charge. This can easily be done but is of no great help because we never have infinite sequences of factual statements of that kind, every one of which has been assigned a truth value. More often than not we switch our interest from one family of propositions to another before we have had a chance to form a sequence long enough to suggest (rather than exhibit) any convergence properties (Bunge, 1963a). Moreover, the corresponding sequence of truth values, i.e. $\langle \mathscr{V}(p_n) \mid n \in N \rangle$, could not possibly exhibit convergence in the strict mathematical sense because the terms of the sequence obey no law. Surely there are sets of theories with the same referent and constituting finite increasing sequences, but these are not very long and there is no reason to believe that any of them could continue indefinitely. In any case there is no confirmed theory of knowledge containing a law statement – not just a Panglossian opinion – to the effect that every sequence of hypotheses (or of theories) concerning any given factual referent should converge to total truth. What we do have is a few generalizations with a restricted scope, such as this one: "The truth value of a statistical estimate approaches unity as the sample size approaches the total population". But this approaching of partial to complete truth is not uniform or lawful, hence it cannot be described with the help of the mathematical concept of limit. Thus if the population consists of A's and B's in the same proportion, sampling may result in picking sheer A's during the first half of the time and only B's the rest of the time, so that during the first period the relative frequency of A's will be 1 instead of the long run frequency $\frac{1}{2}$.

(iv) The valuation function $\mathscr{V}$ is "external" to the algebra of propositions. This tallies with the fact that factual truth values are assigned rather than extracted from the propositions themselves by sheer force of analysis. The latter procedure works only, as noted by Leibniz, for logical truths and falsities. The externality of $\mathscr{V}$ to the algebra has the advantage that we might try functions other than the one determined by Definition 1 while keeping the logic intact. Moreover one might study the whole lot of continuous measures on S_D.

(v) Our claim that truth values, if factual, do not inhere in propositions but are bestowed upon them *ab extrinseco* agrees with our treating truth values, when factual, as values of a certain function $\mathscr{V}$ rather than as elements of the algebra of statements. That factual truth values are assigned (and reassigned) rather than disclosed by logical analysis does not entail that our theory elucidates a pragmatic or methodological concept of truth. It does entail that any application of our alethics calls for methodology. A pragmatic concept of truth would be characterized by (*a*) some function $\mathscr{V}_p$, other than our $\mathscr{V}$, on the set $S_D \times P$ of statement-person pairs, and (*b*) certain assumptions concerning the P's, in particular their truth value assignment habits, or else norms.

(vi) We have defined $\mathscr{V}$ on a proper subset S_D of the totality S of statements. That is, we abstain from assigning truth values to a number of statements – e.g. for lack of relevant evidence or for the absence of a proof. (This aspect of our semantics might be approved of by the mathematical intuitionist.) The reason is simple: as a matter of fact most statements in factual science go unvalued. In short, our alethics makes room for what have been called *truth value gaps* – without requiring any change in logic. It only requires the notion of a partial function, which can be construed as a total function on a domain enriched with a fictitious element embodying the undefined (Scott and Strachey, 1971).

(vii) An alternative solution to the problem of the truth value gaps is of course the adoption of intuitionist logic. But this would require the reconstruction of the whole of mathematics in intuitionist terms, since factual science utilizes, in principle, the totality of mathematics. Our solution to the problem is far less expensive.

(viii) Another solution to the problem of the truth value gaps is to adopt some system of three valued logic involving a third truth value – call it "indeterminate". This move was actually proposed in relation to quantum mechanics, which – like every other theory for that matter – contains empirically untestable statements, such as those referring to the "interphenomena" or events assumed to occur between observations (Reichenbach, 1944). But this proposal, like similar proposals made by a number of authors for different nonreasons, is not workable. First, one should be able to put his finger on at least *one* proof in quantum mechanics requiring rules of inference other than those consecrated by ordinary logic. Second, quantum mechanics should then be reaxiomatized on the basis of the alternative logical calculus. None of these two conditions has been satisfied: this logical revolution is still, after four decades, in the initial proclamation stage. And if it became victorious if would asphyxiate quantum mechanics by isolating it from the rest of physics, which would presumably keep its classical logic. In fact, theories with different logics cannot be conjoined, as they must be if they are to become applicable and testable. (See Bunge, 1973a, and 1973b.)

(ix) The metric Boolean algebra introduced by Definition 1 should not be mistaken for a probability measure. For one thing the arguments of $\mathcal{V}$ are individuals (propositions) not sets. (In other words the domain of $\mathcal{V}$, unlike that of Pr, is not a field of sets.) For another, our normalization condition is $\mathcal{V}(p)=1$ for $p \in \square$, not $\mathcal{V}(S_D)=1$ as it should in order to be a probability measure. Thirdly, our theory contains no semantic assumptions asserting that "$\mathcal{V}(p)$" represents the probability of the proposition p – whatever this expression may mean if indeed it means anything. (It cannot mean "the probability of being true", for this would drag us in a circle: the statement "$Pr(\mathcal{V}(p)=1)=r$" involves the concept of total truth.) This semantic trait of our theory should suffice to distinguish it from the various probability (or improbability) theories of truth even if we were to choose exactly the same mathematical formalism.

There is more: whereas our axioms can be applied right away to situations of interest in real science, the axioms of measure theory yield no probabilistic statements without further ado. Indeed, probability theory proper, as distinct from measure theory, starts where the latter leaves off, namely by specifying (constructing) a probability space or space of "events". (Our basic set $[S]$, on the other hand, is sufficiently characterized by saying that it forms a Boolean algebra.) To put it another way: measure theory provides only the foundations of the probability calculus. These foundations cannot be activated to yield probabilistic results, such as the laws of large numbers, unless enriched with some definite *model* of a possible (though idealized) situation, such as the coin model, an urn model, or a Markov chain model. No such model no probability theory proper. (See, e.g., Kolmogoroff, 1963; Feller, 1968.) And such specifically probabilistic devices are as alien to our theory of truth as they are to measure theory: both truth and measure are independent of randomness. Moreover, all such probabilistic models do is to allow one to assign probabilities to the elementary "events" (the individual sets), never to the corresponding statements. The probability statements themselves, if theoretical, are supposed to be totally true and derived in accordance with ordinary logic. (Their factual truth value is of course another matter.) The widespread view that the theory of probability is a generalization of logic involving probability implications and condoning inductive reasoning ignores the perfectly classical logical structure of the theory. There is somewhat more to all this: we shall look into it in the next section.

(x) Our theory of truth explains what is wrong with Frege's conception of a predicate as a function from individuals in a domain D to truth values (Ch. 1, Sec. 1.3). If we simplify, pretending (with Frege) that every proposition can be assigned a truth value (i.e. if we set $S_D = S$) and keep only the two extremes 0 and 1 of the unit interval, we get the functions

$$P: D \to S \quad \text{and} \quad \mathcal{V}: S \to \{0, 1\}.$$

The composition of these functions yield what may be called the *Frege predicate* F corresponding to the predicate P:

$$F =_{df} \mathcal{V} \circ P: D \to \{0, 1\}.$$

What Frege did was to skip the preceding analysis of F into $\mathcal{V}$ and P.

$$\begin{tikzcd}
D \arrow[r, "P"] \arrow[dr, "F"'] & S \arrow[d, "\mathcal{V}"] \\
& \{0,1\}
\end{tikzcd}$$

4. TRUTH ET ALIA

4.1. *Truth and Probability*

Skeptics and empiricists have rightly insisted on the "probable" nature of factual knowledge. But, until recently, they employed the term 'probable' in a nontechnical acceptation, namely as a synonym for either 'uncertain' or 'corrigible' or both. The probability theories of truth proposed over the past six decades appeared to formalize that view by taking the popular 'probable' in the technical sense that the theory of probability assigns to it. More precisely, these theories equate the degree of truth of a factual statement with its probability or with some increasing (or decreasing) function of the latter. They are thus exact philosophical theories. But they are also hollow, for there exists no procedure, other than arbitrary decree, for assigning probabilities to statements. The passion for exactness is certainly a noble passion but, like any other, it may make fools of us.

Both in applied probability theory and in theoretical science the way to assign primary probabilities is to set up some stochastic model of the *factual* system concerned, such as an urn model. (Recall point (ix) in Sec. 3.6.) This procedure does not work for statements, *e.g.*, scientific hypotheses, if only because these are not picked at random, say by extracting them from a hat full of white (true) and black (false) statements. The very concept of randomness, without which the probability theory finds no application, makes no sense for a unique and carefully contrived object such as a scientific hypothesis.

What can often be assigned probabilities are the *facts* referred to by a (factual) probability statement. Thus we may be able to compute, with the help of a *specific* stochastic theory, or to measure, with the help of a *specific* experimental set up, the probability of a certain *event* belonging to a uniform class of factual items, such as rainfalls in some area. But such probability assignments will be correct or incorrect to some extent that is independent of the objective probability of the given event. For example, the probability of a certain nuclear event e may be exceedingly small, say 10^{-24}, while the degree of truth of this probability assignment may be fairly high, say 0.9. That is, we can have $\mathscr{V}[P(e)=10^{-24}]=0.9$. And we can also have the opposite situation, i.e. a high probability value assignment that is nearly false. In short, probabilities of facts and degrees of truth are mutually independent. Hence there is no way of inferring the degree of truth of a statement from the probability of the fact it concerns, nor conversely. Put in another way: There is no supertheory, concerning both a factual domain and a theory about it, that contains law statements relating facts to our knowledge of them. We do not even know whether such lawful connections between facts (random or otherwise) and our knowledge of them could be found.

In conclusion, since the probability (and the information theoretic) theories of truth are not in a position to assign probabilities to statements, we should stop equating the epistemological 'probable' (='uncertain' or 'corrigible') with the semantical 'partially true'. And it would not hurt looking at the way scientists actually estimate the size of the grain of truth of their theories. They may not use the *word* 'truth' (just as they rarely use the term 'cause') because positivism and conventionalism have given it a bad reputation, but they surely use a (presystematic) *concept* of (factual and partial) truth, as is clear from their relentless search for improved representations of facts.

Besides, the concepts of truth are both *more basic* and *more universal* than the concept of probability. In fact we want to be able to say that a given probability assignment (to a fact) is close to (or far from) the truth. And, while all probability statements have presumably some truth value or other, they are only a proper subset of the totality of statements. In short, there is no surrogate for factual truth, and the theory of truth must preside over both stochastic and nonstochastic factual theories. And alethics as well as applied probability presuppose ordinary logic. Practically every theory does.

4.2. *Truth, Meaning and Confirmation*

In Ch. 7, Sec. 2.2 we stipulated that meaning is a property of constructs and that only those expressions in a language that happen to designate constructs are significant. And in this chapter we have agreed that among constructs only statements may, but need not, be assigned a truth value. Figure 8.7 displays these views.

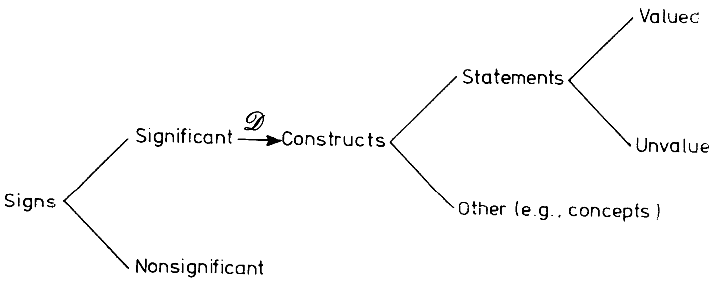

Fig. 8.7. Truth rides on meaning.

Truth depends on meaning (sense together with reference) but not conversely: one and the same factual proposition may be assigned now one truth value, now another, without any change in meaning. (Changes in meaning involve changes in the constructs themselves.) For example, Galilei's refutation of Aristotle's laws of motion did not change the latter's meaning. Galilei could not have accepted either Frege's view that truth values determine meanings or the verifiability doctrine of meaning, according to which meanings are secreted by verification procedures.

However, these doctrines asserting the primacy of truth over meaning survive in various watered down forms. One of these is the view that the truth conditions of a language determine the semantics of the latter. (For the notion of truth condition see Sec. 2.4.) In pragmatic terms: "To give the semantics of a language boils down to stipulating its truth conditions." Let us not quibble over the bizarre belief that languages, rather than theories, come with truth conditions. (For a defense of the alethic neutrality of languages see Ch. 1, Sec. 1.1.) The thesis may fare well in elementary logic but it certainly fails in factual science. First, because in the latter there are hardly any necessary and sufficient conditions under which a statement may be pronounced totally, or even partially, and definitively, or even provisionally, true or false. (Recall Sec. 2.4.) Second, because although every decent scientific theory has a reasonably definite meaning (sense and reference), determined by its basic assumptions, we may be at a loss as to the conditions under which it may be regarded as (approximately) true. In conclusion, the claim that truth conditions determine meanings is as false as the converse thesis. Meaning and truth are equally basic semantic components of propositions.

Nor is truth to be mistaken for confirmation. The two concepts belong in different categories: truth in semantics, confirmation in methodology. But at least in this case taking the one for the other constitutes an intelligent mistake, for confirmation is necessary, though insufficient, to bestow truth values. Indeed, if a statement has been abundantly confirmed by experience and if it coheres with reasonably well corroborated theories, then it may be assigned a truth value close to unity – until new notice. But, as shown by superstition, empirical confirmation alone is insufficient – and refutation may not help. Furthermore empirical tests are sometimes impossible, despite which we may have reasons for allotting a hypothesis a high degree of truth. Figure 8.8 illustrates a frequent situation in theoretical science. (See Bunge, 1967a, I, 5.6.)

What holds for the qualitative concepts of truth and confirmation holds also for their quantitative explicata: confirmation is but an insecure indicator of truth. Thus the statement ⌜All natural numbers are greater than any preassigned natural number⌝ is patently false but, since it has infinitely many confirmers, it could be assigned a maximal degree of confirmation. In sum the two concepts, truth and confirmation, though related, are distinct. A similar relation holds between the semantic con-

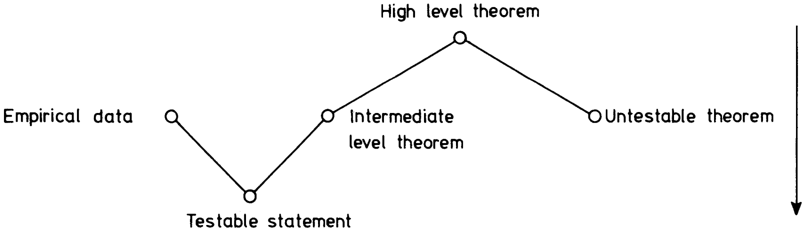

Fig. 8.8. An untestable theorem may be regarded as (more or less) true if it belongs to a theory abounding in corroborated theorems.

cept of truth and the pragmatic (or psychological) concept of acceptance or credence or belief. But this deserves a separate subsection.

4.3. *Truth and Belief*

Except for the dogmatist, truth is not belief: anyone can believe falsities and disbelieve truths – and all of us ignore most truths and most falsities. Let us keep truth and belief distinct – though not necessarily separate. Marry they must if they are to bear fruit or rather edible fruit. The semantic concept of truth and the pragmatic (or psychological) concept of belief (personal or collective) get fused into that of pragmatic truth, or truth for someone. More exactly, there are two such concepts: *personal* (subjective) truth and *collective* (or intersubjective) truth – which, as the fable of the naked king warns us, must not be confused with objective truth. These concepts occur in statements of the form $\ulcorner x$ believes $p\urcorner$, where the substitution instances of x are persons or social groups. The theories dealing with statements of this kind have come to be known as systems of *doxastic logic* and they are closely related to the theories concerning statements of the form $\ulcorner x$ knows that $p\urcorner$, which are the object of the so called *epistemic logic* (Hintikka, 1962).

While there is no doubt that both "logics" are worthy enterprises, it seems clear that they are not *logics* but factual disciplines and consequently in need of empirical tests. Indeed, any belief statement and any knowledge statement of the sort mentioned a while ago concern both propositions and people: they "say" as much or more about persons (or social groups) as about propositions. (They are not metastatements such as $\ulcorner p$ is true$\urcorner$ but object statements with two referents.) This being the case, only psychologists can tell us anything about the truth value of the hypotheses spurned by the doxastic and the epistemic logicians. In other words, although the empirical sciences of belief and knowledge are welcome and moreover long overdue, an *a priori* theory of belief and knowledge stands no chance of being true – hence of contributing to knowledge and compelling our belief in it. To put it another way: Even belief and knowledge statements, i.e., statements of personal (or collective) belief or knowledge, ought to be objective and empirically testable.

Of course objective truths (and falsities) are not Platonic Ideas: *pace* Bolzano there is no such thing as a *Wahrheit an sich*, independent of thinking beings (Bolzano, 1837, I, Sec. 25). Statements in themselves are just useful (as opposed to either idle or evil) fictions. A proposition, viewed from a metaphysical angle, is not an autonomous object (an entity) but perhaps a certain equivalence class of brain processes (thoughts) of some kind. (Note the vagueness, unavoidable at the present stage of cognitive psychology.) And a propositional attitude, such as knowing, believing or doubting a proposition, is another equivalence class of brain processes, this time one concerned with further brain processes. Schematically, we have three levels:

(i) *Class of thoughts* of a kind (judgments).
(ii) *Object proposition* = An equivalence class of thoughts of a kind.
(iii) *Propositional attitude* = An equivalence class of thoughts about thoughts.

   (*a*) *p* is *given* – take it or leave it.
   (*b*) *p* is *examined* with a view to finding out its degree of truth, or its relation to other propositions, or its usefulness to some action, etc.
   (*c*) *p* is *assumed* or hypothesized (not necessarily asserted as true).
   (*d*) *p* is *confirmed* (in particular proved) or *infirmed* (in particular refuted).
   (*e*) *p* is *assigned a truth value.*
   (*f*) *p* is *assigned nonsemantic properties:* systemicity, depth, heuristic power, etc.

(*g*) *p* is *adopted or rejected* for a certain purpose, either theoretical or experimental or practical.

(*h*) *p* is *believed* or *disbelieved* or *left in suspense*.

Etc.

To conclude. Truth and belief are heterogeneous categories. Moreover, *pace* the pragmatists (e.g. Zinov'ev, 1973), truth is not definable in terms of acceptance or credence. Rather on the contrary, to anyone but a mystic, believing *p* consists in admitting *p as true*, at least to a considerable degree at the time of thinking *p*. Which leads us to considering the relation of truth to time.

4.4. *Truth and Time*

If factual truth were an intrinsic property of propositions, as is the case with logical truth, then it would be timeless. And even if it were less than this, namely mere mathematical truth, it would be timeless as well: the property of being true in a model is neither eroded nor accrued in the course of time, because models (in the model theoretic acceptation of the term) are themselves timeless objects. Alas, factual statements are more complicated than this: in addition to being true in some model they must be (sufficiently) true of the world, which is largely beyond our control. And they are assigned truth values on the strength of both conceptual and empirical operations of varying degrees of refinement. The upshot is that factual truth values vary in the course of time. In this sense *Veritas filia temporis* (cf. Bunge, 1967a, II, 10.5.)

The time dependence of factual truth value assignments summarizes a complex process of testing for the truth. This process involves flesh and blood scientists handling a changing array of conceptual and physical tools. Although every one of the inputs participating in this process may be lawful, the output, i.e. the trajectory or curve of the successive truth values does not seem to satisfy any law: it is a time series, at most a trend. (For the concepts of trend and law see Bunge, 1967a, I, 6.2 and 6.6.) This does not mean that truth value assignments and reassignments are capricious, hence that there is no such thing as objective truth. All it means is that, as with most historical processes, sequences of truth value assignments are the outcome of the interplay of numerous factors, some of which escape our control.

What about predictions: do they have a truth value before the facts they refer to come to pass? According to Aristotle (*De interpretatione* Book 9) only propositions about actuals are either true or false. On the other hand propositions about contingent futures have no definite truth values. It might be objected that the predictions computed in factual science do have definite truth values since they are entailed by premises taken to be true. But this would be incorrect: we need not, and usually do not, *assert* our hypotheses but just process them to find out what they entail, and wait and see how some of these consequences fare. That is, we may and often must abstain from assigning any truth values to our predictions. So Aristotle would seem to be right.

However, things are not this simple. If the possibles in question are not unique such as tomorrow's naval battle, but get actualized once and again under suitable conditions, then we may subject them to theory. And we may subsequently contrast some statements in the theory with actuality, or the unfolding of potentiality (to continue Aristotle's train of thought), thus being able to evaluate those propositions. This holds in particular, though not exclusively, for stochastic theories: here we contrast calculated probabilities and their subordinates (averages, mean fluctuations, etc.) with observed frequencies and their relatives. But possibles are not the exclusive property of stochastic theories: all scientific theories concern possible things, possible properties, possible states, possible changes of state. (However, science does not need modal logic. It construes "a possible factual item of kind F" as "an arbitrary member of the set F of factual items", and "a probable fact" as a fact with a definite probability. Hence scientific theory, though concerned with possibility, is strictly truth functional.) Only the applications and tests of scientific theories concern actuals. And no sooner are actuals involved, than we can proceed to an effective (yet provisional) determination of truth values. The foregoing discussion is summarized in Figure 8.9.

5. CLOSING REMARKS

A theory of factual truth is often expected to accomplish at least as much as a theory of formal truth, viz.,

(i) offering a tidy definition of "factually true statement";
(ii) laying down universal truth conditions (criteria); and

(iii) giving rules for computing the truth value of any truth functional compound, such as a conjunction, in terms of the truth values of its constituents.

Our theory of truth fails, nay refuses to undertake the first two tasks and performs only the third. In fact we hold (Sec. 4.2) that the concept of factual truth is much too basic and universal to be demoted to the rank of a defined concept. (And in any event all the attempts to eliminate it in favor of alternative concepts, such as those of satisfaction, probability, information, and confirmation, have failed.) The most we can do for the concept of factual truth is

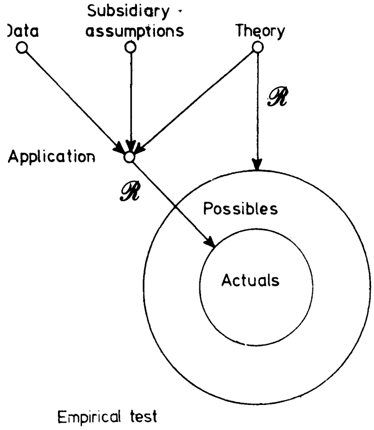

Fig. 8.9. Only the applications and tests of a scientific theory concern actuals: every general theory is about possibles. The outcomes of tests (on actuals) enable one to assign truth values to statements (whether deterministic or stochastic) concerning possibles.

(i) to give an *informal* characterization (Sec. 1);

(ii) to show how it is *used* in scientific practice (Sec. 2); and

(iii) to define it *implicitly* by a set of postulates (Sec. 3).

As to factual truth conditions, we have pointed out that (*a*) in science there are no cut and dried truth conditions in the simple form of equivalences, and (*b*) the complex, regional and changing clues for estimating factual truth values must remain the responsibility of science. Here the semanticist must be a spectator and student not a law giver.

Our theory of factual truth, incomplete though it may look to the philosopher accustomed to the white or black situations encountered in logic, does seem to elucidate in an exact way the concept of degree of truth used by applied mathematicians and scientists. However, we do not claim that it is the best possible (the truest) theory. There may well be alternative measures $\mathscr{V}$ that supply a more adequate explication of the intuitive concept of partial factual truth. (Recall Sec. 3.6, point (iv).) Still, any such alternatives should presuppose classical logic, which is the one inherent in science. And they should satisfy the same desideratum, namely that of supplying an exact version of the imprecise notion of approximate truth (or falsity) of fact.

Note finally that our alethics takes care of the notion of *partial explanation*, which is becoming prominent in the philosophy of science (Scheibe, 1973). A fundamental theory is said to provide only a *partial explanation* of the empirical generalizations (or the phenomenological theory) that motivated the construction of the theory. For example, celestial mechanics does not retrieve Kepler's laws but gives only an "approximate explanation" of them because, strictly speaking, the sun does not stand still and the planets exert perturbations upon one another, all of which complicates the actual planet trajectories far beyond Kepler's simple ellipses. As a matter of fact the explanation of the latter supplied by Newton's celestial mechanics is rigorous: what are not exact, or rather not completely true, are the subsidiary assumptions that the solar mass is infinite and that each planet is acted upon only by the sun. Every application of any theory involves simplifying assumptions like these. Thus in the elementary theory of the simple pendulum one assumes that the oscillation amplitude is small and so he obtains the laws of Galilei and Huyghens, known to be only partially true. The deduction is exact: what is approximate is the simplifying assumption and consequently the conjunction of this subsidiary condition with the general assumptions of the theory. To sum up, if we accept the general concept of partial and relative truth of fact we need not introduce the *ad hoc* concept of approximate explanation. Or at least the latter can be defined in terms of the former.

This closes our exposé of the basic theories in our semantics of science. The rest of the book deals with applications (Ch. 9) and border issues (Ch. 10).

CHAPTER 9

OFFSHOOTS

The ideas on meaning and truth presented and discussed in the preceding chapters may be applied to a variety of problems in philosophical semantics, whether pure (general) or applied (to, e.g., scientific theories). We have dealt with sundry problems in applied semantics throughout the foregoing chapters. Let us now face three problems in pure or general semantics, namely those of extension, vagueness, and definite description: in our system all of them presuppose the theories of reference, sense, and truth.

1. EXTENSION

1.1. *The Problem*

An extension is the extension of some predicate. Thus the extension of "– is a mountain" is the class of mountains. And every extension is a set. But not every set is the extension of some predicate. For example there seems to be no (interesting) predicate corresponding to the set {China, d/dx}. Nor does every construct have an extension: only those constructs can be assigned an extension for which the concept of truth makes sense. It makes sense to ask what are the objects for which a certain predicate P holds: the collection of such individuals is the extension of P, or $\mathscr{E}(P)=\{x \mid Px\}$ if P is a unary predicate. Individual concepts, such as "Archimedes", have a referent but not an extension. (Individual variables, such as "here" or "we", fare even worse, as they have no fixed referents.) Nor do sets have an extension – or, if preferred, they are their own extensions. (Sets are in fact the only purely extensional objects.) Not even closed formulas, whether simple such as $\ulcorner Pa \urcorner$, or complex such as $\ulcorner (x)(\exists y)\, Pxy \urcorner$, are usually assigned an extension – although they might. Normally only predicates are assigned an extension or domain of application. At any rate we shall confine the theory of extensions to predicates.

The concept of extension must be elucidated by a theory of extensions. The theory of reference cannot do this job because the concepts of reference and of extension are quite different and probably not interdefinable. For one thing the notion of reference does not presuppose the concept of truth, which the concept of extension does. For another the extension of an n-ary predicate is a set of ordered n-tuples, whereas the reference class of the same relation is the scrambled set of the individuals concerned. Thus

$$\mathscr{E}(\text{loves}) = \{\langle \text{Abélard, Héloïse} \rangle, \langle \text{Dante, Beatrice} \rangle, \ldots$$
$$\mathscr{R}(\text{loves}) = \{\text{Abélard, Héloïse, Dante}, \ldots\}.$$

Prima facie there are two other theories that could claim to constitute a theory of extensions each, namely ordinary logic and set theory. But the former is truth functional rather than "purely extensional", as we argued in Ch. 4, Sec. 1. Logic determines neither intensions nor extensions: it leaves them indeterminate. Only the semantics of logic introduces extensions when supplying models for the logical calculi. (*A fortiori* logic cannot be construed as universal semantics – *pace* Bar-Hillel (1970).)

As to the claim that set theory is the theory of extensions, its force depends upon the version of the theory one has in mind. Certainly it does not hold for the von Neumann-Bernays-Gödel theory, which does not involve the concept of a predicate, whence it cannot be construed as dealing with the extension of predicates: in that theory a class is an object on its own. (The rationale for this is not that "mathematics has no need for non-classes, like cows or molecules" (Mendelson, 1963, p. 160), but rather that, *once generated*, a set may be handled as an object in its own right. But if the problem is to determine or characterize a particular infinite set, then there is no way except to seize on some property and use the principle of abstraction or its rigorous version, the *Aussonderung* axiom – which is absent from the von Neumann-Bernays-Gödel theory.) As to the Zermelo-Skolem-Fraenkel version of set theory, which does involve the notion of a predicate, it is certainly concerned with extensions since it contains the golden bridge between predicates and sets – namely the *Aussonderung* postulate. However, the central goal of this theory is not to elucidate the notion of extension by relating it to that of truth and distinguishing it from that of reference – which is what semantics is mainly interested in.

We need then a separate theory of extensions, distinct from both logic and set theory though subordinated to them. In fact we need two theories of extension if we are to cope with factual science: (*a*) a theory of *strict* extensions, concerning clear cut (decidable) predicates as well as total (not just approximate) truth, and (*b*) a theory of *lax* extensions, concerning predicates that are either inherently vague or whose instances are known imperfectly. The present section is devoted to strict extensions, the next to lax extensions.

1.2. *Strict Extension: Definition*

While the referents of a predicate are the objects it points to, whether truly or not (Ch. 2), the extension of the predicate is the collection of objects for which it holds and in the order in which it holds. More precisely the extension of a predicate P is the *truth set*, or *solution set*, or *graph* of P. This graph is included in the domain of definition of P. *Example 1* Whereas the reference class of "is literate" is mankind, its extension is the subset of persons who actually read and write. *Example 2* Let P be a binary predicate and, more specifically, one whose relata are tied by P in this way: $Pxy = (f(x) = y)$, for x and y in the real line R. The extension of P is the graph of f – a curve in the plane $R \times R$. See Figure 9.1.

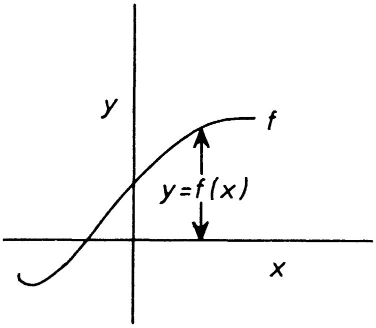

Fig. 9.1. The curve represents the extension of the binary predicate $P = X \times Y \to S$ such that $Pxy = (f(x) = y)$. Indeed, $\mathscr{E}(P) = \{\langle x, y\rangle \in X \times Y \mid y = f(x)\}$.

These ideas are spelled out by the following

DEFINITION 9.1 Let $\mathbb{P}$ be the family of all predicates defined on a domain

$D=A_1 \times A_2 \times \ldots \times A_n$. Then the function

$$\mathscr{E}=\mathbb{P}\to\mathscr{P}(D)$$

such that, for any predicate $P:D\to$Statements, belonging to the predicate family $\mathbb{P}$, $\mathscr{E}$ takes the value

$$\mathscr{E}(P)=\{\langle x_1, x_2, \ldots, x_n\rangle \in A_1 \times A_2 \times \ldots \times A_n \mid Px_1x_2\ldots x_n\},$$

is called the *extension function for P* and its values *extensions* (or *extension values*).

Example 1 The extension of "is a planet of the Sun" is the set of the eight planets certified to be such. The ghostly Pluto is among the referents of the predicate and even in its lax extension but it does not qualify, at the time of writing, as a member of its strict extension. *Example 2* A function f and its restriction $f \mid A$ to a set A, though cointensive, have different extensions: $\mathscr{E}(f \mid A) \subset \mathscr{E}(f)$. Obviously this holds, in particular, when A is a singleton.

Remark 1 The extension function $\mathscr{E}$ maps predicates neither into nor onto their domains: the latter contain regions that correspond to different predicates or to none. *Remark 2* Our very notation shows that we reject the extensionalist identification of a predicate with its graph or extension – for the reasons given in Ch. 4 Sec. 1.2. Thus instead of writing '$\langle x, y\rangle \in R$' for a binary relation R, we prefer to write '$\langle x, y\rangle \in \mathscr{E}(R)$'. This difference, tiny as it is for practical purposes, is important for the foundations and the philosophy of mathematics as well as for semantics. And it avoids funny expressions such as '$= \,=\mathrm{diag} X \times X$' and '$= \subset \subseteq$'. *Remark 3* The distance between extensions and reference classes can be considerably shortened if, instead of conceiving n-tuples as sets of sets (*à la* Wiener and Kuratowski), we construe them as individuals (points). To this end we may adopt the original Bourbaki point of view, now championed by Mac Lane, according to which an ordered pair is a complex individual characterized by the single axiom (not definition): $\langle x, y\rangle = \langle x', y'\rangle$ iff $x=x'$ and $y=y'$. *Remark 4* Definition 1 bridges Platonism ("Only forms are real") and nominalism ("Only individuals are real"). Or rather it shows that the Platonism/nominalism divide is not a reasonable one, as there are neither pure forms nor formless individuals. Every form is the form of something and every individual exemplifies some form or other. *Remark 5* Because truth is relative, so is extension. The extension of a factual predicate grows or shrinks with the advancement of knowledge.

1.3. *Some Consequences*

First an immediate consequence of Definition 1 in Sec. 1.2:

COROLLARY 9.1 The extension of a predicate is included in its domain:

$$\text{If} \quad P{:}D \to \text{Statements}, \quad \text{then} \quad \mathscr{E}(P) \subseteq D.$$

Now the main result. But before stating it we must recall that a compound predicate is defined only on the overlap of its components (Ch. 1, Sec. 1.3).

THEOREM 9.1 The extension of a Boolean function of predicates equals the corresponding Boolean function of their images under the extension function. I.e., if P and Q are predicates defined on a common domain, then

(i) $\mathscr{E}(\neg P) = \overline{\mathscr{E}(P)}$;
(ii) $\mathscr{E}(P \,\&\, Q) = \mathscr{E}(P) \cap \mathscr{E}(Q)$;
(iii) $\mathscr{E}(P \vee Q) = \mathscr{E}(P) \cup \mathscr{E}(Q) \supseteq \mathscr{E}(P \,\&\, Q)$;
(iv) $\mathscr{E}(P \Rightarrow Q) = \overline{\mathscr{E}(P)} \cup \mathscr{E}(Q)$.

Proof. For the sake of simplicity let us confine ourselves to unary predicates defined on a domain D. By Definition 1,

$$\mathscr{E}(\neg P) = \{x \mid \neg Px\} = D - \mathscr{E}(P) = \overline{\mathscr{E}(P)},$$

which proves (i). As to (ii), since $P \,\&\, Q$ is defined on a common domain, it can be treated as a single predicate with values $(P \,\&\, Q)\,x$, where $x \in D$:

$$\mathscr{E}(P \,\&\, Q) = \{x \mid (P \,\&\, Q)\,x\} = \{x \mid Px \,\&\, Qx\} = \\ = \{x \mid Px\} \cap \{y \mid Qy\} = \mathscr{E}(P) \cap \mathscr{E}(Q).$$

Analogously for (iii). Finally, (iv) is proved by replacing $P \Rightarrow Q$ by $\neg P \vee Q$ and using (i) and (ii).

Example 1 $\mathscr{E}(\text{nonliving}) = \overline{\text{Living beings}}$.

Example 2 $\mathscr{E}(\text{small circular}) = \mathscr{E}(\text{small}) \cap \mathscr{E}(\text{circular})$.

On the other hand "is a circular square", which refers to plane figures, has a nil extension. (And it is meaningful: recall Ch. 7, Sec. 2.2.)

Remark 1 The condition of Theorem 1, that the component predicates be defined on a common domain, disqualifies the composition (e.g., conjunction) of referentially heterogeneous predicates such as "metallic" and "jealous". Hence we cannot even say of them that they have empty extensions: they have no extensions at all – nor do they have an intension, as we learned in Ch. 4, Sec. 2.2. *Remark 2* Theorem 1(ii) is the basis of the usual procedure for constructing the (extensionally) smallest of all the predicates satisfying a certain condition – namely to conjoin them. For example, consider the class of equivalence relations $\sim_n$, with $n \in N$, on a given set S. The smallest of them all is $\sim_0 = \bigwedge_n \sim_n$. This is the relation that holds only between an element of S and itself – i.e., strict identity.

COROLLARY 9.2 Double negation restores the original extension:

$$\text{If } P \text{ is a predicate, then } \mathscr{E}(\neg\neg P) = \mathscr{E}(P).$$

COROLLARY 9.3 Inconsistent predicates are extensionally void and tautological ones are universal: If P is a predicate with domain D, then

(i) $\mathscr{E}(P \,\&\, \neg P) = \emptyset$;
(ii) $\mathscr{E}(P \vee \neg P) = D$.

Proof. Let $Q = \neg P$ in Theorem 1 (ii) and (iii) and use (i). To generalize to arbitrary tautologies and contradictions use the theorem that all tautologies are equivalent, hence coextensive.

Remark 1 All of the above formulas concern predicate variables. Being general they hold for any predicate constant regardless of its reference. For example, if P is assigned the value "philosopher" in Corollary 3, then P refers to persons and is true of philosophers, while $P \,\&\, \neg P$ and $P \vee \neg P$ still refer to persons but now $P \,\&\, \neg P$ "applies" to nothing whereas $P \vee \neg P$ is true of everything. *Remark 2* Corollary 3(ii) and its generalization to an arbitrary tautological predicate is a reason for maintaining that logic is universal strictly speaking, i.e., that it "applies" to everything, or that it holds "in all possible worlds". This could be accepted provided it be not interpreted as the assertion that logic is a sort of universal physics (Gonseth, 1938, p. 20) or metaphysics (Scholz, 1969, pp. 399 ff.). This interpretation is mistaken because (*a*) the referents of the above formulas are predicates (universals) not things, and (*b*) the formulas and rules of logic are consistent with mutually incompatible views of the world. It is the business of metaphysics (or ontology), not of logic, to discover the bricks and plans, if any, of the real world (see Ch. 10, Sec. 4). Logic is not metaphysics, it does not depend on the latter, and it suggests no particular metaphysics (Nagel, 1956). More on this in Ch. 10, Sec. 4.2 and in Bunge (1974a).

An equivalent formulation of Theorem 1 is this: Attributes are isomorphic with their extensions. This is why one can think either in terms of attributes or of their extensions, as well as switch back and forth between them. More precisely, Theorem 1 can be reworded thus:

THEOREM 9.2 Let $\mathbb{P}$ be a family of predicates defined on a common domain D. Then the following holds:

(i) The structure $\mathcal{P} = \langle \mathbb{P}, \square, \mathrm{▯}, \vee, \&, \neg \rangle$, where $\square \in \mathbb{P}$ is the null predicate (the one with null extension) and $\mathrm{▯} \in \mathbb{P}$ is the universal predicate (the one that applies to every point in D), is a Boolean algebra.

(ii) The algebra of sets on D, i.e., $\mathcal{D} = \langle \mathcal{P}(D), \emptyset, D, \cup, \cap, ^{-} \rangle$, is a Boolean algebra.

(iii) $\mathcal{P}$ and $\mathcal{D}$ are isomorphic.

This result had to be stated explicitly because occasionally (e.g., Birkhoff, 1961, p. 189) one reads that there is a dual isomorphism (i.e., an anti-isomorphism) between the algebra of attributes and the one of classes. The duality holds between predicates and their extensions: recall Fig. 4.2 in Ch. 4, Sec. 2.3.

Finally a word on the relation between extension and reference. Except in the case of unary predicates this relation is not simple, because (*a*) extension is reference *cum* truth, and (*b*) whereas reference classes are classes of individuals, extensions are sets of n-tuples. A simple relation obtains only between extension and adequate or correct reference. The latter concept is introduced by

DEFINITION 9.2 The *adequate reference* $\mathcal{R}_p^+(P)$ of a predicate P equals the union of the projections of its extension $\mathcal{E}(P)$ on the cartesian factors of the domain of P. In particular, for a binary predicate P defined on $A \times B$,

$$\mathcal{R}_p^+(P) = p_A \mathcal{E}(P) \cup p_B \mathcal{E}(P) \subseteq \mathcal{R}_p(P).$$

1.4. *Comparing Extensions*

Since Definition 1 and Theorem 1 help us to compute individual extensions, we can *a fortiori* compare them. In particular we can ascertain whether two predicates are coextensive in the sense specified by

DEFINITION 9.3 Let P and Q be any predicates. Then P and Q are said to be *extensionally equivalent*, or *coextensive*, just in case they have the same extension:

$$P \sim_e Q =_{df} \mathscr{E}(P) = \mathscr{E}(Q).$$

Remark 1 Identical predicates are coextensive but the converse is false. Thus "lighter than" and "cheaper than" are coextensive in the collection of materials of a given kind but they are intensionally different. If extensionalism were right then coextensives should be identical.
Remark 2 Consequently Leibniz' principle, *"Eadem sunt, quae sibi mutuo substitui possunt, salva veritate"*, is false. In fact let p and p' be two propositions differing only in that the predicate $P' \neq P$ occurs in p' in exactly the same syntactical place P occupies in p. Assume further that P and P' are coextensive. Then p and p' will have the same truth value although different senses: therefore p and p' *non sunt eadem*. Truth values do remain invariant under substitution of coextensives – but truth is not everything and does not determine meaning.

From Definition 3 it is obvious that $\sim_e$ is an equivalence relation. Hence it generates equivalence classes according to

DEFINITION 9.4 Let $\mathbb{P}$ be a family of predicates. Then the class of $\sim_e$-relatives of $P \in \mathbb{P}$ is the subset of $\mathbb{P}$ formed by the equivalence class generated by P, i.e.,

$$[P] = \{Q \in \mathbb{P} \mid Q \sim_e P\}.$$

We can now state a proposition that in a way is the converse of the principle of abstraction or separation of set theory, namely the one predicate-one set axiom. It is the following

PROPOSITION An arbitrary set A determines an equivalence class of predicates under the relation of equiextensionality, namely,

$$\emptyset \subseteq \{Q \in \mathbb{P} \mid \mathscr{E}(Q) = A\} \subseteq \mathbb{P}.$$

Such classes of coextensive predicates need have no structure whatsoever. However the whole lot of such classes does have a definite structure, as will be seen in Sec. 1.5. But we can do better than grouping coextensive predicates: we can compare predicates that are not coextensive provided they are of the same rank. Thus "ellipse" is extensionally included in "conic section", which is in turn extensionally included in "plane figure". In general we have

DEFINITION 9.5 Let P and Q be n-ary predicates. Then P is *extensionally included in* Q iff the graph of P is included in the graph of Q:

$$P \preccurlyeq_e Q =_{df} \mathscr{E}(P) \subseteq \mathscr{E}(Q).$$

We are now in a position to state and prove

THEOREM 9.3 If P and Q are n-ary predicates such that $P \Rightarrow Q$, then P is extensionally included in Q and conversely:

$$P \Rightarrow Q \quad \text{iff} \quad P \preccurlyeq_e Q, \quad \text{i.e.,} \quad \mathscr{E}(P) \subseteq \mathscr{E}(Q).$$

Proof. Assume that Pa holds. Hence $a \in \mathscr{E}(P)$. By hypothesis, if Pa then Qa. Since we did assume Pa, it follows that Qa, which amounts to $a \in \mathscr{E}(Q)$. But a is an arbitrary solution of Px, hence $\mathscr{E}(P) \subseteq \mathscr{E}(Q)$. The converse is proved similarly.

COROLLARY 9.4 Equivalents are coextensive:

$$P \Leftrightarrow Q \text{ iff } P \sim_e Q, \quad \text{i.e.,} \quad \mathscr{E}(P) = \mathscr{E}(Q).$$

THEOREM 9.4 If P entails Q then the extension of P is contained in the extension of Q, i.e., if $P \Rightarrow Q$ is a tautologous predicate then $\mathscr{E}(P) \subseteq \mathscr{E}(Q)$.

Proof. By Theorem 1(iv), $\mathscr{E}(P \Rightarrow Q) = \overline{\mathscr{E}(P)} \cup \mathscr{E}(Q)$ and, by Definition 1, when $P \Rightarrow Q$ is tautologous $\mathscr{E}(P \Rightarrow Q) = D$. Hence $\overline{\mathscr{E}(P)} \cup \mathscr{E}(Q) = D$, which amounts to $\mathscr{E}(P) \subseteq \mathscr{E}(Q)$.

Let us finally consider the extreme cases of null and maximal extension. More explicitly, we introduce the following two concepts:

DEFINITION 9.6 (i) A predicate with null extension is called *minimal.* (ii) A predicate whose extension coincides with its domain of definition D is said to be *maximal relative to D.*

Example 1 The predicate P such that $Px =_{df} (x^2 = -1)$ & x is a real number, is minimal, for it is satisfied by no real number: $\mathscr{E}(P) = \emptyset$. *Example 2* The predicate P such that $Px =_{df} ((x-1)(x+1) = x^2 - 1)$, is maximal in the field of complex numbers, as it holds for every x in it: $\mathscr{E}(P) = \mathbb{C}$.

THEOREM 9.5 (i) There are infinitely many extensionally minimal predicates of a given rank. (ii) A minimal predicate implies any predicate of the same rank. (iii) There are infinitely many extensionally maximal predicates of a given rank. (iv) A maximal predicate is implied by any predicate of the same rank.

Proof. The first part follows from Corollary 3(i) and the third from Corollary 3(ii). The other two parts follow from Theorem 3 and Definition 6 by recalling that the empty set is included in any set.

In logic and mathematics a minimal predicate is an impossible one: not so in factual science. Here we find plenty of minimal predicates, such as "perfectly rigid", with nonempty reference classes as well as nonvoid senses.

1.5. *Algebraic Matters*

Consider a nonempty set $\mathbb{P}$ of predicates defined on a common domain D. Moreover assume that $\mathbb{P}$ is closed under negation, conjunction, and disjunction. The relation $\sim_e$ of coextension, introduced by Definition 3, effects a partition of the family $\mathbb{P}$ into mutually disjoint equivalence classes $[P]$ characterized by Definition 4. Call

$$\mathbb{P}/\sim_e = \{[P] \mid P \in \mathbb{P}\}$$

the family of all the classes of coextensives in $\mathbb{P}$. We define a partial order $\sqsubseteq$ in this quotient set with the help of the relation $\preccurlyeq_e$ of extensional inclusion introduced by Definition 5:

DEFINITION 9.7 If $P, Q \in \mathbb{P}$, then

$$[P] \sqsubseteq [Q] \quad \text{iff} \quad P \preccurlyeq_e Q.$$

Since $\mathbb{P}$ is partially ordered by $\sqsubseteq$, $\langle \mathbb{P}/\sim_e, \sqsubseteq \rangle$ is a poset itself. Moreover we turn it into a richer structure, namely a lattice, upon defining the lattice operations $\sqcap$ and $\sqcup$ in the following way:

$$[P] \sqcap [Q] =_{df} [P \,\&\, Q], \qquad [P] \sqcup [Q] =_{df} [P \vee Q].$$

In fact consider the class $[P \,\&\, Q]$ of all the predicates coextensive with $P \,\&\, Q$. Since $P \,\&\, Q$ entails P, $[P \,\&\, Q] \sqsubseteq [P]$ by Theorem 3 and Definition 7. Exchanging P for Q we also obtain $[P \,\&\, Q] \sqsubseteq [Q]$. This proves that $[P \,\&\, Q]$ is a lower bound of the subset $\{[P], [Q]\}$ of $\mathbb{P}/\sim_e$. Furthermore $[P \,\&\, Q]$ is the greatest lower bound, or infimum, of that subset. In fact let $[R]$ be a lower bound of the latter, i.e., assume that $[R] \sqsubseteq [P]$ and $[R] \sqsubseteq [Q]$. Then, again by Theorem 3 and Definition 7, $R \Rightarrow P$ and $R \Rightarrow Q$. Now, by logic $R \Rightarrow P \,\&\, Q$, whence $[R] \sqsubseteq [P \,\&\, Q]$. That is, $[P \,\&\, Q] = [P] \sqcap [Q]$ is, indeed, the infimum of $\{[P], [Q]\}$. We proceed analogously with $[P \vee Q]$. This time we start from the logical axiom $\ulcorner P \Rightarrow P \vee Q \urcorner$, to derive $[P] \sqsubseteq [P \vee Q]$ and $[Q] \sqsubseteq [P \vee Q]$. which proves $[P \vee Q]$ to be an upper bound of $\{[P], [Q]\}$. It can also be shown that $[P \vee Q]$ is the least upper bound, i.e., the supremum of the subset of coextensives concerned. Furthermore it can be proved that the equivalence classes in $\mathbb{P}/\sim_e$ inherit the distributivity characteristic of the predicates themselves. Since all of this is proved for arbitrary elements of $\mathbb{P}$ we conclude that the family of classes of coextensives forms a distributive lattice. More precisely, we have

THEOREM 9.6 Let $\mathbb{P}$ be a nonempty set of predicates defined on a common domain and let $\mathbb{P}$ be closed under negation, conjunction and disjunction. Furthermore call $\sim_e$ the relation of equal extension. Then the structure $\langle \mathbb{P}/\sim_e, \sqcap, \sqcup \rangle$ is a distributive lattice.

Moreover this lattice contains a null element $\square$ and a unit element ▯, i.e., equivalence classes such that, for every class $[P]$ of coextensives,

$$\begin{aligned} &[P] \sqcap \square = \square \sqcap [P] = \square, \qquad &&[P] \sqcup \square = \square \sqcup [P] = [P] \\ &[P] \sqcap \text{▯} = \text{▯} \sqcap [P] = [P], \qquad &&[P] \sqcup \text{▯} = \text{▯} \sqcup [P] = \text{▯}. \end{aligned}$$

Indeed, since $\mathbb{P}$ is closed under negation and disjunction, we shall find in it at least one tautologous predicate T – one of the infinitely many maximal predicates discussed towards the end of the previous subsection. Then any other predicate S in the family will entail T, i.e., $\vdash S \Rightarrow T$.

Consequently $[S]\sqsubseteq[T]$. This proves $[T]$ to be the maximal element of $\mathbb{P}/\sim_e$: call it ▯. Similarly for a contradictory predicate $\neg T$: for every predicate S in $\mathbb{P}$, $\vdash\neg T\Rightarrow S$. Hence $[\neg T]\sqsubseteq[S]$. This proves that $[\neg T]$ is the minimal element of $\mathbb{P}/\sim_e$: call it $\square$. Finally we can build the complement $\overline{[P]}=[\neg P]$ of any class $[P]$ of coextensives: it is such that

$$[P]\sqcap\overline{[P]}=\square,\qquad [P]\sqcup\overline{[P]}=\text{▯}.$$

In short, we have proved that our distributive lattice is complemented and comes with a universal and a null element – in sum, that it is a Boolean algebra. To put it explicitly:

THEOREM 9.7 Let $\mathbb{P}/\sim_e$ be a family of coextensive predicates. Then the structure $\langle\mathbb{P}/\sim_e, \square, \text{▯}, \sqcap, \sqcup, {}^-\rangle$ is a Boolean algebra.

This particular Boolean algebra may be called the *Lindenbaum algebra of predicates*, by analogy with the Lindenbaum algebra of propositions. If we disregard all differences between individual predicates and propositions except their differences in extension, we shall limit our attention to their respective Lindenbaum algebras. The extensionalist thesis is, in a nutshell, that only such algebras matter. Our view is, on the other hand, that extensions constitute just one aspect, and not even a basic one, of the concepts of the predicate type. Semantics must investigate all the sides and must show how they are related. We proceed to exhibit the relation between extension and intension.

1.6. *Extension and Intension: The Inverse Law*

The richer a concept the smaller its coverage. Thus since the concept of solid is richer than that of body, the set of solids should be included in the class of bodies. The "inverse law" can be stated in set theoretic terms (Bunge, 1967a, I, p. 68) and can now be proved with the help of the calculus of intensions in Ch. 4 and the concept of extension studied in the previous subsections. It consists in the following

THEOREM 9.8 For any two predicates P and Q of the same rank (hence extensionally comparable)

(ii) If $\mathcal{I}(P) \subset \mathcal{I}(Q)$ then $\mathcal{E}(P) \supseteq \mathcal{E}(Q)$.

Proof of (i). Suppose the consequent of (i) to be false. Then we can "balance" the "inequation" by setting $P = Q$ & R, where R is a nontautologous predicate such that $\mathcal{E}(P) = \mathcal{E}(Q \,\&\, R)$. By our calculus of intensions (Def. 1(i), in Ch. 4, Sec. 2.2), $\mathcal{I}(P) = \mathcal{I}(Q) \cup \mathcal{I}(R) \supseteq \mathcal{I}(Q)$, contrary to hypothesis.

Proof of (ii). Assume $\mathcal{I}(P) \subset \mathcal{I}(Q)$. Then $\mathcal{I}(Q) = \mathcal{I}(P) \cup X$, with X a nonempty set. Since by hypothesis $\mathcal{I}$ is onto, there exists a third predicate R such that $\mathcal{I}(R) = X$. That is, $\mathcal{I}(Q) = \mathcal{I}(P) \cup \mathcal{I}(R)$. And, again by our calculus of intensions, $\mathcal{I}(Q) = \mathcal{I}(P \,\&\, R)$. Now, the extension of P & R is, by the calculus of extensions, $\mathcal{E}(P \,\&\, R) = \mathcal{E}(P) \cap \mathcal{E}(R) \subseteq \mathcal{E}(P)$, i.e., $\mathcal{E}(P) \supseteq \mathcal{E}(P \,\&\, R) = \mathcal{E}(Q)$. In brief, the assumption that $\mathcal{I}(P) \subset \mathcal{I}(Q)$ entails that $\mathcal{E}(P) \supseteq \mathcal{E}(Q)$. Since whatever entails implies, the theorem has been proved.

Remark 1 The converse of Theorem 8(i) is false, as shown by the following counterexample. Let P = Mass density, Q = Specific heat. These two are coextensive, as they apply to all bodies and only to them, but they are not cointensive. *Remark 2* Since the intension of a predicate is included in its full sense, the above theorem holds also for the latter: the richer the sense the poorer the extension. *Remark 3* In our semantics sense and reference, rather than intension and extension, occur on an equal footing: extension depends on reference and truth instead of being a basic characteristic. Moreover extension depends pragmatically, though not semantically, on sense as well. Indeed we cannot proceed to find out the extension of a predicate unless we know its meaning, i.e., its sense and reference. (Try to locate a nondescript object.) *Remark 4* To paraphrase the preceding comment: It is not that extension is a function of sense, but that a *knowledge* of sense precedes an *investigation* of extension. *Remark 5* If there were a semantic relation between intension and extension, other than Theorem 8, we would be able to determine extensions by purely conceptual means: the whole of experimental science would be unnecessary.

Theorem 8 can be given an interesting twist if rewritten in terms of the complements of the extensions, with the help of the theorem: $A \supseteq B$ iff $\bar{A} \subseteq \bar{B}$. Just as $\mathcal{E}(P)$ is the collection of objects for which P holds, so $\overline{\mathcal{E}(P)}$ is the set of objects that fail to satisfy P or, in metaphorical terms, whatever P "excludes". If P happens to have factual referents, then $\overline{\mathscr{E}(P)}$ will be the set of things or facts excluded by P. Reformulated in these terms, our last theorem becomes

COROLLARY 9.5 For any predicates P and Q of the same rank:

(i) If P and Q are cointensive then they exclude the same things;

(ii) The richer and predicate the more it excludes: If $\mathscr{I}(P) \supset \mathscr{I}(Q)$ then $\overline{\mathscr{E}(P)} \supseteq \overline{\mathscr{E}(Q)}$.

If it made sense to assign propositions (not just predicates) an extension, the previous proposition might be regarded as a formulation of Popper's idea that the more it is asserted the more is excluded. But then it would be a trivial restatement of the classical "law".

1.7. *Concluding Remarks*

We have restricted the arguments of the extension function to predicates: in the preceding theory it makes no sense to speak of the extension of a construct of a different category, such as a proposition or a theory. Save exceptions it does not even make sense to ask about the extension of the conjunction of the basic predicates of a theory, since the conjunction of predicates must be defined on a common domain (recall Ch. 1, Sec. 1.3). Thus in a group the group operation, which is binary, and the inverse operation, which is unary, cannot be conjoined to form a third predicate.

However, the restriction to predicates can be lifted in at least two ways. One of them consists in equating the extension of a proposition with that of the most complex predicate occurring in it. For example, the (strict) extension or "domain of validity" of Newton's second law of motion is the collection of bodies with size comprised between that of macromolecules and that of galaxies. Now, the law can be compressed into $\ulcorner(x)\, Nx\urcorner$, where x is the object (or referent) variable and N a complex predicate involving functions and differential operators. Hence we can set

$$\mathscr{E}((x)\, Nx) = \{x \mid Nx\} = \mathscr{E}(N)\,.$$

This extension of the theory of extensions explicates the intuitive notion of the "domain of validity" (or truth range) of a formula, familiar to scientists. The systematic development of this idea is left to the reader.

A second generalization has actually been performed by model theory but it applies only to uninterpreted formulas. The extension of an (abstract) "sentence" s is defined as the collection of models of s, i.e.

$$\mathscr{E}(s)=\{\mathscr{A} \mid \mathscr{A}\in R \,\&\, \mathscr{A}\models s\},$$

where R is the class of all relational structures of a given type. Similarly the extension of an abstract theory, such as Boolean algebra, is the set of all its models. This construal has at least two virtues. One is that it looks natural or intuitive to regard the extension of a formula, or even a whole bunch of formulas, as the totality of its realizations – provided the given formula *has* alternative realizations, i.e., it is abstract. Another is, of course, that if one does this then he gets a ready made theory of extensions, i.e. model theory. When suitably reworded this theory contains our basic Theorem 1 in Sec. 1.3 above (see, e.g., Bell and Slomson 1969 p. 159). But such a general theory of extensions is helpful only with reference to formal constructs and moreover abstract ones. As we saw in Ch. 6, Sec. 2.4, in factual science formulas are already interpreted and satisfied in some fixed mathematical structure or other, so that one is hardly interested in the totality of models of an abstract formula.

We conclude by emphasizing that our theory of extensions is not extensionalist, if only because it is based on a non-Fregean analysis of predicates. The contrast becomes most vivid in the case of a statement such as ⌜All unicorns are stars⌝. From an extensionalist point of view this is a true proposition because it is just an instance of the theorem ⌜The empty set is included in every set⌝. On the other hand in our semantics, which starts from predicates not from their extensions, "not-unicorn or star" does not refer, because its constituents "unicorn" and "star" are defined on disjoint domains. (That this is so constitutes of course a bit of empirical information.) Hence its extension is nil. Therefore the statement is false. And extensionalism does not supply an adequate account of extensions.

2. VAGUENESS

2.1. *Meaning Vagueness*

Ideally, a scientific predicate should have an exact sense, a precise reference class, and a definite extension. A predicate satisfying the first two conditions shall be called *exact*. If a predicate fails to meet either condition it will be called *inexact*. Note that exactness is not a question of extension for, in our view, truth valuations are external to constructs. Thus we may build a well organized mathematical theory concerning an unheard-of thing, a theory with an exact sense and a precise reference, but which has so far not been assigned a truth value because it has not been subjected to any tests. The peculiar predicates of this theory will then be exact even though they have been assigned no extension.

In the practice of factual science few predicates are exact. Only those belonging to a well organized theory could be exact, but sometimes they are not because of some uncertainty concerning their precise reference. A typical example of referential uncertainty is quantum mechanics, sometimes said to concern individual microsystems, at other times assemblies of such, and most often either individual systems or ensembles manipulated by observers. Under these circumstances quantum mechanical predicates are bound to be inexact in the open context of research even though they satisfy definite mathematical conditions. It is only within a precise formulation of both the mathematical formalism of the theory and its semantics, that the predicates of the theory can be exact. The applied mathematician and the mathematical physicist will not worry about interpretation problems: they will seize on the mathematical formalism shared by all the rival versions. In other words, all the quantum mechanical predicates have a hard core of meaning determined by the formalism (which includes the skeletons of the law statements) and that remains invariant under reinterpretations. This suggests introducing

DEFINITION 9.8 Let P be a predicate shared by every member T of a family $\mathcal{T}$ of theories. Then the *core meaning* of P has the following components:

(*a*) the *core sense* of P:

$$\mathcal{S}_{\text{core}}(P) = \bigcap_{T \in \mathcal{T}} \mathcal{S}_T(P);$$

(b) the *core reference class of P*:

$$\mathcal{R}_{\text{core}}(P) = \bigcap_{T \in \mathcal{T}} \mathcal{R}_T(P).$$

Our definition applies not only to the alternative interpretations of a given mathematical formalism but also to any theories that share a given predicate. For example, while the full meaning of "temperature" is determined by the totality of theories in which it occurs, their intersection determines the core meaning of that predicate. What remains outside the core is precisely the meaning vagueness of the predicate. More precisely, we adopt

DEFINITION 9.9 Let P be a theoretical predicate with given core sense $S_{\text{core}}(P)$ and given core reference class $\mathcal{R}_{\text{core}}(P)$. Then the *vagueness in the meaning* of P relative to the theory T is

$$\Delta_T\mathcal{M}(P)=\langle\Delta_T\mathcal{S}(P),\ \Delta_T\mathcal{R}(P)\rangle$$

where

$$\Delta_T\mathcal{S}(P)=\mathcal{S}_T(P)\ \Delta\mathcal{S}_{\text{core}}(P)$$
$$\Delta_T\mathcal{R}(P)=\mathcal{R}_T(P)\ \Delta\mathcal{R}_{\text{core}}(P)$$

and 'Δ' stands for symmetric (Boolean) difference.

The preceding considerations apply to theoretical predicates only. In such cases the concept of meaning vagueness turns out to be an exact concept. This is not the case with nontheoretical predicates such as "ugly". In this case one might feel tempted to try a topological approach. For example, one might wish to characterize as vague (exact) any predicate that is a limit (inner) point of a given set of predicates. But the very notion of neighborhood, necessary to define limit points and inner points, presupposes the existence of a topology of predicates. And this is forthcoming just in case the predicate family is structured, which was the case studied in Ch. 4, Sec. 2.4, but is not the case with ordinary knowledge predicates. In the latter case meaning vagueness is vague itself.

What should be done about inexact predicates? Either of two things: dressing them up in an exact garb or schooling them until they become exact. The former policy is partially implemented by allowing inexact predicates to adjust to a permissive logic of their own – e.g., some system of three valued logic (Körner 1964). We do not counsel taking this course: meaning vagueness can originate either in woolly thinking or in genuine theoretical discrepancies, and in either case it should be exhibited and worked on rather than shoved under some respectable rug. If we relax the logical standards we shall be unable to exactify our concepts within a theory as well as to discuss their differences when placed in different theories. What ought to be done is to minimize the meaning vagueness within every theory. To achieve this goal there is but one means: to improve on the logical organization and the semantics of our scientific theories. If necessary we should axiomatize them. Of course this will not guarantee the disappearance of vagueness, because alternative axiomatizations are always possible and some of them may not consist in a mere reshuffling of a fixed set of constructs. In other words, a residual meaning vagueness may be unavoidable – not as an indicator of conceptual fuzziness but rather as a healthy token of theoretical variety. While we should wish to maximize *intra*theoretical exactness we should not minimize *inter*theoretical vagueness, for this is achieved by simply outlawing all rival theories but one.

2.2. *Extensional Vagueness*

An inexact predicate is bound to be assigned an imprecise extension. For, if we are uncertain about its meaning, we shall find that there are border line cases. In this case we speak of *extensional vagueness*. A remedy for it is of course exactification. (Always go to the root of the trouble.) For example, by substituting a quantitative concept of length for the qualitative concepts "long", "medium" and "short", we get rid of meaning vagueness and at the same time decrease extensional vagueness. However, the latter may not be shrunk to nought except in very simple cases, because in general we shall have shades of truth values instead of clear cut cases of truth and falsity. Consequently extensional vagueness is sufficient but not necessary for inexactness: the former may originate in the uncertainty inherent in our truth value assignments. For this reason it is convenient to introduce a concept of extensional vagueness independent of the one of meaning vagueness elucidated in the preceding subsection.

The *strict* extension of an exact predicate P with domain D is the class of objects in D for which P is true:

$$\mathscr{E}(P)=\{x\in D \mid Px\}, \quad \text{or} \quad \mathscr{E}(P)=\{x\in D \mid \mathscr{V}(Px)=1\}.$$

The generalization to partial truth gives rise to the notion of lax extension:

DEFINITION 9.10 Let P be a predicate with domain D and $\mathscr{V}$ a truth valuation, while ε is a preassigned real number comprised between 0 and 1. Then the *extension of P to within* ε is defined as

$$\mathscr{E}_\varepsilon(P)=\{x\in D \mid 1-\varepsilon\leqslant\mathscr{V}(Px)\leqslant 1\}.$$

This concept of lax extension covers the two cases we discussed above: that of extensional vagueness due to inherent meaning vagueness, and the one due to uncertainties in truth valuation. Lax extensions include strict extensions:

$$\text{For every } 0\leqslant\varepsilon\leqslant 1,\ \mathscr{E}_\varepsilon(P)\supseteq\mathscr{E}(P).$$

The excess of the former over the latter is precisely the amount of extensional vagueness. More explicitly, we propose

DEFINITION 9.11 Let P be a predicate with domain D, lax extension $\mathscr{E}_\varepsilon(P)$, and strict extension $\mathscr{E}(P)$. Then the *extensional vagueness fringe* of P is

$$\Delta\mathscr{E}(P)=\mathscr{E}_\varepsilon(P)-\mathscr{E}(P)=\{x\in D \mid 1-\varepsilon\leqslant\mathscr{V}(Px)<1\}.$$

In words: $\Delta\mathscr{E}(P)$ includes all and only the border line cases.

The same ideas can be restated in terms of a generalized membership relation $\in_v$ defined as follows:

$$x\in_v S=_{df}\mathscr{V}(x\in S)=v, \quad \text{with} \quad 0<v\leqslant 1.$$

It is easily seen that, if $x\in_v S$, then $\neg(x\in_v S)=x\in_{1-v}S$. In terms of this generalized membership concept, the extensional vagueness fringe of a predicate P with domain D and strict extension $\mathscr{E}(P)$ becomes

$$\Delta\mathscr{E}(P)=\{x\in D \mid x\in_v\mathscr{E}(P) \quad \text{and} \quad 0<v<1\}.$$

In other words, our very sets may be allowed to be fuzzy to some extent by tying the notion of membership to that of partial truth. (For a different approach see Goguen (1969).)

Still another approach consists in focusing on statements rather than their referents. Consider an obviously vague predicate such as "healthy", or H for short, defined on the set O of organisms, i.e., $H: O \rightarrow \text{Statements}$.

Then H induces a tripartition of this set S of propositions according as the propositions Hx, with $x \in O$, are true, false, or neither. The extensional vagueness fringe of H may then be defined as the set of statements of the form Hx which prove to be neither true nor false – i.e., the statements concerning all the border line cases. If this view is adopted then the amount of extensional vagueness is given by the fraction of such alethically indeterminate statements. (Caution: do not construe such a fraction as a probability. Statements are not random variables and truth values are not allotted at random.)

We shall not pursue this matter any further but shall instead refer to the recent literature for alternative approaches (Körner, 1964; Bunge, 1967a; Gentilhomme, 1968; Goguen, 1969; Castonguay, 1972; Moisil, 1972). All of them share the conviction, laughed away by inexact philosophers, that "vagueness" can be exactified even if vagueness cannot be shrunk. There is no more paradox in this view than in the mathematical theory of approximations – nor more than in the thesis that "exact" can always be rendered more exact.

2.3. *Structural Indefiniteness*

There is a deeper rooted kind of imprecision for which no easy remedy is in sight, namely what we shall call *structural indefiniteness*. First the intuitive notion. A negative statement is less definite or less committed than an affirmative one, an existential statement less so than a universal generalization, and a possibility statement far less definite than the corresponding nonmodal proposition. Unlike the types of vagueness we have investigated before, structural indefiniteness is not due to predicate inexactness or to uncertainty in extension, but seems inherent in logical form.

A possible way of assigning indefiniteness values and thus elucidating the notion of structural indefiniteness is by adopting the following principles.

1 Atomic statements have zero structural indefiniteness.

2 The degree of structural indefiniteness of a molecular statement p equals the number of negations plus the number of disjunctions occurring in p.

3 Possibility statements, though indefinite, have no definite structural indefiniteness value.

Accordingly, for affirmative atomic statements p and q, we have

$$\begin{array}{ll} Ind(p)=0, & Ind(\neg p)=1 \\ Ind(p \,\&\, q)=0, & Ind(p \vee q)=1 \\ Ind(p \Rightarrow q)=2, & Ind(p \Leftrightarrow q)=4 \\ Ind\left(\bigwedge_{i=1}^{n} Fx_i\right)=0, & Ind\left(\bigvee_{i=1}^{n} Fx_i\right)=n-1. \end{array}$$

This concept of indefiniteness or weakness of commitment is of importance in the methodology of science (see Bunge, 1967a, I, pp. 273ff). It is often conflated with those of logical strength, content, and improbability (see Ch. 4, Sec. 3.2). Which is a reflection upon the state of semantics.

3. DEFINITE DESCRIPTION*

3.1. *The Received View: Criticism*

Definite descriptions, such as 'my mother', 'the logarithm of 1', and 'the saint next door', can pose some subtle logical and semantical problems – particularly when they refer to something that happens not to exist. It took *the* Russell to realize this and to try and analyze definite descriptions with the help of the then young mathematical logic. Russell's now classical "theory", or rather definition, boils down to this: A definite description presupposes existence and indicates uniqueness (Russell, 1905, 1919a). That is, "the so-and-so is such-and-such" must be analyzed as "There is a unique thing that is so-and-so and such-and-such". In symbols,

$$G((\imath x)\, Fx) =_{df} (\exists x)\,(Fx \,\&\, Gx \,\&\, (y)\,(Fy \Rightarrow y=x)) \tag{R}$$

Hilbert and Bernays (1968) gave a different version of the idea that "the so-and-so" is no more and no less than "there is a so-and-so and it is unique". They posited the new rule of inference

$$\frac{\begin{array}{c}(\exists x)\, Fx \\ (x)\,(y)\,(Fx \,\&\, Fy \Rightarrow x=y)\end{array}}{F((\imath x)\, Fx)} \tag{HB}$$

---

* Adapted from Bunge (1971c).

subject to certain restrictions. The differences between *HB* and *R* are these: (*a*) while *R* is a definition, *HB* is a rule of inference that, if accepted, must be added to the rules of the predicate calculus; (*b*) *R* is contextual, in the sense that the referent must be assigned a further property (i.e., *G*) to the one it exemplifies uniquely (i.e., *F*); *HB* makes no such demand but as a compensation it forces us to employ correct yet redundant expressions such as 'my mother is a mother' and 'the square of 2 is a square of 2'; (*c*) while in *R* existence and uniqueness are fused together, in *HB* they are stated separately.

Each of the above explications, *R* and *HB*, has its merits and demerits. In particular, *R* is simpler than *HB*, while *HB* involves a neat separation of existence from uniqueness. However, this detachment of the two concepts should be carried even further: one should be able to describe non-existing objects as well as objects the existence of which has not yet been established. In other words, "it is quite natural to employ descriptions *before* they have been proved to be proper" (Scott, 1967, pp. 181–182). Thus the bachelor should be allowed to say 'My wife does not exist' and the cosmologist should be able to wonder whether there is such a thing as the center of the world. Yet neither *R* nor *HB* render this possible, as both make existence a condition for definite description. For this reason both *R* and *HB* are unsuitable. The same objection holds for some other explications of the definite description (e.g., Kalish and Montague, 1957; Eberle, 1969) – certainly not for Hintikka's (1969).

In mathematics as well as in factual science questions of uniqueness are separate from questions of existence: an object satisfying a certain description may not exist or, if it does, it may not be unique. For example, the theory of differential equations contains separate existence theorems and uniqueness theorems. And in theoretical physics one can often give an unambiguous characterization of a certain object whose actual existence is far from certain: thus one may speculate on the ground state of a mesic atom that has not yet been and may never be brought into existence.

Whether in mathematics or in factual science, when attempting to validate uniqueness claims one proceeds in this way. One first assumes or exhibits existence and then one goes on to assume or investigate uniqueness under the assumption of existence: it would be wasteful to look for unique nonexistents. In other words uniqueness theorems take the form: "If there is an x with the property F then there is no y, other than x, that exemplifies F". Thus uniqueness *proofs* depend on existence assumptions or proofs but not conversely. Similarly for the empirical validation of hypotheses of factual uniqueness. But this does not mean that the *concept* of uniqueness depends upon that of existence – unless of course one is an intuitionist or an operationist. In fact the two concepts are not interdefinable. (If they were then every uniqueness theorem would be just a rewrite of some existence theorem.) And uniqueness assumptions are not deducible from existence assumptions alone.

We submit that *definite descriptions indicate only uniqueness*: that they are by themselves uncommitted as to existence – even though establishing the latter is necessary for proving the former. Otherwise the bachelor could not make jokes about his wife, the atheist could not argue about the Christian god, the physicist could not speculate about the element number 110, and the cosmologist could make no hypotheses about the center of the universe. This being so, we cannot accept any explication of definite description that involves existence. In this respect then HB is as inadequate as R. We must therefore look for a different characterization. We shall come up with two definitions, neither of which will force us to augment the set of rules of inference.

3.2. *An Elementary Analysis of Definite Descriptions*

The standard analyses of the definite description equates it with existence and uniqueness. Ours will drop existence and retain uniqueness. Now, the uniqueness condition can be expressed in a number of languages. In the present subsection we shall propose an analysis of definite description within first order predicate logic.

We are concerned with uniqueness irrespective of existence, which should be assumed or denied separately. Furthermore we wish to analyze the notion of *relative uniqueness* or uniqueness in some respect, doing it at first with the limited resources of predicate logic. There are two ways of doing this, depending on the "respect" in which an object is unique. An object may be unique because it is the sole instance of a given property, as is the case with the third power of 2. Or the object may be unique because of a relation it bears to some other object, as is the case with my mother. We shall elucidate these two notions by means of the following conventions.

DEFINITION 9.12 The object a is unique in the respect denoted by the predicate $F =_{df}$ a exemplifies F and there are no further individuals, other than a, that exemplify F:

$$a \text{ is } F\text{-unique} =_{df} Fa \;\&\; \neg(\exists x)(x \neq a \;\&\; Fx)$$

or, equivalently,

$$a \text{ is } F\text{-unique} =_{df} Fa \;\&(x)\,(Fx \Rightarrow x = a).$$

Next we stipulate that "a is F-unique" amounts to "the x such that x is an F". More explicitly, we lay down

DEFINITION 9.13 The object a is (equal to) the x such that x is an F, just in case a is unique:

$$(a = (\lrcorner\, x)\, Fx) =_{df} a \text{ is } F\text{-unique}.$$

We have chosen '$\lrcorner$' to designate the definite descriptor both for typographic convenience and to forestall confusion with Russell's symbol, which designates a different concept.

The above definitions entail our *elementary explication of the definite description*:

$$(a = (\lrcorner\, x)\, Fx) =_{df} Fa \;\&(x)\,(Fx \Rightarrow x = a) \qquad (N)$$

For example, $\ulcorner 2$ is the smallest prime$\urcorner$, i.e., $\ulcorner 2 = (\lrcorner\, x)\, SPx \urcorner$, is now analyzed as: $\ulcorner SP2 \;\&(x)\,(SPx \Rightarrow x = 2)\urcorner$, where in turn SPx is defined as $(y)\,(Px \;\&\; Py \;\&\; x \neq y \Rightarrow x < y)$.

For N to hold Fa need not be true. And if Fa is not asserted (separately) then $(\exists x)\, Fx$ does not follow. Consequently N does not involve (entail) existence. For example, the equality

Zeus = The boss of the Greek Olympus.

which is a substitution instance of the left hand side of N, does not commit us to paganism. It is just a designation convention. If challenged, then the right hand side will be challenged as well but the definitory equality will still hold. Likewise if N is construed as an equivalence, since for $\ulcorner A \Leftrightarrow B \urcorner$ to hold both sides must have the same truth value, e.g., falsity. If we now assert (separately) that Zeus is a boss of the Greek Olympus then we conclude that Zeus exists; and if we deny the same statement, i.e., negate *Fa*, then we commit ourselves to the statement that Zeus does not exist.

So much for definite descriptions in terms of unary predicates. We now generalize our analysis to predicates of any rank. But to keep the exposition readable we limit our definitions to binary relations.

DEFINITION 9.14 The object a is unique in its relation R to $x =_{df}$ a bears the relation R to x and there are no other individuals y, except a itself, that are R-related to x:

$$a \text{ is } R\text{-unique in its relation to } x =_{df} Rax \,\&(y)\,(Ryx \Rightarrow y = a).$$

DEFINITION 9.15 The object a is (equal to) the x such that x bears the relation R to $b =_{df}$ a is unique in its R relation to b:

$$\begin{aligned}(a = (\lrcorner x)\, Rxb) &=_{df} a \text{ is } R\text{-unique in its relation to } b \\ &=_{df} Rab \,\&(x)\,(Rxb \Rightarrow x = a).\end{aligned}$$

To sum up, we have identified definite description with uniqueness. Unlike the accepted view ours does not involve the assumption that the described individual exists in some context: it only asserts the *non*-existence of *other* individuals satisfying the same conditions. This is as it should be, for existence is not a matter of definition, let alone of designation: existence is a matter of either assumption or validation. In other words an existence claim is a hypothesis that must be substantiated not a convention that can be freely introduced. For example, whether or not a function with given properties exists, is a matter for an existence theorem to decide. And whether or not a concrete object with assumed properties exists, is a matter that cannot be decided without performing empirical tests. These methodological requirements are violated by the construals *R* of Russell and *HB* of Hilbert-Bernays (see Sec. 3.1) but not by ours (*N*). Indeed, according to our construal the existence of the described individual may, but need not, be asserted separately, namely thus: $(\exists x)$ (x is F-unique), or thus: $(\exists x)$ (x is unique in its R relation to b). Consequently there will be no *logical* differences between a proper (or full) description and an improper (or empty) description: the differences are solely semantic. The semantic peculiarities of the definite description will be taken up in Secs. 3.5 and 3.6 in the light of a deeper yet simpler analysis of our subject, to which we turn presently.

3.3. *A Mathematical Analysis of Definite Descriptions*

We shall now avail ourselves of the general concept of a function, which goes beyond the predicate calculus. Consider the formula ⌜The cost of x is (equals) y⌝ or, more briefly, ⌜x costs y⌝. For every substitution instance of x there is exactly one value of y such that y equals the cost of x. Hence cost is a function – call it C – so that we can write: ⌜$C(x)=y$⌝. Likewise ⌜The father of x is y⌝, or shorter ⌜y fathered x⌝, can be symbolized as: ⌜$F(x)=y$⌝, where 'F' stands for the fatherhood function. These symbols convey the idea that cost and fatherhood are properties of something and moreover that these properties are adequately represented by functions in the mathematical not in the logical sense, for their values are not statements but further individuals. These examples may also be construed as relational statements with the qualification that the relations C and F be many-one. But this construal, suitable for ordinary knowledge cases such as ⌜Scott wrote *Waverley*⌝, is inadequate for most scientific purposes. In science one prefers functional statements of the form "$F(x)=y$".

Let us now *truncate* the functional formula ⌜The F of x equals y⌝ by leaving out the value of the function. We thus get "The F of x", or "$F(x)$", which may be called a *functional semistatement*. This expression indicates the function of interest and an arbitrary value of its argument but not the corresponding value of the function. If the function does have a value at x, i.e., if F is "defined" at x, then that value is unique by definition of the concept of a function. And this is all a definite description indicates, namely a unique object. We compress the preceding into

DEFINITION 9.16 Let F be a function from a set A into a set B. Then the expression '$F(a)$' is called a *proper definite description* $=_{df}$ F is defined at $a \in A$.

If $F(a)$ is a proper definite description then it names a unique individual, say b, in the codomain B of F. That is, the relation between a proper name b and a definite description $F(a)$ is now the full fledged statement "$b=F(a)$", read 'b is the F of a'. In this case $F(a)$ is a name and it poses no further problems. Otherwise we have an improper or empty definite description. More explicitly we lay down

DEFINITION 9.17 The functional semistatement $F(a)$ is an *improper definite description* $=_{df}$ F is not defined at $a\in A$.

Examples: "The weight of my thoughts", "The father of the universe". Suggestion: a number of metaphors are just improper descriptions. This remark might be useful in analyzing the structure of some metaphors.

An alternative but essentially equivalent explication is obtained with the help of the concept of a partial function, or a correspondence between a *sub*set of A and a set B. Thus "king" and "president" are partial functions on the set of countries: "king" is a total function on the set of monarchies and "president" a total function on the set of republics. In general we have

DEFINITION 9.18 Let F be a partial function with domain A. Then $F(a)$ is a *proper (improper) definite description* $=_{df}$ a belongs (does not belong) to A.

On either of the two functional construals, the description can be stated and analyzed without even having to introduce a special symbol. The link between the preceding elementary elucidation (Sec. 2) and the present one is supplied by

DEFINITION 9.19 Let P be a unary predicate with domain B and let F be a function from a set A into B. Then for all $b\in B$

$$b=(\text{℩}x)\,Px=_{df}F(a)=b.$$

Given a unary predicate P it is always possible to find the corresponding function F that will satisfy the preceding convention and conversely. For instance "golden mountain" may be construed not only as a (molecular) predicate but also as a function on the set of places. Consequently assuming that the name of the golden mountain is 'Shiny', Definition 19 gives

> Shiny = The golden mountain $=_{df}$ The golden mountain at place a = Shiny.

There is more to the relation between predicates and functions: let us look into it.

3.4. *Continuation of the Analysis*

Take “talented” as an example of a unary predicate P and “author of” as an instance of a function F. (We brush aside the case of joint authorship.) Both P and F are mappings: P maps writers into statements while F maps books into writers. That is,

$$\begin{array}{ll} P & \text{Talented: Writers} \rightarrow \text{Statements} \\ F & \text{Author of: Books} \rightarrow \text{Writers} \end{array}$$

In the first case we have, e.g., ⌜Walter Scott is talented⌝ while in the second we may have ⌜The author of *Waverley* is (equal to) Walter Scott⌝. (The *is* in the first statement is predicative while the *is* in the second statement is that of equality.) This allows us to write

$$A(w) = s,$$

where '$A(w)$' stands for “the author of *Waverley*” and 's' for Walter Scott. Consequently ⌜Walter Scott is talented⌝ can be transformed into ⌜The author of *Waverley* is talented⌝, i.e., briefly $T(A(w))$. Now, this is just an instance of the composition of the functions A and T, i.e.,

$$\text{Books} \xrightarrow{\text{Author of}} \text{Writers} \xrightarrow{\text{Talented}} \text{Statements}.$$

This composition may be represented as a commutative diagram.

$$\begin{tikzcd}
\text{Books} \arrow[r, "\text{Author of}"] \arrow[dr, "ToA"'] & \text{Writers} \arrow[d, "\text{Talented}"] \\
& \text{Statements}
\end{tikzcd}$$

Obviously this works only when the functions concerned are defined at all the points of their domains and when the range of the first equals the domain of the second. This remark will help us to solve a problem concerning the relation between definite descriptions and names.

As Russell pointed out, definite descriptions are not names. They may have the same referent but they do not mean the same. Thus 'The mother of God' "says" more than 'Mary' in the context of Catholic theology. Whatever significance a name may be assigned (and this is a controversial point), the associated definite description, if any, must have a sense containing the previous one. Nevertheless for the purposes of deduction proper definite descriptions can be treated just like names. For example, 'the sum of 2 and 3' can be replaced by the numeral '5'. In other words, although a definite description *is* not a name it behaves in inference *as if* it were a name – provided the necessary precaution is taken. The condition for this functional or behavioral identity of names and definite descriptions is, of course, that the function F in question be defined at the point of interest. For only in this case will $F(a)$ constitute a proper or nonempty definite description according to Definition 16. In other words, a definite description can be treated as a name provided there *exists* an individual complying with the description. Example:

$$\begin{array}{rl} Ts & 1 \\ A(w)=s & 2 \\ \therefore T(A(w)) & \text{1, 2, Principle of identity.} \end{array}$$

This inference is valid because, on the interpretation given above, the function A is defined at w: indeed, at w, A takes on the value s. On the other hand if now 'w' stands for the world, then in the context of a naturalistic world view the above inference is invalid no matter how 'T' be reinterpreted, for A is no longer defined at w. In short, with this new interpretation of 'w' $A(w)$ becomes an improper description and the substitution of $A(w)$ for s is invalid because one of the conditions for the composition of functions, i.e., for the existence of the composite $T \circ A$, is no longer met. (We may, if we wish, say with Frege that '$A(w)$' now designates the null individual, but this won't save the inference.) In this regard, then, our treatment does not differ from either Russell's or Hilbert-Bernays'. The difference consists, of course, in that the existence condition is now stated separately instead of being fused with the definite description.

3.5. *Meaning Questions*

We know from Ch. 7 that meaning is contextual. Thus "The creator of the universe" is meaningful in some theodicies but not in physics, where the concept of creator does not occur. Hence we had better start by recalling the notion of a context (Ch. 2, Sec. 3.4, Definition 10). We shall reword it in terms of functions rather than predicates. *Voilà*: The ordered triple $\mathbb{C}=\langle S, \mathbb{F}, U\rangle$ is called a *context* iff S is a set of statements in which only the function constants in the function family $\mathbb{F}$ occur, and the reference class of every F in $\mathbb{F}$ is included in the universe U.

We now postulate the conditions under which a definite description, construed as a functional semistatement (Sec. 3.3), makes sense in a given context and has a referent in it.

AXIOM 9.1 Let $F(x)$ be a definite description and let $\mathbb{C}=\langle S, \mathbb{F}, U\rangle$ be a context. Then $F(x)$ *makes sense* in $\mathbb{C} =_{df} F$ is in $\mathbb{F}$.

AXIOM 9.2 Let $F(x)$ be a definite description and let $\mathbb{C}=\langle S, \mathbb{F}, U\rangle$ be a context. Then $F(x)$ *has a referent* in $\mathbb{C} =_{df} F(x)$ makes sense in $\mathbb{C}$ and F is defined at $x \in U$.

Finally we identify the referent in an unambiguous way:

DEFINITION 9.20 Let $F(x)$ be a definite description that makes sense and has some referent in a context $\mathbb{C}=\langle S, \mathbb{F}, U\rangle$. Then the value $y=F(x)$ is called the *referent* of $F(x)$.

Notice that the above axioms are postulates not definitions: indeed they do not define sense and reference but just stipulate the conditions for a definite description to have them. Now, in our semantics, for an expression to be significant it must have a (vicarious) sense. (Recall Ch. 7.) It follows that "The present king of France" and other referentially vacuous definite descriptions may be meaningful in certain contexts. In other words, an empty description may stand for a concept, i.e., something endowed with a sense, even though it fails to denote, i.e., to have a real counterpart. Consequently ⌜The present king of France is bald⌝ is meaningful as well: it has a sense – and even a referent. Whether this referent exists, i.e., whether the statement is true, is another matter – one to be considered shortly.

Our theory is at variance with the view that empty descriptions and sentences containing them "suffer from infelicity" because devoid of real reference (Austin, 1962). This opinion would be justified if meaning were identified with extension. But, as we have seen in Sec. 1 and before, such a referential view of meaning would be crippling to science, where statements about "theoretical" (i.e., hypothetical) entities have to be made, discussed and put to the test long before it becomes possible to ascertain whether they have any real referents.

Another advantage of our theory is that it dissolves a well known puzzle about "intensional expressions", i.e., non truth functional formulas. Consider the descriptions

The square root of 4. (*A*)
The atomic number of Helium. (*B*)

Since *A* and *B* have the same designatum, namely 2, they are equivalent. And, being equivalent, they should be exchangeable to a nominalist (e.g., Ajdukiewicz, 1967a). But of course the two descriptions have different referents: while *A* concerns 4, *B* is about Helium. Therefore *A* and *B* are not synonymous. Consequently, on our theory they are not everywhere exchangeable, whether in "extensional" (i.e., truth functional) or "intensional" (i.e., non truth functional) contexts. Hence the statement

Archimedes knew that the square root of 4 equals 2. (*C*)

is not the same as

Archimedes knew that the atomic number of Helium is 2. (*D*)

3.6. *Truth Questions*

Consider again the much discussed statement ⌜The present king of France is bald⌝. Can we say that it is false or that it is true? Russell held it to be false and most philosophers seem to share his view for the simple (ergo suspect) reason that it is a proposition and thus (allegedly) either true or false and, not being clearly true, it must be false. However, some philosophers have felt dissatisfied with this view. Thus Frege, and at one time Strawson (1950), held that statements containing empty descriptions are neither true nor false. More recently Strawson (1964) has come to the conclusion that his former stand is not compelling: that each side has its merits and that it is unimportant which is taken.

In our view truth and falsity do not inhere in propositions but are (sometimes) attributed to them (Ch. 8). Now, in order for a statement containing a definite description to be assigned a truth value in a given context, it must point to a definite referent in some context. For, if it fails to have a referent, then the statement cannot be "faced" to it in order to be assigned a truth value. Therefore we stipulate

AXIOM 9.3 A statement containing a definite description $F(x)$ may be assigned a truth value in the context $\mathbb{C} = \langle S, \mathbb{F}, U \rangle$ iff $F(x)$ has a referent in $\mathbb{C}$ and this referent exists.

For example, "the luminiferous ether" is a definite description whose sense may be taken to be determined by some ether theory (recall Ch. 5). In all mechanical ether theories, such as Cauchy's, the statement

$$e = \ulcorner\text{The luminiferous ether is elastic}\urcorner.$$

is not only meaningful but also true. However, since the predicate "ether" is absent from modern optics, by our Axiom 1 (Sec. 3.5) it makes no sense in it. Consequently the definite description "the luminiferous ether" makes no sense in modern optics. Ergo no statement containing this definite description makes sense in modern optics: in particular, e above is not meaningful in modern optics, or *MO* for short. And, not being meaningful in *MO*, e cannot be assigned a truth value in this context. In other words, the truth valuation function $\mathscr{V}$, that may be construed to carry the couples statement-context into truth values, is not defined for the pair $\langle e, MO \rangle$. In short, $\mathscr{V}$ has no value at $\langle e, MO \rangle$ even though $\mathscr{V}(e, E) = 1$, where 'E' is short for "ether theory". (Nor does e take the value "indeterminate", as some interpretations of many valued logic would have it. A function not determined, or not defined, for a certain value of its argument has no value at it. Depending on the theory of truth $\mathscr{V}$ may take two or more values but it cannot take the value "indeterminate".) What holds for the ether holds for contemporary French kings: in the context of contemporary history ⌜The present king of France is bald⌝ is neither true nor false. (It only presupposes a false proposition.) So let us stop arguing about it.

Finally note that the Liar paradox does not occur in our semantics, because 'What I am now saying' is a definite description not a proposition, hence it cannot even be false.

3.7. *The Real Size of the Theory of Descriptions*

The analysis of definite descriptions has been overrated to the point of having been regarded as Russell's chief contribution to philosophy – which is a way of belittling *PM*. On the other hand the theory of descriptions has been underrated and even misplaced by many ordinary language philosophers. Some took it to be a matter of literary criticism, others took it for a grammatical analysis of the definite article – as if 'my wife', 'Plato's teacher', and 'that weird chap in the corner' did not qualify as definite descriptions. As has been pointed out, all advanced languages teem with definite descriptions even if, like Latin, they lack definite articles. Also mathematics, the language of science, is shot through with definite descriptions – just recall 'the sine of 10°', 'the composition of f and g', and 'the indefinite integral of f'. So is contemporary science, which has more use for definite descriptions – e.g., in the form of spatio-temporal coordinates – than for proper names. This renders Quine's proposal of assimilating all names to definite descriptions attractive. However, (*a*) even if in practice we often do proceed this way, it is convenient to have the complex notion of description analyzed into simpler concepts, and (*b*) in metaphysics we need the concept of a non-descript or bare individual that may function as one of the building blocks of the notion of a fully qualified thing. (See Ch. 1, Vol. 3 of this *Treatise*.)

Since definite descriptions are rampant, it behooves the philosopher to analyze them. But the analysis need not introduce any new technical concept: we have seen that descriptors are reducible to standard components of elementary logic and mathematics. Our evaluation of description theory lies thus midway between the two views that are currently dominant: instead of either renouncing definite descriptions or inflating them, we hold them to be normal constituents of any language with a reasonable expressive power. Moreover in our view the syntax of definite descriptions is trivial: only their semantics is somewhat complex, in the sense that it involves the notions of sense, reference, and truth. But then this is what semantics is all about: sense, reference, and truth.

This is as far as we go in applying our basic doctrines to issues in pure semantics. The next chapter, which is also the last, explores some of the relations among semantics and its neighbors.

CHAPTER 10

NEIGHBORS

In this, the final chapter, we shall peek at some of the adjacent fields of inquiry in order to better locate ours. We shall try and see what they look like in the light of our semantic candle. In each case we shall have to limit ourselves to examining a few typical problems. Moreover our discussion will be rather quick, as our aim is to explore the nature of the bonds between the semantics of science and its nearest neighbors rather than to examine the latter in detail. We shall first glance at mathematics, or rather its philosophy, then at three traditional branches of philosophy: logic, epistemology, and metaphysics.

1. MATHEMATICS

1.1. *The Relevance of Semantics to Mathematics*

That mathematics is relevant to exact semantics, is analytically true, for exact semantics is nothing but semantics built *more geometrico.* The question is whether basic semantics is relevant to mathematics – whether the former can add anything to the semantics of mathematics, or model theory. And this is not obvious.

Consider the notions of designation, reference, sense, and truth – all of which would seem to be of interest to mathematics. (The concept of model, in the model theoretic sense, is the exclusive property of the semantics of mathematics and it does not seem portable to other fields: recall Ch. 6, Sec. 2.4.) The concept of designation is almost trivial and so is that of reference in the case of mathematics – though not so in relation to science. Indeed, to all but the literalists it is clear that mathematical symbols designate mathematical constructs. It is equally plain that mathematical concepts and statements either are or concern mathematical objects, which are so many constructs. Thus while "two" does not refer to anything, "even" refers to integers and ⌜Two is an even number⌝ refers to two, which can in turn be designated by the numeral '2'. So far nothing shattering.

As to the third generic semantic concept, namely that of sense, we do have something to say about it, particularly since model theory deals only in extensions. (Recall Ch. 6, Sec. 2.3.) But in our view the full sense of a theory, whether mathematical or factual, is ultimately determined by the postulates of the theory. (See Ch. 5, Sec. 5.) Hence we have nothing to add to what was said in Chapters 4 to 7. (For specifics concerning meaning in mathematics see Castonguay (1972).) However, we may caution against the persuasive or ideological uses of 'sense' and 'meaning' as exemplified by the war-cry that whatever fails to be constructive, such as the axiom of choice, is meaningless (cf. Lorenzen, 1967). This Principle of Intolerance is meaningless unless backed by a definite theory of sense (or of meaning) in the spirit of constructivism – which, alas, is not available. So much for sense in mathematics.

On the other hand we have little to say about the fourth capital term of semantics, namely 'truth', with reference to mathematics. The reason is that, although 'truth' parades as a general term, it is not: 'truth' is an ambiguous term designating two radically distinct concepts, namely those of formal truth and factual truth. Whereas factual truth is elucidated in terms of external reference and empirical evidence, formal truth is elucidated in terms of satisfiability and proof. (From a pragmatic point of view proof has the upper hand, since showing that a formula is true in a certain model, or under a certain interpretation, boils down to proving the formula in the theory of the model.) Whereas factual truth is the object of a special theory, formal truth is elucidated within model theory, which is a multiple purpose theory. (Also the notion of potential formal truth is definable in model theoretic terms: see Robinson, 1965. And even the notion of partial formal truth can be handled by model theory: see Chang and Keisler (1966).) Because our system of semantics is geared to factual science, it is as irrelevant to mathematical truth as the model theoretic concept of truth is alien to factual truth.

In sum, only our theory of sense (Chapters 4 and 5) makes sense with reference to mathematics. Having nothing further to offer we shall close with a couple of critical remarks.

1.2. *On Extensionalism*

'Extensionalism' is sometimes taken to designate the thesis that ordinary logic is the only logic one needs – that, in particular, modal logics are dispensable. We accept this thesis but reject that designation as mistaken and misleading. (See Ch. 4, Sec. 1.3.) The authentic extensionalist thesis is, in a nutshell, that *every concept worth its name is a set.* When adopted in semantics, extensionalism effects a hecatomb: it kills sense (in every sense) and it is apt to conflate reference with extension.

The prestige of the extensionalist thesis stems from the belief that it has subdued mathematics. In fact it is widely held that (*a*) set theory is fully extensional and (*b*) the whole of mathematics is reducible to set theory. However, these two tenets are, to say the least, controversial. First, set theory contains a basic concept, that of membership, which is not construed as a set but as a relation between something (whether individual or not) and a set. Not only is the membership relation not defined as a set (of ordered pairs), but the latter is partially defined in terms of the former, namely by saying that, if $x \in y$, then y is a set. (But of course only the totality of postulates of some set theory does the job of determining the full sense of $\in$.)

Second, set theory contains a postulate, the principle of separation (or its forerunner the principle of abstraction), that relates predicates to sets – the extensions of the former – without defining the former in terms of the latter. (Recall Ch. 4, Sec. 1.2 and Ch. 9, Sec. 1.1.) If this were the sole assumption of every set theory then it would support Russell's view that reasoning on properties is primary – and by the same token it would disqualify Bourbaki's Olympian contempt for the allegedly anachronistic *raisonnement en compréhension.* However, a balance between the two extremes looks more realistic than either.

Third, although nowadays nearly every mathematical theory – much to Wittgenstein's chagrin – uses set theoretic concepts and even some formulas of set theory, it must add something of its own if it is to get off the ground. Without such specific concepts and assumptions, that are not reducible to (definable in or deducible from) set theory, there would be no mathematical theories other than set theory. (The fact that most new mathematical concepts can be characterized with the *help* of set theoretic concepts does not entail that they were already "contained" in set theory. Likewise an organism is not prefigured in its physical components.) Thus the definition of one of the simplest mathematical structures, namely a semigroup, requires the notion of associativity, which set theory does not define.

The upshot of the preceding discussion, conjoined with that in Ch. 4, Sec. 1.2, is that the extensionalist thesis is false in mathematics. On the other hand the program of using set theoretic concepts in the whole of mathematics and its applications has been tremendously fruitful although it may not be the last word. In any case "set theorification" should be kept distinct from extensionalization.

1.3. *On Objectivity*

Our second and last remark will concern objectivity. It is almost universally agreed that mathematics is objective – but this because everyone seems to have his own concept of objectivity. In any event this much seems to be true: Although mathematics is a creature of the brain, it is not in the same category with (wild) dreams and (silly) fairy tales. It does not hold by arbitrary decree or because I want to or because we happen to believe in it. Once born, a piece of mathematics ceases to be subjective and acquires a certain objectivity. In fact it is as objective as factual science – only in a different sense. Let us compare these two modes of objectivity.

The objectivity of factual science consists in its reference to external objects alone (semantic objectivity) and in its impersonal or publicly scrutable checking procedures (methodological objectivity). Even mental processes, when studied by scientific psychology, are handled as external objects and in a publicly criticizable way. Mathematics, on the other hand, fails to refer to external objects, whether ideal or material, hence it is not semantically objective. Nor is it semantically subjective: it is not concerned with our private mental states. The objective/subjective dichotomy, in the semantic sense, applies to mathematics no more than the hot/cold dichotomy does.

But mathematics is *methodologically objective*, though not in the sense that it employs empirical testing procedures (observation, measurement, experiment). The methodological objectivity of mathematics consists in (*a*) impersonality, (*b*) abidance by the assumptions and rules agreed on beforehand – including the general principles of rational argument, and (*c*) the justification of both assumptions and rules in terms of impersonal values such as coverage, systemicity, validity, and clarity. All three traits are shared with factual science, which adds empirical testing to them. Hence mathematical objectivity is but a special case of scientific objectivity: objectivity without objects other than mathematical constructs.

In sum, mathematics does not possess the semantic objectivity that both Platonists and vulgar materialists assign it: mathematics is neither about self existent ideas hovering over the world nor about the latter. Mathematics is methodologically objective in the sense that its procedures are exoteric. But mathematics is not semantically objective. To claim that it is (as Popper (1972), (1974)) does, i.e. to hold that mathematics is just as objective as physics, is to conflate epistemological realism with objective idealism.

2. LOGIC

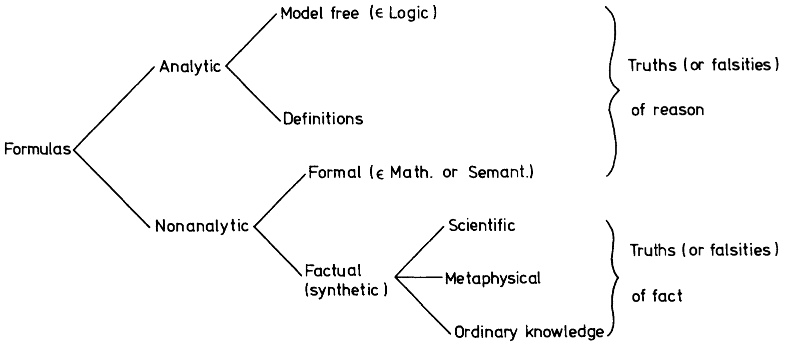
2.1. *Analyticity*

The problem of analyticity has held the attention of philosophical semanticists to the detriment of all other semantical problems, thus creating a serious imbalance and causing boredom. So far in this work we have made a modest use of the concept of analyticity, or rather one of them, without elucidating it. The time is ripe for such an elucidation. As usual we must choose the target before shooting: we must decide whether we want to have a narrow concept or a wide one. Having tried a concept of analyticity of maximal extension in the past (Bunge, 1961b) we shall now choose the most restricted one. The strict (and relative) acceptation of 'analytic' is this: An analytic formula is one that either holds under all interpretations (in all models) or consists in a definition. More explicitly, we adopt the following

DEFINITION 10.1 A formula ϕ in a theory T is *analytic in* $T =_{df}$ ϕ is either a definition in T or model free.

This convention does not employ the notions of logical form and meaning but it fits the statements that are (formally) true "by virtue of their form", i.e. the tautologies, as well as those that hold "by virtue of the meanings of their parts" – e.g. the dictionary definitions (which Carnap called 'semantic postulates').

To call 'synthetic' all those formulas that are not analytic would be misleading in view that 'synthetic' has so often been equated with 'having a factual content' or with 'empirically testable' or with 'informative'. The extralogical formulas of a mathematical theory are not analytic in the sense of Definition 1 but it would be queer to call them 'synthetic': they are *neither* analytic nor synthetic (in the sense of empirical or factual). In other words, *the analytic/synthetic distinction is not a dichotomy.* We must distinguish more than two species of statement, at least the following ones:



Formulas
Analytic
Model free (∈ Logic)
Definitions
Nonanalytic
Formal (∈ Math. or Semant.)
Factual (synthetic)
Scientific
Metaphysical
Ordinary knowledge
Truths (or falsities) of reason
Truths (or falsities) of fact

The preceding definition of "analyticity" seems to be precise and clear but it does not solve the practical problem of spotting analyticity in every single case. Such a problem will come up in ill organized conceptual bodies such as those of ordinary knowledge and of intuitively formulated scientific theories. For example, the statement ⌜Seeds germinate when they fall on fertile soil⌝ may be taken either as a lawlike statement or as a covert (and partial) definition of soil fertility. If ambiguities like this arise in the flabby context of ordinary knowledge, so much the worse for the latter – or for the attempt to draw technical distinctions in nontechnical contexts. No such status ambiguities occur in a reasonably well organized conceptual body. What does happen in the latter case is that one and the same formula may be analytic in one systematization and nonanalytic in the next – but we made room for such switches by relativizing the concept of analyticity to that of theory in Definition 1.

In conclusion, our definition of analyticity solves the theoretical problem of elucidating this notion but is not a fool proof *criterion* for telling whether a given formula is analytic – much less for identifying analytic components in open contexts. (Likewise a definition of consistency is not enough to prove the consistency of any particular theory.) Nevertheless a difficulty in drawing a distinction in particular cases does not prove that there *is* no difference. Nor does it prove that it is impossible to reorganize the body in question so as to bring out the difference, not just between analytic and nonanalytic statements, but also between hypotheses and conclusions, and so on.

If the preceding considerations are substantially correct then the concept of analyticity is far less important to philosophy than that of truth of reason or necessary truth (Leibniz, 1714). While this wider concept serves to distinguish formal science from factual science, the narrower one of analyticity serves to characterize logic *vis-à-vis* the rest and, in particular, mathematics. Indeed, while the two formal disciplines contain only necessary truths, logic has the monopoly of analytic formulas other than (extralogical) definitions. Mathematics does not get started unless some nonanalytic (and nonfactual) formulas, containing extralogical concepts such as "$\leqslant$" and "$+$", are added to a basic logical broth. For example, the theory of groupoids adds the following ingredients to the logical predicates: an abstract set and a binary operation on it.

In sum, given a set R of rules of inference, logic is self-generating, i.e. the totality of analytic formulas follows from no assumption whatever. (The catch is in R.) On the other hand a piece of mathematics requires, in addition, a nonempty set of extralogical (but also nonfactual) assumptions. In symbols: while $\emptyset \vdash_R Logic$, $A \vdash_R Mathematics$, where A is the set of mathematical assumptions. (A change in R may shift the border line without obliterating it.) An equivalent characterization of the difference is this: While the truths of logic are satisfied in all models, those of mathematics are satisfiable only in some models – sometimes just one, at other times infinitely many, but never all.

We uphold then the analytic/synthetic distinction, indicted in recent times (Quine, 1952). However, we do not define analyticity in terms of the information needed for understanding a sentence, this being a pragmatic not a semantic concept of analyticity; hence we are not bothered by Quine's examples. Furthermore we do not regard the distinction as a dichotomy or as being central to the whole of semantics and the philosophy of formal science. The essential distinction, as far as epistemology and the philosophy of science are concerned, is that between truths (or falsities) of reason and truths (or falsities) of fact. Were we to give it up we might be tempted to indulge in either of the following oddities: empiricism with regard to formal science, and apriorism with reference to factual knowledge. To show that these are not imaginary perils we quote an instance of each. The empiricist philosophy of mathematics is defended by no less than Kalmár (1967 criticized by Goodstein 1969). And the converse move, of eliminating extralogical postulates in favor of definitions, is not only a favorite ploy with conventionalists (criticized by Enriques, 1943, pp. 250–251) but has also been tried by Quine and Goodman (1940, Quine, 1964, criticized by Bunge, 1967a, I, pp. 132–133). Finally, many mechanics textbooks contain traces of Mach's attempt to blend the two moves – taking law statements for definitions and conversely (see Bunge, 1966). If only to avoid such errors it is imperative to hold the fort – not the analytic/synthetic nondichotomy but the rational/factual dichotomy. Still, it is equally imperative (*a*) not to insist on drawing such metatheoretical distinctions with regard to conceptual bodies that have not been given a deductive structure, and (*b*) not to forget that pure reason is an invention of certain organisms.

We conclude by sketching an enlarged notion of semantic analyticity, or analyticity by virtue of meaning. This notion is suggested by our incursion into the topology of the intension space and, in particular, by our elucidation of Wittgenstein's coarse notion of family resemblance (Ch. 4, Sec. 2.5). The idea is that an exact tautology can be approximated, arbitrarily closely, by a *quasitautology* or statement that is *almost* completely true (formally). Consider ⌜All A's are A's⌝ and replace one of the occurrences of A by B, where B is a close relative of A in the sense that B belongs to a small neighborhood of A in accordance with Definition 9 in Ch. 4, Sec. 2.5. Then both ⌜All A's are B's⌝ and ⌜All B's are A's⌝ will be *quasitautologies*. The process is reversible: given a nontautologous statement, Theorem 4.11 in Ch. 4 allows us to construct a whole sequence of propositions the limit of which will be a tautology. Take for instance the much debated statement ⌜The fittest organisms survive best⌝. Replace "fittest" by "most fertile" (in accordance with the Pickwickian acceptation adopted by population genetics) and "survive" by "propagate" (or "have the best reproductive survival") and you get an exact tautology. In sum, if meaning is a matter of degree so is analyticity. And, just as in the case of the multiplicity of truth values, the continuum of degrees of analyticity is consistent with rigid two valued logic.

2.2. *Definition*

The concept of a definition has proved more problematic than it deserves (see e.g. Bunge, 1967a, I, pp. 117–139). This is partly due to the adoption of too wide a construal of 'definition' – one that makes room for practically every determination of one group of constructs by another. A number of problems drop out if we adopt a narrower concept – just as with the case of analyticity. The narrowest of all, and that which we favor, is Peano's construal of every definition as an equality of the form: "*the defined = the object defining*", where the object in question is either a sign or a construct (Peano, 1921).

Example 1 The definition of set equality: ⌜If A and B are sets, then $A=B=_{df}$ The membership of $A=$The membership of B⌝. *Example 2* The definition of "$\leqslant$" in the relational structure $\mathcal{N}=\langle N, +\rangle$, where N is the set of natural numbers and $+$ the addition operation: ⌜If x, y and z are natural numbers, then: $x\leqslant y=_{df}(\exists z)(x+z=y)$⌝. *Example 3* The axiomatic definition of a groupoid: ⌜The structure $\mathcal{G}=\langle G, \cdot\rangle$, where G is a nonempty set and $\cdot$ a binary operation on G, is a *groupoid* $=_{df}$ For all x and y in G, $x\cdot y$ is in G⌝. *Example 4* The definition of the energy density of an electric field: ⌜If E represents the intensity of the electric electric field f, then $U(f)=_{df}(1/8\pi)\,E^2$⌝.

Note the following characteristics of a definition, whether explicit or implicit, conditional or unconditional, by abstraction (as Example 1) or axiomatic (as Example 3) or of any other type provided it is centered on the equality concept. Firstly, it may be taken to define a *construct or the symbol* chosen to designate it. One does not define things other than constructs or their symbols. For example one does not define light (but describes it); rather, one defines some concept of light (or the terms 'light', 'lux', 'lumière', etc.). More on this toward the end of this section. Secondly, every definition is *relative* to some context, whether a relational structure (as in Example 2) or a full theory (see Padoa, 1901 and Tarski, 1934). The contextual or relative character of definitions should be kept in mind in order to avoid some of the mistakes mentioned at the end of the preceding subsection and if one wishes to understand why one and the same word, when defined in different contexts, may acquire different significations – i.e. may designate different constructs. Thirdly, the concept "$=_{df}$" of equality by definition should be assigned all the formal properties of *equality* (or congruence), in particular the symmetry property, in order to ensure the exchangeability of definiens and definiendum. This requirement is less trivial than it looks for, from a methodological point of view, there is no such symmetry: the definiendum and the definiens cannot exchange places. In other words, from a pragmatic point of view '$=_{df}$' is a metalinguistic symbol that intends to convey the idea that the left hand side is determined by (is a function of) the right hand side not conversely. (This is how definitions were treated in *Principia Mathematica.*) However, this difference between definiens and definiendum is metatheoretical and methodological not semantical, for it points to a difference in status and role not in meaning. Semantically speaking, to define A as B is to equate A with B. So much so that a justification of a definition may consist in proving the identity of definiens and definiendum: no such proof would be needed if every definition were just a linguistic convention.

The narrow construal of definitions as equalities has the following advantages. First, the identity in meaning (sense and reference) of definiendum and definiens is brought out. (On the other hand an equivalence does not warrant meaning identity since equivalents, though coextensive, need not be cointensive. More on this in a moment.) Second, every definition of the form $\ulcorner A =_{df} B \urcorner$, with A and B propositions, entails the equivalence $\ulcorner A$ iff $B\urcorner$ (or $\ulcorner$For all x, Ax iff $Bx\urcorner$) but not conversely. (If A and B are identical then either can take the place of "the other" in the tautology $\ulcorner A$ iff $A\urcorner$.) Third, every formally correct definition belongs by right in the class of analytic formulas – by Definition 1 in Sec. 2.1. Consequently the old dispute as to whether a convention might be true is settled: All definitional equalities are necessary truths, albeit rather cheap ones. (In fact they are the only necessary truths found in factual science apart from the formal truths employed in inference.) Fourth, any sentence expressing a definitional equality belongs to the object language of the conceptual system concerned: no further language level need be invoked since '$=_{df}$' is no longer a metalinguistic sign but just a metatheoretical status symbol. Fifth, proofs of concept independence may often be simplified, as identities are usually easier to check than equivalences. Moreover instead of employing semantic techniques (e.g. Padoa's) for checking concept independence (or undefinability) in a context one may try the following alternative procedure. Check whether definiens and definiendum meet the necessary condition of coextensiveness: if the extensions do not coincide then the suspected definiens will differ from the definiendum. However, if the *LHS* and the *RHS* are coextensive nothing can be concluded: the technique is one for disproving not for proving concept independence.

In the literature several alternative forms are used or even prescribed for definitions, chiefly the following:

$$\text{`}A\text{' names (designates) } B \qquad (D)$$
$$\text{``}A\text{'' means the same as ``}B\text{''} \qquad (S)$$
$$A \text{ iff } B. \qquad (E)$$

However, each of these formats has some disadvantage from which that of equality is free. In fact *D* multiplies unnecessarily the levels of language and does not guarantee substitutivity. *S* is not applicable prior to interpretation (Padoa, 1901) and moreover it presupposes either an intuitive (muddled) concept of meaning or a universally accepted theory of meaning – which, alas, is not forthcoming. Moreover if *S* is adopted then it prevents us from defining "meaning" without circularity. In any case, notwithstanding a popular view, a definition should not be required to "explain the meaning" of the definiendum – except of course in a pragmatic sense. Otherwise implicit definitions should be unacceptable. Consider, if in doubt, the recursive definition of the addition operation in the relational structure $\langle N, S \rangle$, viz.,

$$x+0=x \quad \text{and} \quad x+Sy=S(x+y) \qquad Df$$

where 'Sx' designates the successor of x. Since "+" appears on both sides, it is neither explained in terms of the previous concepts nor eliminated in favor of them (Goodstein, 1968).

Finally, the equivalence format *E* is open to the following objections. First, equivalents, though coextensive, are not necessarily cointensive – hence they may not be substituted for each other without a concomitant alteration in meaning. Second, it is important to keep the difference between equivalence and equality. Thus the biconditional $\ulcorner A$ is provable iff A is a tautology$\urcorner$ is a metalogical theorem not a definition of provability. Likewise Tarski's principle $\ulcorner$"s" is true iff $s\urcorner$ is a biconditional not a partial definition of truth.

Finally let us emphasize that only signs and their designata can be defined (provided they are not primitive). Factual items can be described, explained or predicted: not being constructs, facts cannot be built out of constructs. In sum there are no "real definitions". Hence, *pace* Suppes (1967, 1969) and Freudenthal (1970, 1971), the technique of axiomatic definition, ideal as it is for characterizing mathematical objects, cannot be expected to define the concrete objects described (not defined) by scientific theories (see Salt (1971) and Bunge (1973b)). For example, the equations of mechanics define (implicitly) a concept of body not bodies. So much for the misprint 'axiomagic'.

Like other methodological categories, that of definition has several dimensions: linguistically it is usually an abbreviation; epistemologically it is a way of building new concepts out of old; pragmatically it is a heuristic device and often a time saving device. We have dealt only with the semantic aspect of definition and cannot go any further.

2.3. *Presupposition*

A presupposition is a tacit or undisclosed supposition – one that can and should be brought to light by analysis. We shall distinguish six concepts of presupposition, all of them relevant to the analysis of scientific knowledge. They shall be introduced by so many definitions. In each of these 'A' and 'B' will designate sets of formulas.

First the *proof theoretic* notion of presupposition:

DEFINITION 10.2 *B presupposes A relative to the proof P* $=_{df}$ A belongs to the set of premises occurring in the proof P of B.

Change the proof and B may cease to presuppose A.

Next a first *semantic* concept of presupposition:

DEFINITION 10.3 *B weakly presupposes A meaning-wise* $=_{df}$ A is sufficient to determine the meaning of B.

For example, if a scientific theory B involves the concept of time then B must weakly presuppose, *inter alia*, some theory A of time. (The whole lot of theories presupposed meaning-wise by any given theory may be called the ***background*** of the theory: Bunge, 1967b.) Any number of alternative presuppositions may do the job, though not all of them equally well. Hence no single presupposition of this kind may be necessary.

For example, Newtonian mechanics can be axiomatized by presupposing either absolute space and time or relational space and time.

DEFINITION 10.4 *B strongly presupposes A meaning-wise* $=_{df}$ *A* is necessary to determine the meaning of *B*.

For example, arithmetic is a strong presupposition of any quantitative theory, both meaning-wise and proof theoretically.

Let us now distinguish two concepts of *alethic* presupposition:

DEFINITION 10.5 *B weakly presupposes A truth-wise* $=_{df}$ The truth of *A* is sufficient for the truth of *B*.

In other words, *B* is a weak alethic presupposition of *A* just in case $A \models B$. Consequently this concept of presupposition belongs to model theory. Therefore it has only an indirect relation to factual science, namely via mathematics. In factual science the most we can do is to check whether *B*, or rather some consequences of *B* conjoined with some extra premises (e.g. data), are approximately true. To put it otherwise: In factual science the most useful concept of entailment is the syntactic ($\vdash$) not the semantic ($\models$) one, since we must feel free to investigate the logical consequences of any assumption before assigning the latter any truth values. (Note that, although $\vdash$ and $\models$ are coextensive, they fail to be cointensive.) Next comes

DEFINITION 10.6 *B strongly presupposes A truth-wise* $=_{df}$ The truth of *A* is necessary and sufficient for the truth of *B*.

If weak alethic presupposition has a remote relation to factual science, strong alethic presupposition is even further removed. Finally we have the *methodological* concept of presupposition:

DEFINITION 10.7 *B presupposes A methodologically* $=_{df}$ The test of *B* uses *A* without questioning *A*.

For example, although electromagnetism is a fundamental theory in the sense that it can be formulated without resorting to any other scientific theory, its empirical tests presuppose a number of other theories – in fact as many as needed to design and control the instruments employed in the tests. Operationism could easily muddle up this issue by claiming that, this being so, then every theory presupposes every other theory. As a matter of fact the so called Copenhagen interpretation of quantum mechanics claims that, although quantum mechanics retrieves classical mechanics without being fully consistent with it, it also presupposes the latter because the former theory must be interpreted in terms of experiments, and every experiment must be accounted for by classical physics (Landau and Lifshitz, 1958, p. 3, criticized by Bunge, 1970b, pp. 310 ff.).

This winds up our examination of the (tiny) impact of our semantics on logical theory.

3. EPISTEMOLOGY

3.1. *The Status of Epistemology*

The collection of opinions concerning human knowledge, i.e., epistemology, used to be the nucleus of modern philosophy. Over the past century three other lines of inquiry have come to dispute the territory of epistemology: biology (following Helmholtz and Mach), psychology (following Piaget), and semantics (after Tarski and Carnap) – not to speak of the philosophy of science, which overlaps with epistemology, and pragmatics, which is still in the foetal state. Each of those disciplines offers persuasive arguments for absorbing the whole of epistemology. Let us weigh them.

The argument for surrendering epistemology to biology and psychology seems compelling: Perception and ideation are but so many aspects of man's effort to adapt himself to, as well as alter, his environment. Hence they belong to the study of man the animal. More particularly since sensing, perceiving, representing, and inferring are functions of the central nervous system, the study of knowledge falls within the province of neurophysiology and psychology.

All this is quite true. It has become ludicrous to speculate about perceiving without regard to the psychology of perception, about knowing without looking into learning theory, and so on. Some of the traditional problems of epistemology have indeed been snatched away by psychology. Epistemology is thus becoming biologized as demanded by Campbell (1959). This process is irreversible despite the efforts of philosophical psychology, which can now thrive only on the shortcomings of scientific psychology. Still, philosophy has a right to investigate knowledge (and for that matter anything) provided it does so from a different angle, with its distinctive means and aims, and as long as it learns from scientific psychology.

The philosophical study of knowledge includes a theoretical examination of the following subjects: (*a*) general nature of man's knowledge of his environment and of himself – i.e. knowledge as a metaphysical subject (in N. Hartmann's words, a subject of the *Metaphysik der Erkenntnis*); (*b*) kinds of knowledge (intuitive, rational, etc.) and their interrelationships; (*c*) relation between physical object statements and sense data statements; (*d*) concepts of factual truth, error, and error correction; (*e*) traditional dichotomies such as subjective-objective, a priori-a posteriori, experiential-conceptual, and intuitive-rational. None of these themes is claimed by biology or psychology – nor can they be studied seriously without the help of these disciplines.

As to the credentials of semantics, they too look impressive: while traditional epistemology dealt with truth in a metaphorical way and neglected meaning altogether, semantics offers exact theories of each of them. This is true, but still it may rejoined (*a*) that those exact theories are not concerned with factual knowledge, which is the main theme of epistemology, and (*b*) semantics pays no attention to the problems listed above. So, epistemology does have a territory of its own *vis-à-vis* semantics. Moreover, it could be argued that semantics, or at least the semantics of factual knowledge, is but *a part of epistemology* – namely that portion concerned with the reference, sense, and adequacy of human knowledge in general as different from the cognitive process.

Whatever view on the semantics-epistemology relations one may adopt, two things seem certain. The first is, that the two fields overlap. The second, that it matters little whether there is a border line (rather than a stripe) between the two as long as something be done about the problems themselves. Let us pick two representative problems of epistemology and see what our semantics has to say about them.

3.2. *Representation vs. Instrument and Picture*

One of the dichotomies tackled by epistemology is that of *a priori* vs. *a posteriori* knowledge. Because 'a priori' is usually taken to signify 'prior to experience' and because 'prior' is an ambiguous word, 'a priori knowledge' can be a misleading expression. Thus while it is true that logic *holds* irrespective of experience, it is false that it *originated* independently of experience: logical investigation is just a fragment of human experience. For this reason – i.e., to avoid the genetic fallacy – it is advisable to draw a clear distinction between origin and validity, and to relativize the notion of *a priori* to a body of knowledge. The two requirements are met by the following conventions.

DEFINITION 10.8 The set S of statements is *a priori* relative to the body of knowledge $K =_{df}$ No member of S presupposes any member of K either meaning-wise or truth-wise.

DEFINITION 10.9 The set S of statements is ***absolutely a priori*** $=_{df}$ S is *a priori* relative to every body of knowledge.

In this sense logic is absolutely a priori, mathematics is a posteriori (=not a priori) with respect to logic, certain branches of mathematics are a posteriori relative to others, science is a posteriori relative to the whole of formal science, and certain branches of science are a priori relative to others. These epistemological notions of a priori and a posteriori are not the same as the psychological and the methodological concepts similar to them. For example, a new conjecture in logic is a priori and moreover absolutely so, but it is methodologically a posteriori in the sense that it must be checked before being included in logic. And a new scientific hypothesis, though a posteriori in the epistemological (or semantical) sense, is psychologically a priori in the sense that it comes to us before any new data.

Whatever bit of human knowledge is prior to some other bit may be said to function as an *instrument* for the latter. The epistemological questions are (*a*) whether the whole of factual science is but an instrument for action – as pragmatism and the anti-science movement hold, and (*b*) whether every scientific theory is nothing but a data processing instrument (conventionalism, nominalism, pragmatism, and computerism). That factual knowledge can be used as an instrument, for good or for evil, is beyond dispute: the question is whether, in addition, it represents reality (or at least experience) and if so how.

There are, of course, as many answers to the above question as there are epistemological schools. The most popular are direct (naive) realism and classical empiricism, according to which sensations and ideas, even if logical or mathematical, represent and moreover reflect or copy factual items. According to critical realism, on the other hand, our perceptual and conceptual representations of external objects are "only *signs* [symptoms] of external objects, and in no sense *images* of any degree of resemblance. An image must, in certain respects, be *analogous* to the original object (...) For a *sign* it is sufficient that it become apparent as often as the occurrence to be depicted makes its appearance, the conformity between them being restricted to their presenting themselves simultaneously" (Helmholtz, 1873, p. 391). This is, roughly, the view we adopted in Chs. 2 and 3: factual knowledge *refers* to external objects and *represents* them but it is *symbolic* rather than pictorial. Moreover the representation it effects is one-sided rather than full, and *global* (whole theory-factual domain) rather than pointwise. (Cf. Ch. 6, Sec. 3.4.) How else are we to explain that scientific theories so often go wrong and that they do not depict anything although they explain and predict?

Theoretical concepts and scientific theories do not *picture* physical objects, let alone pointwise. (Cf. Ch. 3, Sec. 1.) They cannot picture because they are constructs. Of course they may represent and, as long as they are factual, they all refer to supposedly real items. However, only some of the elements of a theory represent: others, like lagrangians and partition functions, discharge no representational function even if they do refer. (Recall Ch. 3, Sec. 1.1, and Ch. 7, Sec. 3.4.) Conversely there are real traits, such as individual idiosyncrasies, that no scientific theory will capture unless it happens to be a theory of an individual. Even so, no scientific theory attempts to provide a complete description of its referents. (Consequently Bohr and Heisenberg were wrong in claiming that quantum mechanics provides a complete description, and Einstein was right in holding that it does not. But Einstein was misguided in his search for an alternative theory that would supply "a complete description of reality". It is not only that a description requires empirical data in addition to theories if it is to describe individual things: both the history of science and an analysis of the way theories are constructed suggest that the process of taking in more and more factual items is never ending, as stressed by dialectical materialists: see Lenin (1909).)

Furthermore theoretical concepts and theories are not abstracted from sense experience, not even from scientific experiments, so they should not be placed in the same bag with empirical concepts. For one thing they need not have the same referents. For another they never have the same sense: for, if they were cointensive, then the theory concerned would be pointless. Of course there is some correspondence between concepts and percepts, but (*a*) it is not one to one and (*b*) it is symbolic or indirect (Einstein, 1936, p. 353). Materialists need not panic: the view that our representations of the external world are symbolic rather than cinematographic is perfectly consistent with the theses that there are no autonomous ideas and that our ideas, if they happen to concern autonomous external objects, sometimes do succeed in representing the latter in a more or less adequate way. In any event the point we wished to make is that critical realism is more adequate than the picture view of knowledge, which has not gone beyond the metaphor stage anyway. Nonetheless it must be owned that the symbol doctrine, proposed one century ago, is in dire need of elaboration. We are still far away from the systematic realism demanded by Hooker (1974).

3.3. *Objectivity vs. Subjectivity*

A representation, by definition, represents something: there can be no representation in and by itself, or *Vorstellung an sich.* In particular, a conceptual representation of a factual item x is a construct y that maps (some of) the features of the object x. A representation is not a part, let alone the whole, of its object. So much for the semantics of the concept of representation – some of the complexities of which were examined in Ch. 3. In epistemological terms: "Unless the content of knowledge is recognized to have a condition independent of the mind, the peculiar significance of knowledge is likely to be lost. For the purpose of knowledge is to be true to something which is beyond it" (Lewis, 1929, p. 192). This is, of course, the realist or objectivist thesis.

The subjectivist, on the other hand, holds that the world is our representation or part of the latter. Thus Goodman claims that there is no such thing as *the* way the world is: the world is as many ways as it can be truly described, seen, pictured, etc. (Goodman, 1960). Further: "That nature imitates art is too timid a dictum. Nature is a product of art and discourse" (Goodman, 1968, p. 33). The rationale is that representations are creations not copies. True enough, but the point is that a representation, however creative, does not create its object. To claim that it does is to muddle things up (as Frege (1894) noted) and to make a mockery of the age long striving for objectivity, that supreme accomplishment of the creative scientist. For it is a declared aim of scientific research to obtain objective (impersonal and publicly testable) representations of the world. This is why scientists keep checking them and trying to improve on them. This is why any subjective elements, when spotted, are weeded out. And because of this need for keeping the distinction between objectivity and subjectivity, it behooves the semanticist to clarify it.

Whether or not a representation is objective is a matter for semantics and methodology, since a construct is said to be semantically objective if it concerns external objects alone and can be subjected to impersonal tests. (But of course those objects may be persons and they may even prove to be nonexistent.) On the other hand a construct *a* is a *subjective representation* of an object *b* just in case *a* refers not only to *b* but also to the subject *c* responsible for *a*. If this subject dependence is genuine then it must show up upon substituting a different subject for the original one. This is how it can be shown that quantum mechanics, reputedly a subjectivistic theory, is perfectly objective – namely by analyzing the referents of the basic predicates of the theory and proving the cognitive subject to be absent from them (Bunge, 1967e, 1973b).

A methodological examination should confirm or infirm the results of a semantical test for the objectivity of a representation. That examination may consist either in the control of the suspected variables or in some other empirical procedure. Consider a sequence of events of a kind assumed to be mutually independent. On a subjectivist interpretation the events should occur only when observations are actually performed – e.g. every minute. Consequently the distribution in time will be binomial or similar. On an objectivist interpretation the events will occur whether or not they are observed. In particular it may happen that the process goes on continuously over a time interval. Hence the distribution could be Poisson's or similar. We have then two rival distributions of elements among the various accessible states, i.e. two different conceptual representations or models. The conflict can be resolved by sampling. Needless to say, the problem hardly arises in the physical sciences. But it does arise in psychology, and in any case it is philosophically important to know that the problem of objectivity can in principle be solved by theoretical modeling and subsequent empirical tests.

We take it then that science espouses, albeit tacitly, a realist epistemology. Moreover science confirms critical (or indirect) realism rather than naive (or direct) realism, as shown by its distrust of the "immediately given" and its relentless effort to improve on every theoretical representation of facts. In order to better appreciable this point we list the main theses of these two versions of realism. (Cf. Bunge, 1973a.)

Direct (naive) realism	*Indirect (critical) realism*
$\mathcal{DR}$ 1 Everything is knowable.	$\mathcal{CR}$ 1 Many things and facts are knowable. Many others are not – e.g., extinct things that have left no perceptible traces.
$\mathcal{DR}$ 2 Physical objects are perceived directly: the eye is innocent.	$\mathcal{CR}$ 2 Perception can be improved or distorted by preconception (superstition, hypothesis, etc.): the eye is biased – for better or for worse.
$\mathcal{DR}$ 3 All objects are conceived directly.	$\mathcal{CR}$ 3 Constructs are formed within a body of background knowledge, unevenly true and largely social.
$\mathcal{DR}$ 4 Every conceptual representation is at least homomorphic.	$\mathcal{CR}$ 4 Conceptual representations are rarely pointlike (e.g. homomorphic), mostly global (whole theory-whole factual domain).
$\mathcal{DR}$ 5 All sensations and conceptions mirror real objects.	$\mathcal{CR}$ 5 Some constructs are representational while others are purely syntactic. And many hypotheses and theories intended to represent real factual items turn out to be wholly fictitious.
$\mathcal{DR}$ 6 Perfect knowledge (complete and fully true) is possible.	$\mathcal{CR}$ 6 Factual knowledge is always imperfect (incomplete and at best partially true). But it is perfectible.

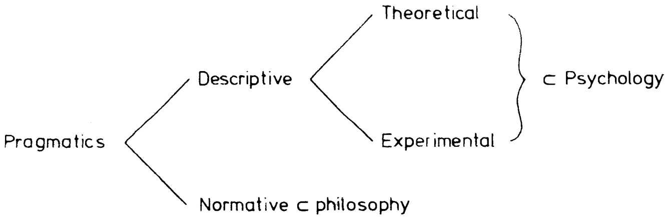
Note the following points. First, although realism (whether direct or indirect) presupposes the ontological hypothesis that there are things in themselves, i.e., objects existing independently of any mind, it does not espouse materialism. Indeed a realist need not entertain the ontological hypothesis that every existent is material. (Nor does materialism entail realism: a materialist need not believe that matter can be known: witness Spencer.) Second, realism does not entail rationalism: the former is consistent with Meyerson's thesis about the unavoidable and irreducible irrational remainder left by every cognitive venture (Meyerson, 1908, pp. 272ff). Third, realism is not committed to the causal theory of perception, i.e., the hypothesis that sense impressions are causally related to physical objects. It is possible to hold to realism while assuming that perceptions, though caused by external (and internal) objects, are stochastically (rather than causally) related to them. In any event it is for science, not for epistemology, to find out what the mechanisms of perception and ideation are. Epistemology is concerned with knowledge (the end product) rather than with cognition (the process). Which brings us to our next theme.

3.4. *The Knowing Subject*

There is no knowledge without both an object of knowledge and a knowing subject. The claim that there is absolute knowledge, or knowledge in itself, above and beyond concrete knowing subjects, is fantastic. Moreover it violates the very syntax of 'to know', for 'x is known' is short for 'There is at least one y such that y is a knowing subject and y knows x'. Obliterate mankind and no human knowledge will remain. Furthermore every individual learns, imagines, and remembers (in sum, knows) in his own way: real cognition is as personal as ignorance. For this reason knowing or cognition is a subject for psychology. Epistemology takes knowing for granted and focuses on what is alleged to be known. In other words, epistemology is not concerned with personal knowledge, the only cognition there is. Epistemology makes the useful pretense that there exists *impersonal knowledge*, just as semantics pretends that there are propositions – not just judgments and sentences – and just as mathematics pretends that there are proofs whether or not they have actually been produced by anyone. To call what is known, i.e., knowledge, a *world* and assume that it is superimposed on the world of fact (Popper, 1968) is an unnecessary Platonic fantasy. There is only one world and cognitive subjects are part of it and intent on knowing (or ignoring) some chunks of it. Human action, whether cognitive or of another kind, does not create new worlds (except metaphorically) but variously transforms the only world there is.

Some philosophers, following certain suggestions of Peirce's and Morris', hold that personal knowledge is to be studied by a special discipline concerned also with other facets of human activity. This discipline, *pragmatics*, would consist of an empirical branch and a philosophical one. Philosophical (or pure) pragmatics would seek to establish logical relations among pragmatic concepts such as those of belief and intention (Martin, 1959) or to develop theories such as tense logic and the logic of personal pronouns, in which the subject or user plays a central role (Montague, 1968, 1970).

It may be questioned whether pure pragmatics, as currently developed, is on a sound methodological basis. Indeed if a discipline is concerned with factual items, such as users and circumstances of use, without benefiting from any empirical investigations, then it belongs with speculative metaphysics – with *Naturphilosophie* or with *Kulturphilosophie.* Theoretical pragmatics, if descriptive of fact, should be methodologically similar to theoretical psychology: it ought to build mathematical models of certain aspects of human behavior and have them tested in the laboratory. Only when normative might pragmatics be exempted from this requirement. For example, although actual problem solving is studied by psychology, the analysis of *well* conceived and *well* posed conceptual problems in general can be the concern of philosophers. That is, the logic and semantics of problems (like the logic and semantics of norms) belong to philosophical pragmatics. In conclusion, we have the following branching:



The relation between philosophical pragmatics and semantics could be this: each should investigate its own side of the coin of knowledge, but pragmatics would, in addition, take up problems concerning action. To put it differently: Epistemology can be split into two branches, according as the knowing subject is or is not reckoned with explicitly: (*a*) the study of personal knowledge, which is a branch of pragmatics, and (*b*) the study of impersonal knowledge, which overlaps with semantics. For example, the very concept of knowledge will split up into those of a set of statements, and opinion (or belief); the concept of truth into those of objective truth and personal truth; and the concept of meaning into those of semantic meaning and pragmatic meaning (or normal linguistic usage in a community).

It is well known that pragmatics is not married to pragmatism: that one may hold either a pragmatist view of pragmatics or an alternative conception of it. The extreme pragmatist theses about pragmatics seem to be these: (*a*) All genuine syntactical and semantical concepts have pragmatic counterparts, and (*b*) the former should all be reducible to (e.g., definable in terms of) pragmatic terms. While the first thesis is interesting, possibly true, and therefore deserves being investigated, the reduction thesis (*b*) is false. For example, Wittgenstein's reduction of meaning to use is, to put it charitably, a proposal to redefine 'meaning' so as to suit the purposes of the lexicographer. Usage is nothing but an (unreliable) indicator of significance. Besides, there is such a thing as correct (as distinct from widespread) use. And the relation of this normative concept to the semantic concept of significance is roughly this: The correct use of a sign is determined by its significance as revealed by an analysis of the system in which it occurs.

Moreover the pragmatic concepts presuppose syntactic and semantic concepts not the other way around. For example, the pragmatic statements $\ulcorner t$ has been proved from $A\urcorner$ and $\ulcorner x$ claims to have proved t from $A\urcorner$ presuppose the metamathematical concept of proof. Without the latter the previous statements would be unintelligible and untestable. Likewise and for the same reason the pragmatic proposition $\ulcorner$'*a*' means "*b*" to $c\urcorner$ presupposes a semantic concept of meaning. The same holds for belief assertions: In order to believe p we must first know p, which in turn presupposes p (quite apart from any truth value assignment). On the other hand we can pretend that there are propositions known to nobody. (This is what we do when we play around with the totality $\mathscr{C}n(A)$ of consequences of a given set A of assumptions.) And, of course, we can know p without believing p, just as we can believe p without professing to understand p.

A final warning: by an egocentric habit acquired in infancy we tend to employ pragmatic terms where they do not belong, thus contributing to an inflation of pragmatics. For example, we are prone to say that organic compounds are *found* in certain stars instead of asserting that *there are* organic compounds in stars; or that p is a possible result of *measuring* P rather than stating that p is a possible value of P; or that t

can be proved from A, instead of saying that t follows from A. The fact of the matter is that x may be found (or measured) if it *exists* to begin with, and that t may be proved provided it *is* a consequence. The phony use of pragmatic terms only creates confusion and fosters the illusion that pragmatics is a going concern rather than a project. In any case the semanticist's mode of speech is objective (subject-free) and tenseless: he considers matters *sub specie aeternitatis.*

So much for the relation of semantics to epistemology. Let us finally take a look at the most substantial yet also least reputable neighbor of semantics – metaphysics.

4. METAPHYSICS

4.1. *The Metaphysical Neutrality of Language*

We met metaphysics at the outset (Ch. 1, Sec. 3) when listing the kinds of object we should distinguish, as well as when discussing the nature of constructs. We also encountered metaphysics along the way, particularly when discussing reference, the representational function of some scientific constructs and, tangentially, factual truth. There are several other contacts between semantics and metaphysics. And, if the two are approached with a modicum of reason, their contacts need not be points of friction. Semantics can supply metaphysics with some tools for dissipating conceptual obscurity and confusion, and metaphysics can reciprocate by helping semanticists to avoid the extremes of vulgar materialism (e.g., literalism) and Platonism. We shall not pursue this line here. Instead, we will point to a place or two where semantics does *not* meet metaphysics. In fact we propose to discuss the alleged ontological commitment of language (the Whorf-Sapir doctrine) and, in particular, the claim that all existence sentences make such a commitment (Quine's thesis).

The celebrated Whorf-Sapir hypotheses are, in a nutshell, that (*a*) ordinary languages are loaded with world views or metaphysics, and (*b*) one's language determines at least in part the way he perceives and conceives the world. These two conjectures are, to say the least, gross exaggerations of the undeniable feedback of language into thought. It is false that every language reflects some world view, let alone some metaphysical system: any advanced language, by definition of 'advanced', can express any number of mutually incompatible world views, as witnessed by the diversity of metaphysics expounded in Sanskrit or in ancient Greek. And it is false that language is an important causal factor in perception and conception: a language permits or restricts our expressing what we perceive or conceive rather than what we perceive or conceive. Perception and conception occur in an epistemic framework not in a linguistic one: what determines in part whatever we perceive and conceive is experience, whether spontaneous or disciplined, personal or collective, rather than our mother tongue. Language is fortunately neutral with respect to our sensing and conceiving the world. Otherwise it would be impossible to formulate and discuss mutually incompatible views, and the very concept of expressive power of a language would be devoid of meaning.

Moreover the Whorf-Sapir doctrine is refuted by educational psychology: verbal teaching is inefficient unless the subject has already acquired some of the ideas he has been talked to about. If no words are available to express new ideas then one invents them at any age and in any culture. But if there are no ideas then words won't help – except to disguise the poverty in ideas, as Mephisto pointed out. Piaget and his coworkers have shown that a child who has learned the correct use of 'long', 'short' and cognate words may fail to understand that the amount of clay does not change when turned under his eyes from a ball into a sausage. Here again what matters is knowledge not language. In sum the Whorf-Sapir hypotheses are false: language is a tool that carries no ontological burden. It is rather the other way around: every ontology is constrained by the language it employs, in the sense that the latter may or may not be rich enough to express certain ontological ideas. (For example, ordinary language is insufficient to formulate a general theory of space.) Only theories can be ontically committed, and they are so provided they are not theories in logic or in pure mathematics. Language cannot even suggest a bad theory. But we went through this in Ch. 1: let us turn to a more interesting problem.

4.2. *The Metaphysical Neutrality of Logic*

If logic were nothing but a language then the arguments of the previous subsection would apply to it: logic should be ontologically neutral because it is the universal language. But logic is also and primarily a theory

– the theory of deduction – even though it can be used as a language (recall Ch. 1, Sec. 1.3). Therefore the relation of logic to metaphysics must be investigated separately. However, this is not the place for a thorough investigation of this problem, treated elsewhere (Bunge, 1974a). We must restrict our attention to those aspects of the question that involve semantics. We will limit ourselves to the question whether logic, in addition to being a reasoning organon, has a semantics similar to that of factual science. In other words, we shall ask the question whether logic involves a reference to reality or is ontologically neutral.

The thesis that logic does call for an ontological interpretation has been championed in recent times by Scholz and by Quine though on different grounds. According to Scholz (1941) the logical formulas hold for all possible worlds, ergo in particular for ours: logic would thus constitute a minimal ontology. This argument hinges on the identification of "possible world" and "model". But this is just a verbal trick: whereas a model is a conceptual object, the actual world is not a model of an abstract structure but the maximal self existent thing, and a possible world is something that neither logic nor ontology are in a position to characterize. Logic does not hold in all possible worlds – except metaphorically, in the sense that it is independent of the constitution and structure of the world. What model theory says is something more modest, namely, that a formula is a logical formula just in case it is satisfied in all models, i.e., if it holds under all interpretations of the nonlogical variables it contains. And the model independence of a logical identity consists in a particular matching of it with a whole set of constructs: it is an intraconceptual affair that has nothing to do with the actual world (Ch. 6, Sec. 2). Therefore the notion of universal validity (or analyticity) does not involve that of factual truth, which characterizes the semantics of factual science (Ch. 8). In conclusion, model theory is not concerned with any worlds and it does not exhibit logic as an ontology.

Unlike Scholz' approach, Quine's is direct: the latter finds ontology in the very bones of logic, particularly in quantification. Indeed he holds that "referential quantification is the key idiom of ontology" (Quine, 1969, p. 66). More explicitly: "Existence is what existential quantification expresses. There are things of kind F if and only if $(\exists x)\, Fx$. This is as unhelpful as it is undebatable, since it is how one explains the symbolic notation of quantification to begin with" (*op. cit.*, p. 97). The set of "things" a theory takes to exist is called by Quine the "ontological commitment", at times also the "ontology", of the theory (*op. cit.*, p. 106). Actually the word 'commitment' is too strong, since "that commitment can be momentary" (Quine, 1970, p. 99). That is, we have, if at all, ontological hypotheses.

If 'commitment' is unfortunate so are 'ontological' and 'ontic' in this context. Indeed, all that is intended to point to is the collection of *referents*, whether hypothesized or certified, intended or unintended, physical or conceptual, of a theory couched in some system of predicate logic. For example the referents of arithmetic are integers or perhaps the field of rationals. But a statement such as ⌜There are infinitely many prime numbers⌝ commits no one to believing in the *autonomous* existence of prime numbers. Far from being "an ontic idiom *par excellence*" (Quine, 1970, p. 92) existential quantification, unless qualified, is ontologically neutral. It is up to factual science, not to philosophy, to decide whether an unqualified existence statement has an ontic import.

The existential quantifier can be eliminated in favor of negation and the universal quantifier: "There are F's" is short for "It is not the case that everything fails to be an F". On the other hand, the concept of physical (real, ontic) existence cannot be so eliminated. In fact, to indicate physical existence we must assert unqualified existence and add that the objects in question happen to be physical objects – where the predicate 'is a physical object' is elucidated in ontology not in logic. There are *real* things of kind F if and only if $(\exists x)$ (Fx & x is a physical object). Only objects of this kind are of possible interest to ontology conceived, not as the general theory of objects of any kind, but as general cosmology. And only such statements of physical (real, ontic) existence will "commit" us to the objects they refer to – or rather to the task of finding out whether such objects are part of the actual world. (Incidentally, the collection of such referents of a statement constitutes its reference class, not its ontology: an ontology is a theory.)

Conceptual existence is parallel. There are *conceptual* objects of kind F if and only if $(\exists x)$ (Fx & x is a construct). This is the kind of existence the mathematician is interested in. Thus, notwithstanding the nominalist prohibition against classes, the mathematician deals with them all the time – only, he does not claim more than conceptual existence for them.

He has no reasons for thinking that the members of a set in a mathematical theory are more real than the set itself: if assumed or proved to be nonempty, a class enjoys the same conceptual existence as its members. Surely the metaphysician is entitled to asserting that classes have no physical existence – but then the mathematical individuals are just as unreal as classes, so that the metaphysician's remark is irrelevant.

In sum, while logic needs only a general concept of existence, the moment we cross the border of logic we need two specific concepts of existence – conceptual and physical. We have thus at least three different concepts of existence: neutral, conceptual, and physical. (These are concepts of existence not modes of being. Consequently there is no question of a general ontology branching off into an ontology of things and another of constructs. Let us not get carried away by words.) Let us emphasize the differences:

$(\exists x)\, Fx$	*Neutral existence*
$(\exists x)\,(Gx \,\&\, x$ is a construct$)$	*Conceptual existence*
$(\exists x)\,(Hx \,\&\, x$ is a physical object$)$	*Physical existence.*

Correspondingly we have three kinds of existence problem: neutral, conceptual, and physical. The last two kinds are irreducible. Thus the question of the (conceptual) existence of classes has nothing to do with the question of the (physical) existence of things: this is why conceptualism is compatible with ontological individualism, or the belief that only individuals can have physical existence. And, since all classes are constructs, infinite sets pose no special problem of existence.

Nor are those kinds of existence question reducible to a fourth, more basic type of question. In particular it is not possible to reduce all questions of existence to the existence *in* or *of* a linguistic framework – the so called internal and external questions (Carnap, 1950). Thus the problem whether a "theoretical entity", such as the parton or the black hole, has a real counterpart is not a question concerning exclusively a man made "framework", let alone a linguistic one: it is an empirical problem – namely that of subjecting the factual theory concerned to observational tests. To hold that physical existence questions are not scientific but concern linguistic frameworks is no better than claiming, with Mach and the Vienna Circle, that those are sheer metaphysical questions. In either case the typical features of the semantics of scientific theories are missed. (For further criticisms see Ferrater Mora (1967).)

The upshot of our discussion is this: (*a*) just as we distinguish constructs from things so we must distinguish conceptual existence from physical existence; (*b*) logic employs a generic or neutral concept of existence, hence it is not in a position to assert or deny anything concerning the real world: it is ontologically neutral; (*c*) mathematics uses the more special notion of conceptual existence but it is equally unconcerned with reality; (*d*) factual science and metaphysics utilize the concept of physical (material) existence.

4.3. *Metaphysical Commitments of the Semantics of Science*

Logic, mathematics, and their semantics (i.e., model theory) are metaphysically neutral: they do not even have to assume the existence of any objects other than constructs and their symbols. Not so the semantics of factual science. Indeed the latter has the following presuppositions of a metaphysical character: (i) there are both constructs (in particular concepts) and physical objects (in particular signs); (ii) some signs designate constructs and some constructs refer to physical objects; (iii) the theories referring to physical objects constitute more or less adequate (true) representations of aspects of the world.

If the above assumptions were denied then the very concepts of designation, denotation, reference, representation, and factual truth would become pointless. Our own realist brand of semantics adds two further assumptions: (iv) constructs are ideal objects: unlike physical objects, constructs have no separate (physical) existence, and (v) the putative referents of a factual construct are supposed (rightly or wrongly) to be self existent not just possibilities of perception.

This is all the metaphysical load our semantics carries. It is necessary and sufficient to make sense of the rules of denotation and of the semantic assumptions included in scientific theories (when reconstructed according to our semantics) as well as to make sense of the testing for truth of fact and of the correction of hypotheses and theories in the light of fresh experience. Beyond this point there is room for any number of possible ontological theories sketching the basic constitution and structure of the world. The author's own preference lies with cross disciplinary metaphysical theories, mathematical in form and contiguous with factual science (Bunge, 1971b). But this is another story to be told in a different work. (Cf. Volumes 3 and 4 of this *Treatise.*)

5. PARTING WORDS

Up till now philosophical semantics has led a rather secluded life: it has had hardly any contacts with other branches of philosophy and with factual science. Whence its main failing: its nearly total irrelevance to anything lying outside logic and mathematics – and consequently its inability to be of any help in understanding what goes on in that external world.

It has become an urgent task to reset semantics in its philosophic context – the one in which it used to dwell from Socrates through Buridan to Russell – as well as to open it up to the winds of factual science, without thereby relinquishing the ideals of rigor and systemicity bequeathed upon us by Tarski and Carnap.

Secondly, semantics should become a service discipline like logic and mathematics – one ever ready to offer a helping hand to whichever neighbor may need it. (See Table 10.1.) But in order to become useful semantics must mix with its neighbors and even meddle with their affairs, thus learning their ways and needs. The watchword should no longer be 'Come and behold my neatness' but rather 'Let us go and see how we can fix that mess'.

Thirdly, semantics should be freed from its associations with obsolete philosophies, and fresh semantic theories answering the needs of science and inspired in critical realism should be built. We need far more work in realist semantics and we should look everywhere for inspiration and control: a philosophy that minds only its own business does not mind its main business.

May this work contribute to implementing Kanenas T. Pota's ideal of "an exact, systematic, realist, and above all useful semantics". In any case this semantics of ours is to serve as a prolegomenon to the substantive portions of the philosophical system set forth in this *Treatise*, namely ontology, epistemology, and axiology.

TABLE 10.1

Semantics and its neighbors

Trait	Science	Mathematics	Philosophy			
			Logic	Semantics	Epistemology	Metaphysics
Referents	Things (concrete systems)	Conceptual structures (categories)	Constructs	Constructs & signs	Knowledge	Reality
Range	Aspects and levels of things	Theories	Universal	Universal	Universal	Universal
Truth type	Factual	Formal	Logical	Philosophical	Philosophical	Philosophical
Accuracy	Limited	Complete (except in numerical analysis)	Complete	Complete with reference to formal science	Limited	Limited
Method	Hypothesis & theory, observation & experiment	Postulation & proof, example & counter-example	Postulation & proof, example & counter-example	Postulation, proof, & checking with logic, mathematics, or science	Analysis, postulation, & checking with substantive knowledge & methodology	Postulation & checking with science
Goals	Finding laws, describing, explaning & predicting	Building theories about conceptual structures & inter-relating them	Depuration & systematization of general methods of analysis and proof	Elucidation & articulation of concepts of meaning, truth & cognates	Elucidation & articulation of all the concepts about factual knowledge & ignorance	Finding overall (cross-disciplinary) structures & patterns in the world

Table 10.1 (Continued)

Trait	Science	Mathematics	Philosophy			
			Logic	Semantics	Epistemology	Metaphysics
Roles	Basing technology, controlling world views	Forging conceptual tools for science & philosophy	Keeping watch on reasoning	Conceptual hygiene, spotting genuine referents, clarifying sense, and scotching myths in the philosophy of scientists	Methodological alertness & open-mindedness	Elucidating concepts common to several sciences, posing fruitful problems & proposing illuminating hypotheses about the world
Employs	Logic, mathematics & philosophy	Logic	Mathematics	Logic, mathematics & science	Logic, mathematics & science	Logic, mathematics & science

Treatise on Basic Philosophy – Volume 3

Ontology I:

THE FURNITURE OF THE WORLD

The *Treatise on Basic Philosophy* expounds the first philosophical synthesis to have been conceived after the end of what has been called the Age of Analysis. Unlike many a system in traditional philosophy, Bunge's is formulated in a clear fashion and with the assistance of formal tools such as elementary modern algebra. Besides, it is science-oriented and its author hopes it may help understand science as well as freeing scientific research from obsolete philosophical maxims. In sum, the *Treatise* presents a new system of philosophy in tune with our time.

The first two volumes propose a new semantical theory and, indeed, the only existing theory that elucidates and interrelates all of the key semantic concepts met with in the analysis of ordinary knowledge and science. In particular, these volumes present original theories of reference (as distinct from extension), of intensions, of meaning, and of truths of fact. Some use is made of elementary set-theoretic and algebraic concepts, such as those of lattice and Boolean algebra. On the other hand modal logics are not employed and model theory is dealt with only tangentially. This work constitutes the first detailed and systematic treatment of the semantics of empirical knowledge (as distinct from the semantics of either mathematics or natural language).

GENERAL PREFACE TO THE *TREATISE*

This volume is part of a comprehensive *Treatise on Basic Philosophy*. The treatise encompasses what the author takes to be the nucleus of contemporary philosophy, namely semantics (theories of meaning and truth), epistemology (theories of knowledge), metaphysics (general theories of the world), and ethics (theories of value and of right action).

Social philosophy, political philosophy, legal philosophy, the philosophy of education, aesthetics, the philosophy of religion and other branches of philosophy have been excluded from the above *quadrivium* either because they have been absorbed by the sciences of man or because they may be regarded as applications of both fundamental philosophy and logic. Nor has logic been included in the *Treatise* although it is as much a part of philosophy as it is of mathematics. The reason for this exclusion is that logic has become a subject so technical that only mathematicians can hope to make original contributions to it. We have just borrowed whatever logic we use.

The philosophy expounded in the *Treatise* is systematic and, to some extent, also exact and scientific. That is, the philosophical theories formulated in these volumes are (*a*) formulated in certain exact (mathematical) languages and (*b*) hoped to be consistent with contemporary science.

Now a word of apology for attempting to build a system of basic philosophy. As we are supposed to live in the age of analysis, it may well be wondered whether there is any room left, except in the cemeteries of ideas, for philosophical syntheses. The author's opinion is that analysis, though necessary, is insufficient – except of course for destruction. The ultimate goal of theoretical research, be it in philosophy, science, or mathematics, is the construction of systems, i.e. theories. Moreover these theories should be articulated into systems rather than being disjoint, let alone mutually at odds.

Once we have got a system we may proceed to taking it apart. First the tree, then the sawdust. And having attained the sawdust stage we should move on to the next, namely the building of further systems. And this for three reasons: because the world itself is systemic, because no idea can

become fully clear unless it is embedded in some system or other, and because sawdust philosophy is rather boring.

The author dedicates this work to his philosophy teacher

Kanenas T. Pota

in gratitude for his advice: "Do your own thing. Your reward will be doing it, your punishment having done it".

INDEX OF SUBJECTS 348

PREFACE TO *ONTOLOGY I*

This book and its companion, namely Volume 4 of our *Treatise*, concern the basic traits and patterns of the real world. Their joint title could well be *The Structure of Reality*. They constitute then a work in ontology, metaphysics, philosophical cosmology, or general theory of systems. Our work is in line with an old and noble if maligned tradition: that of the pre-Socratic philosophers, Aristotle, Thomas Aquinas, Descartes, Spinoza, Leibniz, Hobbes, Helvetius, d'Holbach, Lotze, Engels, Peirce, Russell, and Whitehead. But at the same time it departs from tradition in the matter of method. In fact our aim is to take the rich legacy of ontological problems and hints bequeathed us by traditional metaphysics, add to it the ontological presuppositions of contemporary scientific research, top it with new hypotheses compatible with the science of the day, and elaborate the whole with the help of some mathematical tools.

The end result of our research is, like that of many a metaphysical venture in the past, a conceptual system. It is hoped that this system will not be ridiculously at variance with reason and experience. It is intended moreover to be both exact and scientific: exact in the sense that the theories composing it have a definite mathematical structure, and scientific in that these theories be consistent with and moreover rather close to science – or rather the bulk of science. Furthermore, to the extent that we succeed in our attempt, science and ontology will emerge not as disjoint but as overlapping. The sciences are regional ontologies and ontology is general science. After all, every substantive scientific problem is a subproblem of the problem of ontology, to wit, *What is the world like*?

After a long period underground, talk about metaphysics has again become respectable. However, we shall not be talking at length about ontology except in the Introduction. We shall instead do ontology. In the process we shall attempt to exhibit the mathematical structure of our concepts and we shall make the most of science. Being systematic our ontology may disappoint the historian. Being largely mathematical in form it will be pushed aside by the lover of grand verbal (but sometimes deep and fascinating) systems – not to speak of the lover of petty verbal matters. And being science-oriented it will fail to appeal to the friend of the esoteric. Indeed we shall be concerned with concrete objects such as atoms, fields, organisms, and societies. We shall abstain from talking about items that are neither concrete things nor properties, states or changes thereof. Any fictions entering our system will be devices useful in accounting for the structure of reality. (Constructs were dealt with in Volumes 1 and 2 of this work.)

The first ideas for this work dawned upon me when I was engaged in axiomatizing some basic physical theories involving ontological concepts such as those of thing, property, possibility, change, space, and time, none of which are the exclusive property of physics but all of which belong to the metaphysical background of this science, or protophysics (Bunge 1967b). And the earliest plan for this work occurred to me a bright day of June 1966 when travelling from Freiburg im Breisgau to Geneva at the invitation of Jean Piaget. I have been working on this project ever since, on and off, stimulated by what seemed a grand design and occasionally inhibited by the difficulties met with in carrying it out. The result is a system but not a closed and final one: there is much room for improvement and of course also for divergent developments.

This volume deals with the concepts of substance, form (or property), thing (or concrete object), possibility, change, space, and time. The companion volume, *A World of Systems*, will tackle the concepts of system, novelty, biosystem, psychosystem, and sociosystem.

ACKNOWLEDGEMENTS

It is a pleasure to thank the various generations of curious, bewildered and merciless students who survived my ontology courses at McGill University and the Universidad Nacional Autónoma de México from 1969 to 1976. I am also indebted to Professors Rutherford Aris (Chemical Engineering, Minnesota), Thomas A. Brody (Physics, UNAM, México), Máximo García Sucre (Physics, IVIC, Caracas), Tomás Garza (IIMAS, UNAM, México), Andrés J. Kálnay (Physics, IVIC, Caracas), and Roberto Torretti (Philosophy, Puerto Rico) for critical remarks and suggestions. My former research assistants Dr David Salt and Dr Gerhard Vollmer made a number of useful remarks. My research assistant Mr Robert Blohm enhanced the clarity, improved the grammar, and asked questions still to be answered. But my greatest debt is to my former research associates Professors Adalberto García Máynez (Mathematics, IPN, México), William E. Hartnett (Mathematics, SUNY, Plattsburgh), and Arturo A. L. Sangalli (Mathematics, Ottawa), none of whom understood friendship to be in the way of rigor.

The Alexander von Humboldt-Stiftung covered my first incursions into the intersection of physics and metaphysics (1965-66). The Canada Council contributed to this project by awarding me research grants (1969–72, 1974–76), one of them on behalf of the Killam Foundation. And the John Simon Guggenheim Memorial Foundation awarded me a fellowship that gave me a happy and fruitful year (1972–73). It was during the tenure of that fellowship, at the ETH Zürich, that I started to write this book. I am grateful to all those organizations for their support, and to Professors Gerhard Huber and Peter Huber for their hospitality at the ETH. Last, but not least, I thank my guide in the fascinating and puzzling Mexican labyrinth, Professor Fernando Salmerón, director of the Instituto de Investigaciones Filosóficas of the UNAM, where this volume acquired its final shape during the 1975–76 academic year.

MARIO BUNGE

SPECIAL SYMBOLS

$x \rhd y$	x *acts* on y
$c = a \circ b$	c is the *association* of individuals a and b
$A \times B$	the *cartesian product* of sets A and B
$\langle s, s', g \rangle$	the *change* from state s to state s' along curve g
C	set of constructs
$\mathscr{C}(x)$	the *composition* of thing x
$x \lfloor y$	x and y are *detached*
$E_{\mathbb{L}}(x)$	the *event space* of thing x
$E_A x$	x *exists* in A
$\mathscr{E}(A)$	the *extension* of attribute (predicate) A
$f: A \to B$	*function* f maps set A into set B
F	set of *facts*
$\mathbb{F} = \langle F_1, F_2, \ldots, F_n \rangle$	*state function*
$h(x)$	the *history* of thing x
$a \vert c \vert b$	c *interposes* between a and b
$c = a \dotplus b$	c is the *juxtaposition* of a and b
$k(\mathbb{R})$	the *kind* of things sharing all properties in $\mathbb{R}$
$G_{\mathbb{L}}(x)$	the set of *lawful transformations* of the states of x
$\mathbb{L}(x)$	the *laws* of thing x
$\langle x, y \rangle$	the *ordered pair* of x and y
$\square$	the *null thing*
$x \sqsubset y$	x is a *part* of y
$\mathscr{P}(S) = 2^S$	the *power set* of S
$P \preccurlyeq Q$	property P *precedes* property Q
$\mathbb{P}$	the set of *all properties*
$p(x)$	the collection of *properties of thing* x
Pr	*probability* function
$\mathbb{R}$	the *real line*
$S_{\mathbb{L}}(x)$	*lawful state space* of thing x
$c = a \dot{\times} b$	c is the *superposition* of things a and b
S	the set of *all substantial (concrete) individuals*
$\mathscr{S}(P)$	the *scope of property* P
$[T] = \inf T$	the *additive aggregation* of all things in T
$(T) = \sup T$	the *multiplicative aggregation* of all things in T
Θ	the *set of all things*
▯	the *world* or *universe*

INTRODUCTION

In this Introduction we shall sketch the business of ontology, or metaphysics, and shall locate it on the map of learning. This has to be done because there are many ways of construing the word 'ontology' and because of the bad reputation metaphysics has suffered until recently – a well deserved one in most cases.

1. Ontological problems

Ontological (or metaphysical) views are answers to ontological questions. And ontological (or metaphysical) questions are questions with an extremely wide scope, such as 'Is the world material or ideal – or perhaps neutral?', 'Is there radical novelty, and if so how does it come about?', 'Is there objective chance or just an appearance of such due to human ignorance?', 'How is the mental related to the physical?', 'Is a community anything but the set of its members?', and 'Are there laws of history?'.

Just as religion was born from helplessness, ideology from conflict, and technology from the need to master the environment, so metaphysics – just like theoretical science – was probably begotten by the awe and bewilderment at the boundless variety and apparent chaos of the phenomenal world, i.e. the sum total of human experience. Like the scientist, the metaphysician looked and looks for unity in diversity, for pattern in disorder, for structure in the amorphous heap of phenomena – and in some cases even for some sense, direction or finality in reality as a whole. Metaphysics and science have then the same origin. However, they can be distinguished up to a certain point, namely by the scope of their problems. Whereas the scientific specialist deals with rather specific questions of fact, the ontologist is concerned with all of the factual domains: he is a generalist not a fragmentarian. His enterprise is more ambitious, hence also riskier, than any one scientific project. But the two concerns are not mutually exclusive and, in fact, sometimes they are indistinguishable: an extremely general scientific question may be a special ontological one.

Ontological questions are not easy to characterize or even to recognize as meaningful in isolation from ontological frameworks or ontological theories. Consider for example the following questions:

(i) Why is there something rather than nothing?
(ii) Does essence precede existence?
(iii) What is being?
(iv) Where is one?
(v) What is there?

The first question makes sense in any creationist system of theodicy, such as Leibniz', but it makes no sense elsewhere. The second, at first blush unintelligible, makes good sense in a Platonic metaphysics, where essences are ideal and prior to physical existents. The third question becomes meaningful if reformulated as 'What are the features common to all existents?'. The fourth question was asked by my son Eric when he was 18 months old. It must have made some sense in his own *Weltanschauung* and, rewriting 'one' with a capital O, it might be safely attributed to Parmenides. The fifth – which is how Quine seems to understand the task of ontology – calls for either an exhaustive inventory of existents – a job for scientists of the Baconian persuasion – or a simplistic answer such as 'There are bodies and persons' (Strawson, 1959).

The preceding questions make hardly any sense in the system to be developed in this book. On the other hand the following problems do make sense in it and moreover can be given definite answers:

(vi) Are things bundles of properties? (No.)
(vii) Are there natural kinds? (Yes.)
(viii) Is change possible without an unchanging substrate? (Yes.)
(ix) How do emergent properties come about? (Wait for Volume 4.)
(x) What is the mind? (Ditto.)

These questions are both fundamental and extremely general. Moreover they are factual questions – only, comprehensive or cross-disciplinary rather than special. There are as many such questions as we care to ask. The more we come to know, the more problems we can pose and the less final our solutions prove to be. In both regards then – factual content and open-endedness – ontological questions are no different from scientific ones. (For the latter see Bunge, 1967a, Vol. I, Ch. 4.) They differ only in scope. And even this difference is often non-existent, as will be seen in Sec. 7.

2. THE BUSINESS OF ONTOLOGY

At least the following ten conceptions of the concern of ontology (or metaphysics) have followers nowadays:

(i) Metaphysics is a discourse (in either ancient Greek or modern German) *on Being, Nothingness, and Dasein* [human existence] (Heidegger, 1953). Objection: impossible, because the said discourse is unintelligible and moreover avowedly irrational. If in doubt try to read Heidegger or Sartre.

(ii) Metaphysics is a collection of *instinctive* (as opposed to intellectual) *beliefs* (Bergson, 1903). Objection: if metaphysics is to be a discipline then it cannot collect blindly any received ideas, be they "instinctive" or gotten from tradition. The fact that cave men held "instinctive" beliefs without subjecting them to methodic criticism does not justify us in upholding an attitude that would never have taken us out of the cave.

(iii) Metaphysics is the *justification of instinctive beliefs*: "the finding of reasons, good, bad or indifferent, for what we believe on instinct" Strawson, 1959, p. 247). Objection: our least educated tenets must surely be studied – by the cultural anthropologist. Scholars, whether scientists or metaphysicians, are supposed to examine, refine or reject that starting point – and above all to propose new ideas. Reassuring the cave man in his primitive metaphysics is worse than sharing it.

(iv) Metaphysics is "*the science of absolute presuppositions*" (Collingwood, 1940). That is, metaphysics is the study of all presuppositions, of any discipline, in so far as they are absolute, i.e. lurk behind every question and every answer, and are moreover beyond question. This is a respectable view. However, it is open to the following objections: (*a*) most presuppositions are not absolute but are bound to rise and fall with the special theory concerned: look at the history of ideas; (*b*) even though metaphysics does study some of the presuppositions of science, it does not handle them all, as some of them are purely formal (logical or mathematical) and others are methodological.

(v) Metaphysics deals with *everything thinkable*, whether or not it actually exists, whether reasonable or absurd: it is concerned with "the totality of the objects of knowledge" (Meinong, 1904, in Chisholm, 1960, pp. 78–79). Objections: (*a*) no theory is possible that will encompass both concrete objects and conceptual ones; in particular, logical truths may refer to anything but they do not describe or represent any objects except the logical concepts ("or", "all", etc.); (*b*) objects known to be fantastic, such as Pegasus, may be imagined but cannot constitute the subject of any discipline: only our beliefs about such mythological objects can be studied scientifically.

(vi) Metaphysics is *the study of objects neither physical nor conceptual* – i.e. of spiritual beings, and of God and his celestial court in the first place. This opinion is quite popular and was occasionally voiced by Thomas himself (1259 Bk. I, Ch. IV). Objection: that is the proper subject of theology, which is no longer recognized as a part of philosophy.

(vii) Metaphysics is *the science of being as such*: unlike the special sciences, each of which investigates one class of being, metaphysics investigates "all the species of being *qua* being" and "the attributes which belong to it *qua* being" (Aristotle, *Metaphysics* Bk. IV, Chs. 1 and 2). This is what nowadays one would call *general* ontology by contrast to the various *special* or *regional* ontologies (of the biological, the social, etc.). Certainly the Philosopher had a correct grasp of the relation between metaphysics (general) and the sciences (special). Still, the following objections must be raised: (*a*) the formulation is too imprecise, so much so that it has suggested to some that becoming is not within the purview of metaphysics – an opinion certainly not shared by the Stagirite, who was centrally concerned with change; (*b*) a science of pure being is a contradiction in terms because it has no definite subject matter (Collingwood, 1940, pp. 10–11).

(viii) Metaphysics is *the study of change*: of events and processes – because this is what things are (Whitehead, 1929). Objection: an event is a change in the condition (state) of some thing and therefore cannot be studied apart from it any more than things can be studied apart from their changes.

(ix) Metaphysics concerns *all possible worlds*: it is an ontological interpretation of logic. A system of metaphysics is a set of statements satisfying two conditions: (*a*) "The horizon [set of referents] of a significant metaphysical statement must surpass in an unambiguous way the horizon of a physical statement", and (*b*) "A metaphysical statement must not lag behind a physical statement as far as exactness and stability [*Standfestigkeit*] are concerned" (Scholz, 1941, pp. 138–139). While I have no quarrel with the exactness condition, I dispute the others. My objections are: (*a*) the fact that logic may refer (apply) to anything does not render it a theory of all possible worlds; (*b*) while some metaphysical statements do concern all concrete things, others refer to things belonging to certain genera such as physical objects or organisms or societies; (*c*) metaphysical statements cannot be any less fallible than scientific (e.g. physical) statements.

(x) Metaphysics is *general cosmology or general science*: it is the science concerned with the whole of reality – which is not the same as reality as a whole. "Its business is to study the most general features of reality and real objects" (Peirce, 1892–93, p. 5). It "is concerned with all questions of a general and fundamental character as to the nature of the real" (Montagu, 1925, p. 31; see also Woodger, 1929; Williams, 1937; and Quinton, 1973). In other words, metaphysics studies the generic (nonspecific) traits of every mode of being and becoming, as well as the peculiar features of the major genera of existents. This is the task Hegel (1812–16) assigned to "objective logic" and Engels (1878) to what came to be known as dialectical materialism.

We adopt the latter position: we maintain that the ontologist should stake out the main traits of the real world as known through science, and that he should proceed in a clear and systematic way. He should recognize, analyze and interrelate those concepts enabling him to produce a unified picture of reality. (The word 'reality' is here understood in a strict and non-Platonic sense, namely as the concrete world.) In this sense the reader is real and so is any utterance of the word 'reader'; but the concept designated by this word is unreal.

Because unreal objects have nonphysical properties, they satisfy nonphysical laws if any. For this reason it is impossible to make any nontautological statements applying to all objects: ontology, as conceived by Meinong and Leśniewski, i.e. as a general theory of objects of any kind, and yet different from logic, is impossible. So is the modern version of this doctrine, namely general systems theory construed as a mathematical theory "dealing with the explanations of observed phenomena or conceptual constructs in terms of information-processing and decision-making concepts" (Mesarović in Klir, 1972, p. 253). If the "system" is purely conceptual, as is the case with a number system, then it cannot combine with material systems to form supersystems, it cannot interact with them, it does not obey laws of the same kind and therefore it cannot be studied with the special methods of factual science. Whatever we may think of the construct-thing duality, whether we take a Platonist or a materialist stand, or whether or not we wish to reduce objects of one kind to objects of another, we should keep the duality at the methodological level. (Recall Vol. 1, Ch. 1, Sec. 3.)

We leave formal science, i.e. logic, mathematics, and semantics, the task of studying (and creating) formal or ideal objects of the law-abiding kind, such as sets and categories. (More in Sec. 6.) We take factual (natural or social) science and ontology to be the only disciplines concerned with concrete objects. And we assign ontology the task of constructing the most general theories concerning such and only such objects. But is this task possible?

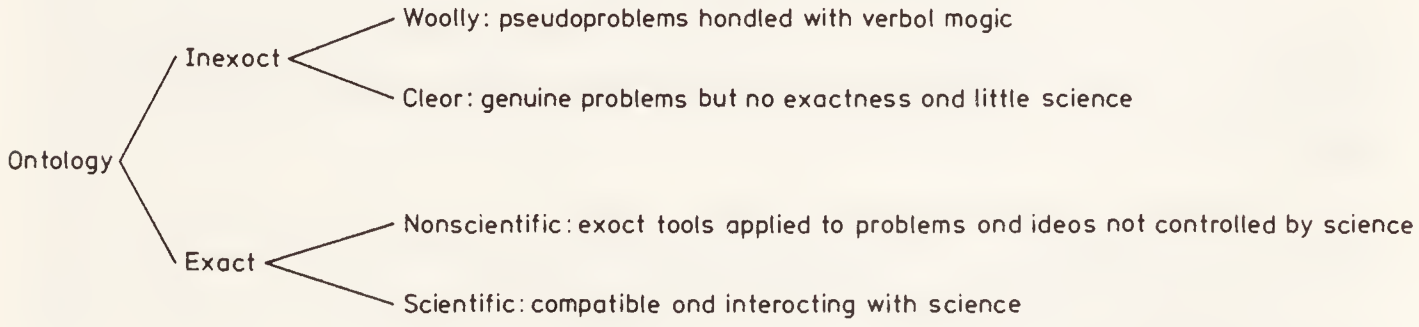
3. IS ONTOLOGY POSSIBLE?

Up until the first scientific revolution, in the early 17th century, metaphysics was taken for granted and was usually regarded as an adjunct to theology. Thereafter the formidable successes of science, jointly with the failure of the grand metaphysical systems – chiefly those of Aristotle, Aquinas, Descartes and Leibniz, and later on Hegel's and Heidegger's – suggested, nay "proved", that metaphysics had become impossible and had been replaced with science.

Those who deny the possibility of metaphysics as an authentic and creative intellectual endeavor hold that metaphysical sentences are either meaningless (hence neither true nor false) or meaningful but untestable; or, if meaningful and testable, then false. Or they hold that, aside from questions of meaning and truth, such statements have no value either practical or heuristic. That many metaphysical statements – e.g. most of Hegel's and all of Heidegger's – are hardly meaningful, is true and sad enough but speaks only against bad metaphysics. (Likewise the fact that most statements about the mental are nonscientific does not disqualify psychology as a science.) That metaphysical propositions cannot be checked for truth the same way scientific statements are tested, is correct but in no way proves that they are beyond criticism and confirmation. That many, perhaps most metaphysical propositions have turned out to be false, and many more will be refuted, is again true but does not render metaphysics any less possible than science, which is in the same predicament. Finally, it is not quite correct that metaphysics lacks in heuristic or even practical import. For one thing scientific research makes use of a number of ontological hypotheses, as will be seen in Sec. 7. For another the philosophic core of every world view and every ideology is, for better or (usually) worse, some ontological system or other together with some value system. In short, it is not true that ontology has become impossible after the birth of modern science. What has become impossible *de jure* – though unfortunately not *de facto* – is nonscientific ontology.

The sceptic may not deny the possibility of ontology but will regard it as inconclusive. With this we concur: metaphysics is indeed inconclusive – but so is factual science. Genuine knowledge is characterized not by certainty but by the possibility of correction in an endless effort at attaining truth and depth. This holds for ontological knowledge no less than for scientific knowledge. Let the sceptic criticize every single metaphysical system: let us keep him busy by offering him new metaphysical theories.

Ontology is not just possible but very much alive these days. (As a matter of fact it has never ceased to exist: it just went underground for a while.) A casual look at the literature will bear out this contention. Moreover, metaphysics only recently has undergone a revolution so deep that nobody has noticed it: indeed ontology has gone mathematical and is being cultivated by engineers and computer scientists. As a matter of fact a number of technologists have developed, over the past three decades, certain exact theories concerning the most basic traits of entities or systems of various genera. Switching theory, network theory, automata theory, linear systems theory, control theory, mathematical machine theory, and information theory are among the youngest metaphysical offspring of contemporary technology (Bunge, 1971, 1974d, 1977a). This kind of ontology, both exact and scientific, is the one we wish to develop and systematize. Its place in the map of metaphysics is shown in the following table. (Nonacademic varieties of metaphysics, mostly esoteric, have been left aside.)



Ontology
Inexact
Woolly: pseudoproblems handled with verbal magic
Clear: genuine problems but no exactness and little science
Exact
Nonscientific: exact tools applied to problems and ideas not controlled by science
Scientific: compatible and interacting with science

4. THE METHOD OF SCIENTIFIC ONTOLOGY

The ontology we wish to build is both exact and contiguous with science. ‘Exact’ means of course logical or mathematical in form. Exact metaphysics is then the set of metaphysical theories built with the explicit help of logic or mathematics. For example, a mathematical theory of the synthesis of wholes out of lower level units would qualify as a piece of exact metaphysics. Not so a theory, however interesting, tackling the same problem in ordinary knowledge terms: it would remain at the level of inexact metaphysics because of the ambiguity and imprecision of ordinary language.

We are interested in the scientific variety of exact metaphysics, that is, in the ontological theories that, in addition to being exact, are scientific. The difference between 'exact' and 'scientific' is this: the latter implies the former but the converse is false. That is, there are systems of exact metaphysics that are out of touch with factual (natural and social) science. For example, Leibniz, Bolzano, Scholz and Montague were exact metaphysicians but they conceived of metaphysics as an a priori science (see e.g. Bolzano, 1849, p. 29); hence their work is not in tune with the science of their day. Likewise most of the contemporary essays on possible worlds, temporal logic, and causality, though often exact, are far removed from science and sometimes even incompatible with it. There is little if any philosophical meat in these theories; and when there is some, it turns out to be stale.

As for scientific metaphysics, it is still largely a program. Even Peirce (1892–93), perhaps the first to employ the expression, did not advance beyond some programmatic remarks. To implement that program we need some guidelines. Here are some of the *regulae philosophandi more geometrico et scientifico* we shall try to abide by:

R1 *Take the metaphysical tradition into account but do not stick to it*: go ahead revising the traditional stock of problems and solutions, posing new problems, and trying new solutions to both old and new questions.

R2 *Avoid any words that fail to convey clear ideas*: obscurity is not the mark of profundity but of confusion or even of intellectual swindle. As for fuzzy ideas – all ideas are fuzzy when newly born – try and refine them.

R3 *Try and formalize everything*: whatever is worth saying in any theoretical discipline, including metaphysics, can be said with the help of mathematics and ought so to be said for the sake of clarity and systematizability.

R4 *Do not mistake symbolization for mathematization*: stenography does not elucidate and does not systematize. Unless a construct is assigned a definite mathematical status (as set, relation, function, group, topological space, or what have you) it is not exact and may be a fake, i.e. a *flatus vocis* rather than a genuine concept.

R5 *Strive for rigor but do not allow it to curtail vigor*: exactness is a means not an end – a means to attain clarity, systemicity, cogency and testability. Insisting on rigor for its own sake and at the price of giving up deep intuitions is a mark of sterility.

R6 *Explain the concrete by the abstract* rather than the other way around. Invert Russell's advice to replace "inferred" (unobserved, hypothetical) entities with logical constructions out of sense impressions. Imitate the atomists and the field theorists. Admit observable, ostensive and secondary properties only if they can be analyzed in terms of primary properties.

R7 *Keep clear of subjectivism* – e.g. avoid definitions in terms of personal experience. Example of the strategy to be avoided: Whitehead (1920, p. 13) defined the concept of a fact as "the undifferentiated terminus of sense-awareness". Every ontological elucidation, even of concepts concerning subjective phenomena, should be couched in purely objective (subject-free) terms.

R8 *Do not reify whatever is not a thing*, and do not treat as an autonomous entity what is but the result of abstraction. E.g. do not talk about events apart from or even as constituting changing things.

R9 *Strive for systemicity*: try to build theories and establish links among them. Do not introduce – except by way of extrasystematic remarks – concepts that have not yet been elucidated: proceed in orderly fashion, and if necessary axiomatically. Philosophical analysis is indispensable but not enough, and is best done in the context of a system anyway.

R10 *Check* your metaphysical hypotheses and theories not only for internal consistency but also for compatibility and even contiguity with contemporary science.

Abiding by these rules should help us in building science-oriented ontological frameworks and even theories, though it won't secure them.

5. The goals of scientific ontology

Every philosophical activity has two possible intellectual goals: analysis or synthesis – i.e. taking apart or building. Philosophical analysis examines certain concepts and propositions in order to clarify them. Philosophical synthesis creates frameworks and theories in order not only to elucidate notions and statements but also to understand what goes on in the world. The two operations are complementary rather than mutually exclusive. In fact the best analysis is that performed in a definite theoretical context, just as the best synthesis is that which articulates analyzed notions. In any case it is synthesis, not analysis, that provides some understanding of a field of reality or of human experience. Thus only a theory of ideation, rather than an analysis of the notion of ideation – let alone an analysis of the word 'ideation' as used in a given community – can account for ideation.

In the case of ontology, analysis bears on any metaphysical concepts or propositions – or candidates for either role. Ontological analysis bears, in particular, on ontological categories – such as those of quality and society – and ontological principles – such as the hypothesis that every concrete thing is in flux. The analysis we expect from scientific ontology concerns, in particular but not exclusively, the ontological categories and hypotheses that occur, either in a heuristic or in a constitutive capacity, in scientific research. Some such categories are those of thing, property, fact, and value. As for the ontological principles inherent in science, suffice it to mention the assumption that a society, far from being either an amorphous set of individuals, or a totality transcending individuals, is a system of interacting persons. More in Secs. 7 and 8.

However, the ontological analyst need not confine himself to listing and classing the ontological categories and principles actually employed – usually with neither acknowledgement nor apology – in scientific inquiry. He may be more ambitious and criticize certain ontological theses, be they proposed by philosophers or by scientists, and he may even propose his own theses on the matter. Take for example the generic or ontological notion of a mental event. The ontological analyst may not only examine the various construals of the expression 'mental event' but also have an axe to grind – or ought to if he is a philosopher at all. But he may not be able to accomplish much without the help of some general (ontological) theory of events (of all kinds) and some general (ontological) theory, or at least framework, of the mental. That is, ontological analysis, if profound, calls for ontological synthesis or theory, or at least a framework for such.

Ontological theories are of course those involving ontological categories. A general theory of changes of any kind, physical or mental, quantitative or qualitative, is an ontological theory. And a theory of mental events of any kind – feeling visceral processes, perceiving physical stimuli, forming images or concepts, etc. – is an ontological theory too, though a regional one instead of a universal theory. A complete ontology should include both *universal* and *regional* ontological theories. The former serve as frameworks for the latter, which will in turn illustrate and in a way test the former. Take again the case of mental events. In our own ontology the dualistic tenet concerning the mind-body problem makes hardly any sense because it presupposes that mental events are exceptional in that, unlike all others, they fail to be changes in some concrete thing. In fact in our ontology all and only things change, and every change (event of process) is a modification in the state of some concrete thing or other. Once this general ontological view has been adopted and systematized (made into a theory or at least a framework) there is no room left for changes that fail to be changes in or of some concrete thing, be it an electron or a neuron, a brain or a society. Only one view of mental events is consistent with that general ontological theory of change, namely that according to which the mind is a certain activity of the brain (Hebb, 1949). Moreover it is clear that any alternative view should be shown to be consistent with some general theory of change. This is certainly possible: a mentalistic (e.g. idealistic) ontology will include a mentalistic view of the physical. But of course such an ontology will be at variance with physics, chemistry and biology, none of which is animistic. We shall discuss these matters in detail in Vol. 4, Ch. 10. The point of bringing them up here was to defend the view that a full fledged ontology must consist of theories – or at least theory embryos – some universal and some regional, and that these theories should be mutually consistent. There is no salvation outside a system.

Needless to say, when using the word 'theory' we mean a hypothetical-deductive system rather than a stray opinion or an unsystematic set of opinions. In particular, an *ontological theory* is a theory that contains and interrelates ontological categories, or generic concepts representing components or features of the world. (Our own set of categories includes those of thing, property, law, possibility, change, spacetime, life, mind, value, and society.) Ideally, an ontological system or theory is a system, not just a set, of interrelated ontological categories. But we shall not always succeed in building theories proper. Sometimes we shall offer just ontological frameworks, which are constructs intermediate in structure between shapeless views and closed hypothetical-deductive systems. (For the general concept of a framework see Vol. 1, Ch. 2, Sec. 3.4, Def. 2.10.)

We shall agree to call an ordered triple $\mathbb{C} = \langle S, \mathbb{P}, D \rangle$ an *ontological framework* iff S is a set of statements in which occur only the predicate constants in the predicate family $\mathbb{P}$, which includes a nonempty set $\mathbb{O}$ of basic ontological concepts (i.e. categories), and the reference class of every P in $\mathbb{P}$ is included in the universe or domain D of hypothesized entities, or objects assumed to exist (in our case concrete objects or things). Though no substitute for an ontological theory, an ontological framework serves as a matrix for any number of ontological systems or theories, and has thus a guiding or heuristic power. (For the difference between theory and framework, and the heuristic role of the latter, see Bunge (1974e).) Indeed the mere display of D's and their properties (i.e. the members of $\mathbb{P}$) invites the formulation of hypotheses (statements in S) concerning the mode of being and becoming of those alleged entities.

An ontological framework will be *monistic* or *pluralistic* according as both the domain D of individuals and the collection $\mathbb{P}$ of their properties (and relations) are taken to be a single genus each or the union of two or more genera. (In short, monism is reductionistic in some sense or other, pluralism is not.) And, whether monistic or pluralistic, an ontological framework can be either *spiritualistic* or *naturalistic*, according as it postulates that D includes, or fails to include, a set of spiritual (disembodied) entities such as immaterial souls. But whereas according to spiritualistic monism all entities are spiritual and of the same kind (e.g. sensations, or ideas), according to pluralistic spiritualism all entities are spiritual but there are several types of them and these kinds are not reducible to one basic kind. And whereas according to monistic naturalism all entities are concrete and of the same kind (e.g. physical), pluralistic monism asserts that, although all entities are concrete, there are several irreducible kinds of them. The ontological frameworks and theories to be developed in the present volume and its sequel, Vol. 4, will turn out to be both *naturalistic and pluralistic*: we will assume only concrete existents but will assert their qualitative variety.

In summary, the goals of scientific ontology are *to analyze and to systematize the ontological categories and hypotheses germane to science.* These are the aims served by the construction of frameworks and theories close to science rather than closed to science.

6. Ontology and formal science

Formal science, or at least some of it, constitutes both the language and the formal skeleton of scientific ontology. In particular, scientific ontology presupposes *abstract mathematics*, including deductive logic. The choice of abstract mathematics as the formal backbone of metaphysics is only natural, for only abstract systems can be assigned alternative interpretations, in particular ontological interpretations. The theories of semigroups and of lattices, which are abstract, have far more potential use for metaphysics, and for philosophy in general, than number theory and the infinitesimal calculus, which are fully interpreted (in mathematical terms), hence nonabstract. In any case, metaphysics can make use of mathematics and must employ it if it is to become exact and contiguous with science. Is there more to it? Let us see.

Many philosophers, from Parmenides through Leibniz and Hegel to Gonseth and Scholz, have believed that logic is a sort of universal physics, i.e. the most general theory of being or becoming. The Leibnizians put it this way: (*a*) the real world is merely one among many equally possible worlds; (*b*) logic is true of all possible worlds, hence also of ours. (See e.g. Lewis, 1923; Scholz, 1941; Hasenjäger, 1966.) The rationale for this view is that a tautology of ordinary logic, such as $\ulcorner (x)(Px \vee \neg Px) \urcorner$, is true of anything, i.e. no restrictions are placed on the individual variable or the predicate variable. This is certainly true: logic refers to everything and holds for anything in any respect. It would seem therefore that logic is a sort of minimal ontology, a *physique de l'objet quelconque* (Gonseth, 1938).

However, although logic is indeed indifferent to the kind of referent, it does not describe or represent, let alone explain or predict, any factual items. The statement "Every organism is either alive or dead" concerns organisms but does not say anything definite about them; hence it is not a biological statement or even an ontological one. Rather, the proposition says something about the particular combination of "or" and "not" that occurs in it. Logic is the set of theories describing the properties of logical concepts – the connectives, the quantifiers, and the entailment relation. So much so that none of these concepts has a real counterpart or at least a unique one. Indeed, there are neither negative nor alternative things, properties, states, or events. Generalization, whether existential or universal, is strictly a conceptual operation. And the entailment relation has no ontic correlate either, although it has sometimes been likened to the causal relation. Further, if it be admitted that tautologies are analytic, hence a priori, they cannot be also synthetic a priori truths. In sum logic is not ontological.

The relation between logic and ontology is that of presupposition or logical priority: any cogent metaphysics presupposes logic. (This may be why Heidegger (1953) pushed logic aside with contempt and hatred.) In our work we shall take second order ordinary logic for granted. *Ordinary* logic because it is the one employed in mathematics, hence in theoretical science, neither of which has found use for any deviant logics. And *second order* logic because we want to analyze ontological statements such as "Everything has some property or other", and "Every property of a thing is related to some other properties of it".

The relation between ontology and mathematics is similar: if exact, ontology presupposes mathematics, but the latter is in turn free from any ontological commitments. Surely certain mathematical structures can be assigned ontic interpretations. For example group theory can be construed as describing all possible reversible transformations. But such interpretations, like those inherent in theoretical physics, go beyond pure mathematics. The latter stands on its own feet. If anyone wants to make use of it he is welcome: mathematics (including logic) is a service discipline. If a given field of research finds no use for mathematics, then this suggests only that it is in a backward state – that it has few clear notions and general propositions. The possibility of mathematizing a field of knowledge does not depend upon the subject matter but upon the state of the art, for what get mathematized are not facts but our ideas about them. As long as the latter are confused they are impregnable to mathematization, as was the case with the much overrated *impetus* concept (Koyré, 1957), later on with that of energy, and nowadays with that of the "neural correlate" of a mental event. So much for the relations between ontology and mathematics.

The relation between semantics and metaphysics is another matter. Tarski (1944, p. 363) held that ontology "has hardly any connections with semantics." However, the correspondence theory of truth presupposes that there is a real world – and this is a metaphysical assumption. Moreover the applications of any theory of reference calls for definite assumptions about the furniture of the world. Consider e.g. "The plane is 1 hr late". Does it refer to the plane, to both the plane and the airport, or only to the event of its arrival in the airport, or to both and the duration of the delay? The answer to this question depends on one's cosmology – on the assumed furniture of the world. If things are regarded as the only constituents of reality, the answer is that the statement concerns the plane and the airport; if events are declared the stuff of reality, then the referent will be the plane's arrival; and if time is assumed to have an absolute existence then it, too, will count among the referents. In sum semantics, or at least its application, does have metaphysical presuppositions. (More in Bunge, 1974c, and Vol. 2, Ch. 10, Sec. 4.3.) On the other hand ontological theories seem to have no semantic presuppositions although they do employ semantic concepts such as those of designation, reference, and representation.

To sum up. Deductive logic and pure mathematics, in particular abstract mathematical theories, are ontologically neutral. Precisely for this reason they can be used in building ontological theories. There is no a priori limitation on the variety of mathematical theories that can be employed in metaphysical research. The choice will depend largely upon the metaphysician's background and preferences. Some (e.g. Scholz, 1941) will try to make do with formal logic and model theory only. Others would like to extract an entire cosmology out of modal logic (see e.g. Munitz (ed.), 1971 and 1973). Suppes (1974) seeks instead "to replace the concept of logical empiricism by probabilistic empiricism" in constructing a probabilistic metaphysics. Finally, other philosophers will adopt what may be termed *mathematical opportunism*, or the strategy of using whatever mathematical theories seem promising. The present work exemplifies this strategy.

So much for the relation of metaphysics to formal science. (More in Bunge 1974c.) Let us now look at the other component of science.

7. THE ONTOLOGY OF SCIENCE

Metaphysics has often been contrasted with science for allegedly being speculative rather than empirical, hence irrefutable. So it is in many cases. However this is far from necessary: ontology can be consonant with science and just as scientific as physics, even though there will never be any metaphysical laboratories. Moreover we shall argue that (*a*) scientific research is guided or misguided by metaphysical principles – some good, others bad; (*b*) both basic science and technology have produced theories that are scientific as well as metaphysical, and (*c*) it is possible to build systems of scientific ontology. If this is so then there need not be any hostility between science and (scientific) metaphysics. There is not even a gap, let alone an abyss, between them: *ontology is general science* and *the factual sciences are special metaphysics*. In other words, both science and ontology inquire into the nature of things but, whereas science does it in detail and thus produces theories that are open to empirical scrutiny, metaphysics is extremely general and can be checked solely by its coherence with science.

That scientific research proceeds on a number of metaphysical hypotheses has been pointed out from time to time – e.g. by Woodger (1929, p. 228), Collingwood (1940), Russell (1948, pp. 506 ff.), Margenau (1941, 1950), Bunge (1961, 1967a I pp. 291 ff.), Harré (1961, 1972), Agassi (1964, 1975), Lakatos (1969), Harvey (1969), Körner (1970) and Rosenblueth (1970, Chs. 7 and 10). The following list of ontological principles occurring in scientific research (Bunge, 1974d) must suffice here:

M1 There is a world external to the cognitive subject. If there were no such world it would not be subject to scientific inquiry. Rather we would resort to introspection or to pure mathematics instead of attempting to discover the unknown beyond the self.

M2 The world is composed of things. Consequently the sciences of reality (natural or social) study things, their properties and changes. If there were real objects other than things it would be impossible to act upon them with the help of other things.

M3 Forms are properties of things. There are no Platonic Forms in themselves flying above concrete things. This is why (*a*) we study and modify properties by examining things and forcing them to change, and (*b*) properties are represented by predicates (e.g. functions) defined on domains that are, at least in part, sets of concrete objects. (Think of fertility, defined on the set of organisms.)

M4 Things are grouped into systems or aggregates of interacting components. There is no thing that fails to be a part of at least one system. There are no independent things: the borders we trace between entities are often imaginary. What there really is, are systems – physical, chemical, living, or social.

M5 Every system, except the universe, interacts with other systems in certain respects and is isolated from other systems in other respects. Totally isolated things would be unknowable. And if there were no relative isolation we would be forced to know the whole before knowing any of its parts.

M6 Every thing changes. Even the so-called ultimate components of matter end up by changing in the course of their transactions with other things. Even the supposedly stable particles can be absorbed by other systems or merge with their corresponding antiparticles to form photons that may in turn be absorbed.

M7 Nothing comes out of nothing and no thing reduces to nothingness. If this were not so we would make no effort to discover both the origin of new things and the traces left by things that have been destroyed.

M8 Every thing abides by laws. Whether natural or social, laws are invariant relations among properties, and they are just as objective as properties. Moreover a law is a property. If there were no laws we would never discover any and would not utilize them in order to explain, foresee and do. In particular the experimental method would not be feasible, for its essence is the deliberate and controlled wiggling of a component or a variable of some system to find out what effect that change may have on some other feature of the system. Our unrelenting attempt to find out facts of this kind presupposes that there are lawful relations among the items concerned.

M9 There are several kinds of law (nomological pluralism). There are causal (or predominantly causal) laws and stochastic laws, as well as laws exhibiting these two and even further modes of becoming. There are same-level (e.g. biological) laws and cross-level (e.g. psychosocial) laws.

M10 There are several levels of organization: physical, chemical, biological, social, technological, etc. The so-called higher levels emerge from other levels in the course of processes; but, once formed – with laws of their own – they enjoy a certain stability. Otherwise we would know nothing about organisms and societies before having exhausted physics and chemistry – which are inexhaustible anyway.

There are certainly further ontological principles utilized more or less overtly in the selection of problems, in the formation of concepts and hypotheses, in the design of techniques, and in the evaluation of results of scientific research. However, the ones we have listed are enough to establish the thesis that *all science presupposes some metaphysics*. Surely most scientists are not aware of this fact or else they call such principles ‘scientific’ (e.g. Rosenblueth, 1970). But the fact is there and once in a while we come across some great scientist who does realize that he is upholding certain metaphysical hypotheses, i.e. who has a definite and conscious world view that guides his research. Galilei, Descartes, Leibniz, Newton, Euler, d'Alembert, Priestley, Faraday, Darwin, Maxwell, Einstein, Born, Heisenberg, Schrödinger, J. B. S. Haldane, Bernal, and Dobzhansky – to cite but a few – were among the great scientists aware of some of their own ontological principles. And if scientific research is guided – or misguided – by ontological axioms then it behoves the historian of science to dig them up, and the philosopher of science to formulate them clearly, to justify or criticize them, and eventually to systematize them. This is in fact the task of the *metaphysics of science* (Bunge, 1974d, 1974f). Some of it will motivate, and some will be incorporated into, our system of scientific metaphysics.

To be sure not all of the metaphysical hypotheses proposed or adopted by scientists are reasonable or fertile: some are unreasonable or obstructive. To cite but a few examples: (*a*) the Copenhagen interpretation of quantum mechanics claims that, whereas macrophysical objects are objectively real, their atomic components come into being only as a result of observations; (*b*) the many-worlds interpretation of quantum mechanics holds that at each instant the world we live in branches off into countless parallel universes, mutually disconnected and therefore unknowable; (*c*) a number of scientists deny that chance is an objective mode of being and are therefore committed to the subjectivist or personalistic interpretation of probability: they are die-hard classical determinists; (*d*) according to a widespread interpretation of the theory of evolution, natural selection leads to gradual perfection, which in turn is what lends "meaning" to life; (*e*) behaviorism rests on the Aristotelian principle that nothing can change spontaneously: that the organism is a deterministic automaton every output of which is caused by some environmental input; (*f*) many eminent neurophysiologists and neurosurgeons believe that the mind is something separate from the body that does the minding; (*g*) while some social scientists claim that there are no societal properties and laws above those characterizing the individuals, others refuse to recognize that societal emergents are rooted to the individuals and their interplay. In sum, science is shot through with metaphysics – good and bad, fertile and sterile.

Let us now turn to some areas of scientific research where metaphysics makes itself felt with particular acuteness.

8. ONTOLOGICAL INPUTS AND OUTPUTS OF SCIENCE AND TECHNOLOGY

We shall presently defend the thesis that ontology can be found not only among the heuristic crutches that guide scientific research, but also (*a*) in some of the very *problems* handled by research, (*b*) in the *axiomatic reconstruction* of scientific theories, and (*c*) among *extremely general theories* in both basic and applied science.

That some of the most interesting scientific problems are at the same time metaphysical, is shown by the following examples:

(i) Is there an ultimate matter (*ápeiron* or *Urmaterie*)? This question triggered Heisenberg's 1956 theory of elementary particles.

(ii) Is life characterized by an immaterial principle (spirit, entelechy, *élan vital*, or any other substitute for ignorance), or has it emerged in a strictly natural evolutionary process? This question has prompted the current experimental studies on the origin of organisms.

(iii) Are biological species embodiments of Platonic archetypes, or just concrete populations, or something else? This question is being asked every day by almost every thoughtful taxonomist.

(iv) Is the mental anything disjoint from and beyond the neural? Are the two correlated, or do they interact, or finally is the mental a function of the nervous system? The latter alternative is no less than the motor of physiological psychology.

(v) Is a society anything beyond and above the individuals that compose it or are there societal laws in addition to the laws concerning individual behavior? This is one of the central disputes in today's methodology and philosophy of the social sciences.

The above questions have proved fruitful: they have triggered entire research lines. Alongside them there are other questions that result from a dubious metaphysics often at work in science, one that is a source of confusion and a sink of efforts. Here is a sample:

(vi) Why are μ-mesons different from electrons? (Why should they not be?)

(vii) Why are there no superluminal particles? (Why should there be?)

(viii) Is it possible to observe time reversal? (Inverting the sign of t in an equation of motion has no "operational" counterpart.)

(ix) Why should the study of behavior be hitched to an investigation of the behaving thing, i.e. the organism? (Because there is no change apart from a changing thing.)

(x) What is the liaison officer between body and mind? (Why presuppose that body and mind are separate entities?)

In sum, ontology inspires or blocks the most interesting research problems and plans. (This being so, the intervention of ontological principles in the design of research policies ought to be studied.)

A second area where ontology overlaps with science is the axiomatic foundation of scientific theories. If a scientific theory is axiomatized, some of the following concepts are likely to occur in it in an explicit fashion: part, juxtaposition, property, possibility, composition, state function, state, event, process, space, time, life, mind, and society. However, the specific axioms of the theory will usually not tell us anything about such fundamental and generic concepts: science just borrows them leaving them in an intuitive or presystematic state. Only ontology is interested in explicating and systematizing concepts which, since they are used by many sciences, are claimed by none. For example, physics asks not 'What is time?', biology 'What is life?', psychology 'What is the mental?', and sociology 'What is sociality?'. It is the task of ontology, jointly with the foundations of science, to try and supply answers to such questions and, in general, to clarify whatever idea science takes for granted or leaves in the twilight. That is, the metaphysician must fill some of the gaps in science.

There are such gaps in scientific knowledge not because certain facts are impregnable to the scientific method and require an esoteric intuition but because there are certain ideas which scientists use freely without bothering to examine, perhaps because they look obvious. The ontological theories that clarify and articulate the general ideas underlying a scientific theory T may be called the *ontological background* of T. This background becomes part and parcel of the axiomatized scientific theory (Bunge, 1967b, 1973b). That is, the metaphysical hypotheses contained in that background become blended with the scientific hypotheses proper. Note that such metaphysical ideas are now *constitutive* not just *regulative* or heuristic like those listed in Sec. 7. Whereas the latter may go down with the scaffolding the former remain in the theory.

In short, the axiomatic reconstruction of any fundamental scientific theory is bound to dig up, exactify and systematize certain ontological concepts. In this way the line between ontology and science is erased.

A third region where science merges with ontology is constituted by certain extremely general theories such as Lagrangian dynamics, the classical theory of fields (of any kind), and the quantum theory of fields (misnamed 'axiomatic field theory'). All these theories are generic in the sense that, far from representing narrow species of things, they describe the basic traits of whole genera of things. For example Lagrangian dynamics, which started out as a reformulation of classical particle mechanics, was eventually generalized to cover mechanical, electrical, and even biological and social systems. As long as the Lagrangian function is not specified, and its independent variables are not interpreted, the theory remains so general as to be indistinguishable from metaphysics. In fact Lagrangian dynamics may have been the earliest member of scientific metaphysics.

In sum, science itself has produced ontological theories by a process of generalization. Here again there is no border to be drawn.

A fourth and last area where ontology mingles with science is contemporary technology. In fact some of the theories included in the so-called information sciences and in systems theory are so general, and at the same time so precise, that they qualify as theories in scientific metaphysics. For example a general control (or cybernetic) theory will apply not only to machines with feedback loops but also to goal-seeking systems (members of higher animal species). Being so general, a theory of this kind will not represent any details of the system of interest: for example it will be insensitive to the nature of the materials and mechanisms involved. Hence it will not replace any of the special theories built by scientists and technologists. But such general theories provide insights and they link previously isolated fields of research. (Cf. Bunge, 1977a.)

In short, post-war technology has produced a number of ontological theories. In fact it has been more fertile than academic metaphysics.

The upshot of our discussion so far is this: science, whether basic or applied, is permeated with ontological ideas, now heuristic, now constitutive – so much so that some scientific theories are at the same time metaphysical. More precisely: every scientific theory, if extremely general, *is* ontological; and every ontological theory, if exact and in tune with science, *is* scientific. Therefore the expression *scientific metaphysics*, though perhaps shocking at first, designates an existing field and one that is hardly distinguishable from science.

True, ontological theories, whatever their degree of scientificity, cannot be tested empirically. Nor, for that matter, can extremely general scientific theories. (For example the basic equations of continuum mechanics cannot even be solved, let alone put to the test, unless they are adjoined special assumptions concerning the forces, the mass distribution, and the internal stresses.) Like the generic theories of science, those of ontology are *vicariously testable*, i.e. through the checking of more special theories gotten from the general ones by conjoining them with subsidiary assumptions (Bunge, 1973a, Ch. 2). In sum, concerning testability as much as concerning reference, there is no distinction between an ontological theory and an extremely general scientific one.

Because there is no clear-cut border between science and ontology, it is pointless to try to find the correct criterion for the strict demarcation between these two fields. The demarcation problem, which has occupied so many eminent brains from Kant on (see e.g. Popper, 1963), has disappeared. Another, far more interesting and rewarding task, has replaced it: namely that of digging up the metaphysics of science and technology, and building a scientific ontology.

9. USES OF ONTOLOGY

Metaphysics is a traditional branch of philosophy and as such it need not be justified in the eyes of the philosopher provided he is either pre-Kantian or post-positivist. (It has been remarked many times, and rightly so, that an antimetaphysician is one who holds primitive and unexamined metaphysical beliefs.) A philosopher may dislike the word and prefer some substitute for it, such as 'ontology', 'philosophical cosmology', 'general science', or 'scientific outlook'. But, since he acknowledges the existence of certain problems that have traditionally been called 'metaphysical', unless he is an irrationalist he won't deny that those problems deserve an answer and, moreover, that the best answer to any theoretical problem is supplied by a theory.

If metaphysics is a part of philosophy then it must be related to the other branches of this field: otherwise it would not constitute such a part. It can certainly be distinguished from the other branches of philosophy – mainly logic, semantics, epistemology, value theory, and ethics – but not separated from them. Thus it makes a lot of difference for ontology if one adopts a realist epistemology or a phenomenalist one: with the former one will attempt to disclose the structure of reality, with the latter only the structure of appearance. In turn, one's epistemology depends to a large extent upon one's ontology: if the latter is naturalist one will conceive of epistemology as the ontology of knowing; but if one adopts a spiritualist ontology then the way to a subjectivist epistemology is open. To generalize: ontology is closely linked to the rest of philosophy.

However, the close interactions between ontology and its sister disciplines should not blind us to their differences. In particular we must not mistake the categories of knowing (e.g. truth) with those of being (e.g. property). And yet this distinction is sometimes overlooked. For example Strawson (1959) has claimed that material bodies are basic among particulars, not because they are the ultimate constituents of everything, but because every particular is allegedly identified or reidentified in terms of material bodies. Surely material bodies are a condition for our knowledge of the external world. Yet so are our senses and our intellect and yet these are not basic particulars. In sum, while defending the unity of philosophy, i.e. the interrelations among its branches, we must not forget their differences.

In any case ontology hardly needs a defense among contemporary philosophers. It has even become fashionable among them to talk about ontology. On the other hand scientists will not be impressed by the statement that metaphysics is worthy because it happens to be part and parcel of philosophy. (After all, they were told by philosophers, over a century ago, that metaphysics is balderdash.) But scientists might learn to tolerate ontology if shown that, though at first blush useless (or even nonsense), it can be of some use, namely in the following ways:

(i) *Metaphysics can help dissolve pseudoquestions* that arise in science and originate in misconceptions. Example: "What is the root of the arrow of time: irreversibility, ignorance of microscopic details, experiment, the expansion of the universe, or what?" This question dissolves upon realizing that time has no objective arrow: that only processes can have an "arrow", i.e. be irreversible. But this realization requires a full-fledged theory of time, and this is a typical task for ontology.

(ii) *Metaphysics can dig up, clarify, and systematize* some basic concepts and principles occurring in the course of scientific research and even in scientific theories – constructs that are common to a number of sciences, so that no single science takes the trouble to regiment them, as is the case with "property" and "space". Some of these constructs are included in the ontological background of scientific theories: recall Sec. 8.

(iii) *Metaphysics can suggest new scientific problems, research plans, and even theories.* Example: the mechanistic metaphysics born in the early 17th century inspired scientific research for two centuries. Another: Nobel laureate Yukawa (1973) blames the current cult of blind computation and measurement, and the concurrent lack of a deep understanding of high energy physics, on the lack of an inspiring metaphysics.

(iv) *Metaphysics can render service by analyzing fashionable but obscure notions* such as those of system, hierarchy, structure, event, information, and possible world, as well as by criticizing popular misconceptions such as that the world is a collection of facts and the mind the control of the body.

(v) *Metaphysics can perform another public service by examining the ontological kernel of the current ideologies* and finding out whether they live up to the standards of contemporary intellectual work.

Briefly, ontology is far from useless: sometimes it fuels good work, at other times it is an obstacle to research, and at all times it is there, in the very midst of our speculations about the world.

10. Concluding remarks

By way of summary:

(i) Ontology can be exact or inexact, according as it uses any formal tools or fails to employ them.

(ii) Exact (or mathematical) ontology may be meaty or hollow, according as it tackles or evades the great problems concerning the nature of reality.

(iii) Exact and meaty metaphysics may or may not be scientific, according as it is contiguous with science or alien to it.

(iv) Scientific ontology is a collection of general or cross-disciplinary frameworks and theories, with a factual reference, mathematical in form and compatible with – as well as relevant to – the science of the day.

(v) There is no gap between good metaphysics and deep science: every scientific theory with a wide scope may be regarded as metaphysical, and every ontological theory that brings together and generalizes scientific results, or else occurs in the background of an axiomatized scientific theory, qualifies as scientific.

(vi) Science, both basic and applied, teems with metaphysical concepts and hypotheses: it presupposes certain ontological principles of both the heuristic and the constitutive kind, and it is a powerful source of metaphysical conjectures. In fact some theories are both metaphysical and scientific. Since there is no definite border line between the two fields, there is no demarcation problem left.

Enough of meta-metaphysical discourse. Let us build a new ontology.

CHAPTER 1

SUBSTANCE

One of Descartes' *regulae philosophandi* counsels us to start by simplifying, and one of our own maxims (Introduction, Sec. 4) enjoins us to hypothesize unobservables in order to account for appearances. A radical joint implementation of these two rules consists in stripping real things of all their properties – only for a start of course. What remains is the qualitatively indeterminate particular, the *bare individual.* Our bare individual will turn out to be similar to, though not identical with, Plato's formless matter and Aristotle's primary substance. Similar because neither has inherent properties (except possibly composition in our case), different because our bare individuals are endowed with the capacity of associating, i.e. of forming composite entities. Whereas each bare individual is nondescript, an aggregate of bare individuals has the definite property of being composed, i.e. of having parts. The association of bare individuals is then a beginning of complexity and thus a step towards realism.

Surely every real thing consists of some definite stuff endowed with definite properties: there are no bare individuals except in our imagination. This is a tacit assumption of factual science. In other words the Platonic concept of formless matter and the Aristotelian notion of unchanging substratum have been shelved by science. Still, although we no longer believe in the actual existence of nondescript things, we find it methodologically convenient to feign them – only to endow them with further properties later on, namely in Ch. 2. A fully qualitied individual, if substantial or concrete, will be called a *thing* in Ch. 3. And a complex thing with coupled components will be termed a *system* in Ch. 5. This is how we shall tackle the basic problem of traditional metaphysics, i.e. that of substance and attribute. First, then, we address ourselves to the concept of substance.

1. Association

1.1. *Concatenation and Its Ontological Interpretation*

Individuals can associate to form further individuals. When neither the kind of individual nor the manner of association are specified, we have the (bare) association of (bare) individuals. This notion of association can be formalized by the algebraic concept of concatenation, which is elucidated in the theory of semigroups. (Cf. Ljapin, 1963.)

A semigroup is a set S together with a binary, internal and associative operation $\circ$ of concatenation. The operation is said to be internal because it is defined in S, i.e. because S is closed under $\circ$. (I.e., concatenation does not give rise to individuals alien to S.) And concatenation is associative because it satisfies the law of associativity: if $x, y, z \in S$, then $x \circ (y \circ z) = (x \circ y) \circ z$. More succinctly: the structure $\langle S, \circ \rangle$, where S is a nonempty arbitrary set and $\circ$ a binary operation in S, is called a *semigroup* if and only if (i) S is closed under $\circ$, and (ii) $\circ$ is associative in S. The semigroup $\langle S, \circ \rangle$ is finite if S has a finite number of elements, infinite otherwise. A simple example of a finite semigroup is this: $S = \{0, 1, 2\}$ with the multiplication (concatenation) table

$\circ$	0	1	2
0	0	1	2
1	1	1	2
2	2	2	2

And a simple example of an infinite semigroup is the set $\mathbb{N}$ of positive integers with respect to addition. In other words the structure $\langle \mathbb{N}, + \rangle$ is a model of a semigroup. (For the semantic concept of a model see e.g. Vol. 2, Ch. 6, Sec. 2.)

If we interpret S as the totality of bare individuals and $\circ$ as their pairwise association, we obtain the simplest, most basic and most useful theory in scientific metaphysics: we call it *association theory*.

We shall do slightly better by adding the assumption that our semigroup, when written additively, contains the null element, and interpret the latter as the *null individual*. Roughly, the neutral element $\Box$ of S is that (fictitious) individual which, when coupled to an arbitrary member x of S, leaves x unaltered, i.e. $x \circ \Box = \Box \circ x = x$. Formally, $\Box$ is the two-sided zero of S. The new structure, $\langle S, \circ, \Box \rangle$, is called an (additive) semigroup with neutral element, or *monoid* for short. This structure is slightly richer than the corresponding semigroup, for it is more specific: now one of the elements of S, namely $\Box$, is no longer a faceless individual but is distinct from all the others – not by an intrinsic quality but by its inane behavior in company. Since $\Box$ is the nonentity or nonbeing, it is even more fictitious than any of the nondesignated elements of S. The introduction of $\square$ is justified by the fact that it will allow us to state that nothing starts from $\square$ or ends up in $\square$ – an important ontological principle indeed. (More on $\square$ in Sec. 3.1.)

1.2. *Axiomatic Foundation of Association Theory*

We postulate then that the set of individual things, when stripped of their properties and interactions – except for the property of composition – has the monoid structure. Moreover we assume that the association order makes no difference, i.e. that the concatenation $\circ$ is *commutative*: if $x, y \in S$, then $x \circ y = y \circ x$. We also assume that the association of an individual with itself leaves it unchanged, i.e. that the elements of S are *idempotent*: $x \circ x = x$. (On the other hand we do not postulate that the association operation has the cancellation property, i.e. that, for all a, b, x in S, the equality $a \circ x = b \circ x$ implies that $a = b$.) The previous assumptions entail that the result of the association of two individuals is non-null provided at least one of them is not null: for all x, y in S, if $x \neq \square$ or $y \neq \square$, then $x \circ y \neq \square$. (I.e., association does not result in annihilation.) We call this property *substance conservation*.

In sum, we assume that the set S of bare individuals is a commutative monoid of idempotents. And we assume that this structure carries over to all real things: that is, we postulate that the totality of concrete or substantial particulars, whether viewed as bare or as fully qualitied, has the monoid structure. (Caution: S is not the world, or reality, but the set of its elements. The world is one more individual, the supreme one, whereas a set is a concept. More on this in Sec. 3.1.) The preceding assumptions are compressed in the following compound

POSTULATE 1.1 Let S be a non-empty set, $\square$ a selected element of S, and $\circ$ a binary operation in S. Then the structure $\mathcal{S} = \langle S, \circ, \square \rangle$ satisfies the following conditions:
(i) $\mathcal{S}$ is a commutative monoid of idempotents;
(ii) S is the set of all substantial or concrete individuals;
(iii) the neutral element $\square$ is the null individual;
(iv) $\circ$ represents the association of individuals;
(v) the string $a_1 \circ a_2 \circ \ldots \circ a_n$, where $a_i \in S$ for $1 \leqslant i \leqslant n$, represents the individual composed of the individuals a_1 to a_n.

Remark 1 This axiom has a factual content insofar as it refers ultimately to real things and is far from being tautological. *Remark 2*

However, our postulate is hardly refutable. For, if any thing seemed to fail to satisfy our axiom, we would not say it associates. (More on this peculiarity of ontological theories in Bunge (1973a).) *Remark 3* The condition of commutativity is the only law statement involved in the above postulate. It can be rephrased thus: Association is a symmetric relation in the sense that "x associates with y" is equivalent to "y associates with x". *Remark 4* Since Postulate 1.1 states that entities can associate to form complex entities, it is inconsistent with Parmenides' block universe. *Remark 5* We have interpreted concatenation as association, whether natural or brought about by man. A narrower, operationist interpretation would view $\circ$ as the putting together of perceptible things by somebody. *Remark 6* It would be interesting to investigate even poorer structures, namely the nonassociative algebras such as groupoids (cf. Bruck, 1958). But we shall not take up this matter here. Likewise we shall not study the ontological applications of noncommutative semigroups.

Before introducing further assumptions we need some definitions. First

DEFINITION 1.1 An individual is *composite* iff it is composed of individuals other than itself and the null individual. I.e., $x \in S$ is composite iff there exist substantial individuals $y, z \in S$ such that $x = y \circ z$ and each differs from x as well as from $\square$. Otherwise the individual is *simple*.

Remark 1 According to the definition, the trivial composition $x \circ x = x$ does not count. *Remark 2* Note the difference between the composite entity $z = x \circ y$ and the set $\{x, y\}$ of its constituents or components. The latter is a concept and does not satisfy Postulate 1.1.

COROLLARY 1.1 The null individual is simple.

Proof $\square$ is simple because, for every non-null individual x, $x \circ \square \neq \square$ by Postulate 1.1 (ii).

Remark The null individual need not be the only simple one.

And now another key concept:

DEFINITION 1.2 If x and y are substantial individuals, then x is a *part* of y iff $x \circ y = y$. Symbol: $x \sqsubset y$.

Justification The relation $\sqsubset$ is a *partial order* relation, which is what the part-whole relation is supposed to be. In fact, from the previous definition and the properties of $\circ$ (Postulate 1.1) it follows that, for all x, $y, z \in S$,

(i) $\sqsubset$ is *reflexive*, i.e. $x \sqsubset x$;
(ii) $\sqsubset$ is *asymmetric*, i.e. if $x \neq y$ then: $x \sqsubset y \Rightarrow \neg(y \sqsubset x)$;
(iii) $\sqsubset$ is *transitive*: $x \sqsubset y \ \& \ y \sqsubset z \Rightarrow x \sqsubset z$.

Remark 1 The part-whole relation $\sqsubset$ must not be mistaken for the set inclusion relation $\subseteq$, much less for the set membership relation $\in$. Indeed whereas $\subset$ and $\in$ are relations among concepts of a certain kind (sets), $\sqsubset$ is a relation among substantial individuals. Besides, unlike $\sqsubset$, $\in$ is not transitive. (For example, if $A = \{x\}$ and $B = \{A\}$, then $x \in A$ and $A \in B$ but $x \notin B$.) *Remark* 2 We could have defined the converse $\sqsupset$ of $\sqsubset$. This is actually Whitehead's concept of "extension": x *extends over* y iff $x \circ y = x$ (Whitehead, 1919). But because here neither relation is construed in spatial terms, we might as well avoid geometric metaphors at this point. Indeed, an individual on our planet and another in a distant galaxy may be taken to associate to form a third individual, so that each component will be a part of the whole, just as much as the two components of a miscible fluid poured into a glass. *Remark 3* With the help of the previous definitions we can easily prove that

For any $x \in S: x$ is simple iff, for all $y \in S$, $y \sqsubset x \Rightarrow y = x$ or $y = \Box$.

Remark 4 The condition "For every $x \in S : x \circ \Box = \Box \circ x = x$", defining the null individual, can now be read as follows: The null individual is part of every individual. We proceed to introduce the dual of this concept:

POSTULATE 1.2 There exists an individual such that every other individual is part of it. I.e., $(\exists x)[x \in S \ \& \ (y)(y \in S \Rightarrow y \sqsubset x)]$.

DEFINITION 1.3 The universal individual introduced by Postulate 1.2 is called *the world* and is denoted by ▯.

Remark 1 Note again that the world, i.e. ▯, is an individual not to be confused with the set S of all individuals, which is a concept not a physical object. *Remark 2* The distinguishing algebraic property of ▯ is this: for every $x \in S$, $x \circ \text{▯} = \text{▯} \circ x = \text{▯}$. See Corollary 1.5.

DEFINITION 1.4 Let x denote an arbitrary object and ▯ the world. Then
(i) x is *worldly* iff $x \sqsubset \text{▯}$;
(ii) x is *unworldly* iff x is not worldly (i.e. if x does not satisfy Postulate 1.1 and a fortiori x is not a part of ▯).

Example The world is worldly but cosmology is not.

DEFINITION 1.5 Let x and y be substantial individuals. Then

(i) x and y are *detached* (*separate*) iff neither is part of the other:

$$x \rceil\!\lfloor y =_{df} \neg(x \sqsubset y) \,\&\, \neg(y \sqsubset x);$$

(ii) x and y *intersect* iff they are not detached:

$$x \bigcirc y =_{df} x \sqsubset y \vee y \sqsubset x.$$

The part-whole relation allows us to define yet another interesting concept that will be used throughout this work:

DEFINITION 1.6 The *composition* of an individual equals the set of its parts. I.e., let $\mathscr{C}: S \to 2^S$ be a function from individuals into sets of individuals, such that $\mathscr{C}(x) = \{y \in S \mid y \sqsubset x\}$ for any $x \in S$; then $\mathscr{C}(x)$ is called the *composition* of x.

Let us now derive a few consequences from our assumptions and definitions.

1.3. *Consequences*

First of all the trivial yet necessary

COROLLARY 1.2 The totality S of substantial individuals is partially ordered by the part-whole relation $\sqsubset$. I.e., $\langle S, \sqsubset\rangle$ is a poset.

Proof Immediate by recalling the justification of Definition 1.2.

THEOREM 1.1 The association of any two individuals is the supremum (least upper bound or l.u.b.) for them with respect to the part-whole ordering:

$$\text{If } x, y \in S \quad \text{then} \quad sup\{x, y\} = x \circ y.$$

Proof By associativity and idempotence $x \circ (x \circ y) = (x \circ x) \circ y = x \circ y$. By Definition 1.2 the last formula is the same as: $x \sqsubset (x \circ y)$. Likewise $y \circ (x \circ y) = x \circ y$, whence $y \sqsubset (x \circ y)$. Hence $x \circ y$ is an upper bound of x and y. It is also their least upper bound. In fact call z an upper bound of x and y, i.e. $x, y \sqsubset z$. Then $x \circ y \circ z = z$. Thus $x \circ y \sqsubset z$.

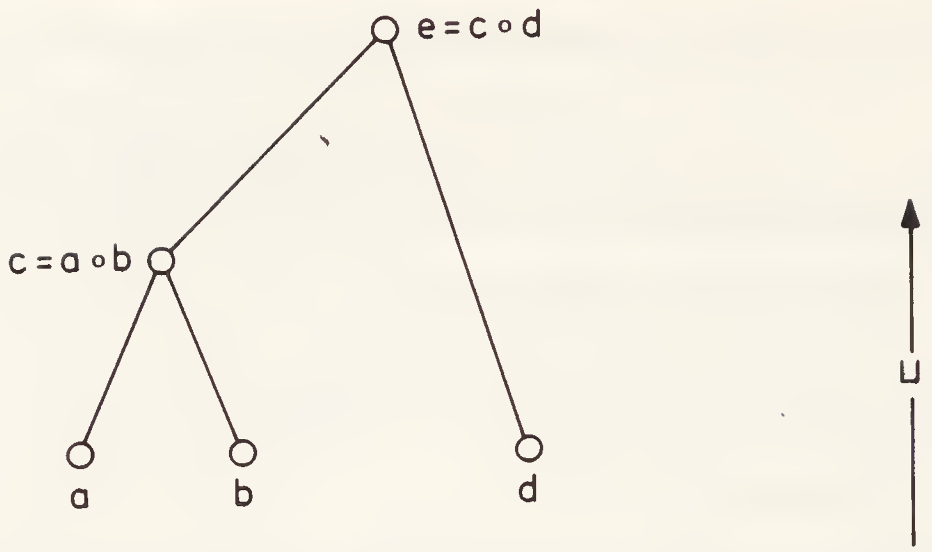


Fig. 1.1. All entities associate and they are ordered by the ⊏ relation.

The concept of supremum generalizes to arbitrary (in particular infinite) sets that of concatenation, which is defined only for pairs of individuals. We had postulated that, if x and y are substantial individuals, so is $x \circ y$ (Postulate 1.1). We now generalize that hypothesis to an arbitrary set of individuals: see Figure 1.1. That is, we assume

POSTULATE 1.3 Every set $T \subseteq S$ of substantial individuals has a supremum, which is denoted by $[T]$. I.e., for any $T \subseteq S$, there exists an individual $[T] \in S$ such that

(i) $x \sqsubset [T]$ for all $x \in T$;

(ii) if $y \in S$ is an upper bound of T, then $[T]$ precedes y: i.e., if $x \sqsubset y$ for all $x \in T$, then $sup\, T = [T] \sqsubset y$.

This axiom allows us to elucidate an important metaphysical notion:

DEFINITION 1.7 Let $T \subseteq S$ be a set of substantial individuals. Then the *aggregation* or *association* of T, or $[T]$ for short, is the supremum of T. I.e., $[T] = sup\, T$.

Remark 1 If T is a finite set then its aggregation $[T]$ is the association of all the members of T. I.e., if $T = \{x_1, x_2, \ldots, x_n\}$, then $[T] = sup\, T = x_1 \circ x_2 \circ \ldots \circ x_n$. In particular, the aggregation of a singleton is its sole occupant: if $T = \{x\}$, then $[T] = x$. *Remark 2* Because association is a finitary operation it is not possible to define the aggregation of an arbitrary (possibly infinite) set $T \subseteq S$ as the concatenation of all its members. This is why we had to employ the more general concept of *sup* or l.u.b. Let us now apply it to the entire collection of substantial individuals.

THEOREM 1.2 The world is the aggregation of all individuals:

$$\text{▯} = [S] = \mathit{sup}\, S.$$

Proof By Postulate 1.2, ▯ exists and is the last individual, i.e. for every $x \in S$, $x \sqsubset \text{▯}$. But this individual fits the conditions of Definition 1.7, i.e. $\text{▯} = \mathit{sup}\, S$.

The preceding material is compressed into

THEOREM 1.3 The ordered quadruple $\langle S, \circ, \square, \text{▯} \rangle$ is a sup-semilattice with least element □ and last element ▯ with respect to the part-whole relation $\sqsubset$.

Proof By Theorem 1.1 there exists a supremum for any two individuals, namely their association. Besides, □ is part of every individual, so it lies at the bottom of the net. Dually, ▯ contains every individual, so it perches on top. These conditions, together with the commutativity of association, define a sup-semilattice. See Figure 1.2.

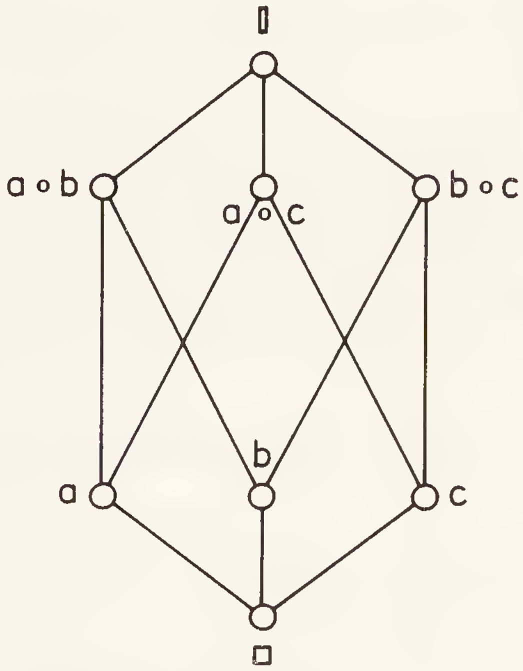

Fig. 1.2. Semilattice generated by $S = \{\square, a, b, c, \text{▯}\}$.

THEOREM 1.4 Every substantial individual is the aggregation of its parts, i.e. of its composition. I.e., for every $x \in S$,

$$x = [\mathscr{C}(x)] = \mathit{sup}\, \{y \in S \mid y \sqsubset x\}.$$

Proof Apply Definition 1.7 to $\mathscr{C}(x)$ characterized by Definition 1.6.

COROLLARY 1.3 Every individual with a finite composition is the association of its predecessors with respect to $\sqsubset$.

Example If $\mathscr{C}(c)=\{a, b\}$, then $c=a\circ b\circ c$, and $a, b\sqsubset c$.

Now two further consequences of Postulate 1.2. First

THEOREM 1.5 There is just one world.

Proof By Postulate 1.3 every $T\subseteq S$ has a supremum and by Theorem 1.2 $[S]=\Box$. And all suprema are unique. *Alternative proof* Suppose there were a world W different from $\Box$. Then since every substantial individual is part of $\Box$, so must be W. Hence W deserves being called a subworld rather than the world.

Remark Like many statements in this chapter, this one is mathematically trivial. However, it is philosophically nontrivial in view of the fashionable possible worlds metaphysics (Ch. 4, Sec. 6.2), the many-worlds (mis)interpretation of quantum mechanics (Ch. 4, Sec. 6.6), and Popper's three worlds.

COROLLARY 1.4 Whatever is unworldly is not a substantial individual.

Proof By Postulate 1.2, for every $x\in S$, $x\sqsubset\Box$. By contraposition, if $\neg(x\sqsubset\Box)$ then $\neg(x\in S)$.

Remark Classes, such as S, every one of its subsets, and its power set, are unworldly. So is any object constructed out of classes. So is any object that fails to satisfy the clauses of Postulate 1.1. Any object other than a substantial individual (or member of S) will be called a *construct*. I.e., nothing is both a construct and a substantial individual. More on this in Sec. 3.2.

Next we prove a bunch of conservation principles. First

THEOREM 1.6 If association ensues in the null individual then the associates were null to begin with:

$$\text{For all } x, y\in S,\ x\circ y=\Box\Rightarrow x=\Box\ \&\ y=\Box.$$

Proof Assume the antecedent, i.e. $x\circ y=\Box$. Now, $x=x\circ\Box=$ $=x\circ(x\circ y)=(x\circ x)\circ y=x\circ y=\Box$ by associativity, idempotence, and hypothesis. Similarly for y.

THEOREM 1.7 No substantial individual associates destructively with another: If $x\neq\Box$ then there is no $y\in S$ such that either $x\circ y=\Box$ or $y\circ x=\Box$.

Proof Assume $x \in S$ different from $\square$ and suppose there is in S an element y such that $x \circ y = \square$. Then, by Theorem 1.6 and modus tollens, $x = \square$, contrary to hypothesis.

Remark 1 In other words, except for $\square$, S has no inverses. Hence (*a*) S cannot possibly attain a group structure, and (*b*) the belief that there is an anti-thing for any given thing, such that they annihilate each other, is wrong. *Remark 2* It is sometimes said that, when particles of matter and antimatter join, they "annihilate" reciprocally. There is no such annihilation; there is rather the conversion of a pair of material entities (e.g. an electron and a positron) into a field chunk (e.g. a gamma ray photon).

COROLLARY 1.5 Provided it starts with something, association does not end up in nothingness:

$$\text{For all } x, y \in S, x \neq \square \;\&\; y \neq \square \Rightarrow x \circ y \neq \square.$$

Proof By Theorem 1.6 and contraposition.

COROLLARY 1.6 Nothing comes by association out of nought.

Proof This is the ontological interpretation of the implicit definition of the null individual, i.e. $x \circ \square = \square \circ x = x$.

COROLLARY 1.7 The world is not enlarged by associating it with any of its parts: For any $x \in S$, $x \circ \text{▯} = \text{▯} \circ x = \text{▯}$.

Proof By the definition of world.

Remark Corollaries 1.5 and 1.6 were first stated by Epicurus, then restated by Lucretius, in the form of postulates: "Matter is indestructible" and "Matter is uncreatable". (Cf. DeWitt, 1954; Lucretius 55 B.C.)

Another axiom of Greek atomism was that every thing is either basic (simple) or composed of basics (simples). We shall adopt this hypothesis that there are basic building blocks out of which every thing, from molecule to star, from cell to ecosystem, is composed, because it has been tremendously fruitful in modern science. That is, we lay down

POSTULATE 1.4 There is a proper subset B of S such that every substantial individual is the aggregation of members of B. I.e., for every $x \in S$ other than the null individual, there is a unique subset $B_x \subset B$ such that $x = [B_x]$.

Consequently instead of using the full aggregation function $[\ ]: 2^S \to S$, we need only its restriction to the power set of the simples or basics, i.e. the bijection $[\ ]|2^B: 2^B \overset{\sim}{\to} S$.

We shall make explicit use of Postulate 1.4 in our theory of space (Ch. 6). By the way, simples (basics) need not be spatially unextended. By Definition 1.1 a simple or basic individual is one that is not composed of any other individuals. For example, according to present day theories an electron is such a simple or basic because it is an indivisible whole even though both its electromagnetic field and its ψ-field are spatially extended. Another way of putting this is to say that electrons, though spatially extended, have no proper parts. In general,

$$\text{If} \quad x, y \in B \quad \text{and} \quad x \sqsubset y, \quad \text{then} \quad x = y.$$

So much for association theory. We shall generalize it in Sec. 2, but before that another two interesting notions have to be explored.

1.4. *Atom Aggregates*

A tacit assumption of association theory is that no two individuals are identical. In fact if a subset T of S consists of two identical individuals then, by the extensionality principle of set theory, T is a singleton. Association theory makes therefore no room for the possibility that some individuals come in multiple copies, as in the case of the letters of an alphabet, which can be duplicated *ad libitum*. Let us explore this alternative.

Assume there are simples and that every thing is either a simple or an association of simples – i.e. accept Postulate 1.4. And assume also that a single simple a may be found repeated any number of times, forming the composite entities $a \circ a$, $a \circ a \circ a$, etc. Two simples a and b will of course give rise to a greater variety: $a \circ a$, $a \circ a \circ a$, ..., $b \circ b$, $b \circ b \circ b$, ..., $a \circ b$, $a \circ a \circ b$, $a \circ a \circ b$, ..., $a \circ b \circ b$, $a \circ b \circ b \circ b$, ... Obviously even a few basic individuals, provided there are enough copies of them, will give rise to both numerosity and variety: this was a capital discovery of the ancient atomists, both Greek and Indian: *Multum ex parvo.*

To formalize the previous idea we start from a basic set A of distinct atoms or simples and give up the postulate of idempotency. Call then $A = \{a_i | i \in \mathbb{N}\}$ the set of basic elements or atoms and allow them to associate, as in $a_i \circ a_j$ and $a_j \circ a_i$, counting the association of two replicas of a given atom a_i, i.e. $a_i \circ a_i$, as a third individual distinct from a_i. Since an atom aggregate is not an atom itself, A is not closed under association. What is closed is the set A^* of all the concatenates. For example, a single atom generates infinitely many complexes. Indeed, if $A=\{a\}$, then $A^*=\{a^n | n \in \mathbb{N}\}$, where a^n abbreviates the concatenation of n identical copies of a. The set A^* is isomorphic to the set of natural numbers, so a universe formed of atoms of a single kind could still be infinitely complex. In general, if A is a non-empty set of atoms or basics, the collection A^* of concatenates of members of A is called the *free monoid generated by* A.

Example 1 The set of all conceivable chemical compounds is the free monoid generated by the set of chemical elements or atom species – just over 100. However, the set of compounds permitted by the laws of chemical binding is a finite subset of that free monoid. Thus the molecule HHHHHH, though thinkable, is not chemically possible. More on real possibility as distinct from conceptual possibility in Ch. 4.

Example 2 The minimal structure of a language with alphabet Σ is the free monoid generated by Σ: cf. Vol. 1, Definition 1.1.

We could assume, as a crude model of the world, that its furniture is a free monoid over some finite set S of simples. However, we know this to be an oversimplification: in the real world things do not come in strictly identical copies but, at most, in semi-copies. Moreover not all conceivable concatenations are really possible. However, certain subsets of S – elementary particles, atomic nuclei, atoms, molecules, cells, etc. – do come in *almost* identical copies. Hence for such things the free monoid over a finite set of atoms or simples is a sufficiently adequate (approximately true) model.

1.5. *Clustering*

The associations and dissociations of real things are brought about in specific ways – e.g. by motions or by forces –, hence their study pertains to the special sciences. However, certain features of such processes, such as the grouping of a collection of individuals into clusters, can be described a priori. So much so that this problem is the subject of a branch of pure mathematics, namely combinatorics (or combinatorial analysis). Let us take a glimpse at a couple of typical problems in combinatorics.

Problem 1 In how many ways can n individuals associate if association (concatenation) is not assumed to be commutative? That is, how many permutations of n objects (conceptual or physical) are possible? Answer: $n!$ (i.e. $1.2.3 \ldots n$). Example: the individuals a, b, c can associate thus: abc, bca, cab, bac, acb, cba.

Problem 2 Consider n objects grouped into clusters (or cells or blocks) of m individuals each (where $m \leqslant n$) without regard to order. How many such clusters are there? Answer: there are $n!/(n-m)!m!$ combinations of n individuals taken m at a time.

Problem 3 A set of n objects is partitioned into m clusters, with $m < n$. How many clusters will contain two or more individuals? Answer: at least one (Dirichlet's pigeonhole principle).

Problem 4 Consider a set of n objects. In how many ways can it be partitioned? For example, $S = \{a, b, c\}$ can be partitioned in the five following ways:

$$\{a\}, \{b\}, \{c\} \qquad \langle 3, 0, 0\rangle$$

$$\{a, b\}, \{c\}; \{b, c\}, \{a\}; \{a, c\}, \{b\} \qquad \langle 1, 1, 0\rangle$$

$$\{a, b, c\} \qquad \langle 0, 0, 1\rangle.$$

Every partition is characterized by its type $\langle m_1, m_2, \ldots, m_n\rangle$, where m_1 is the number of singles, m_2 that of couples, and so on. In every partition the number of blocks is $b = m_1 + m_2 + \ldots + m_n$, and $n = m_1 + 2m_2 + \ldots + nm_n$.

Like arithmetic, combinatorics is a theory of objects of any kind. It is therefore too general to pass for an ontological theory. (Recall the Introduction, Sec. 6.) But of course it can enter ontology, along with other mathematical theories, as an auxiliary.

1.6. *Historical Remark*

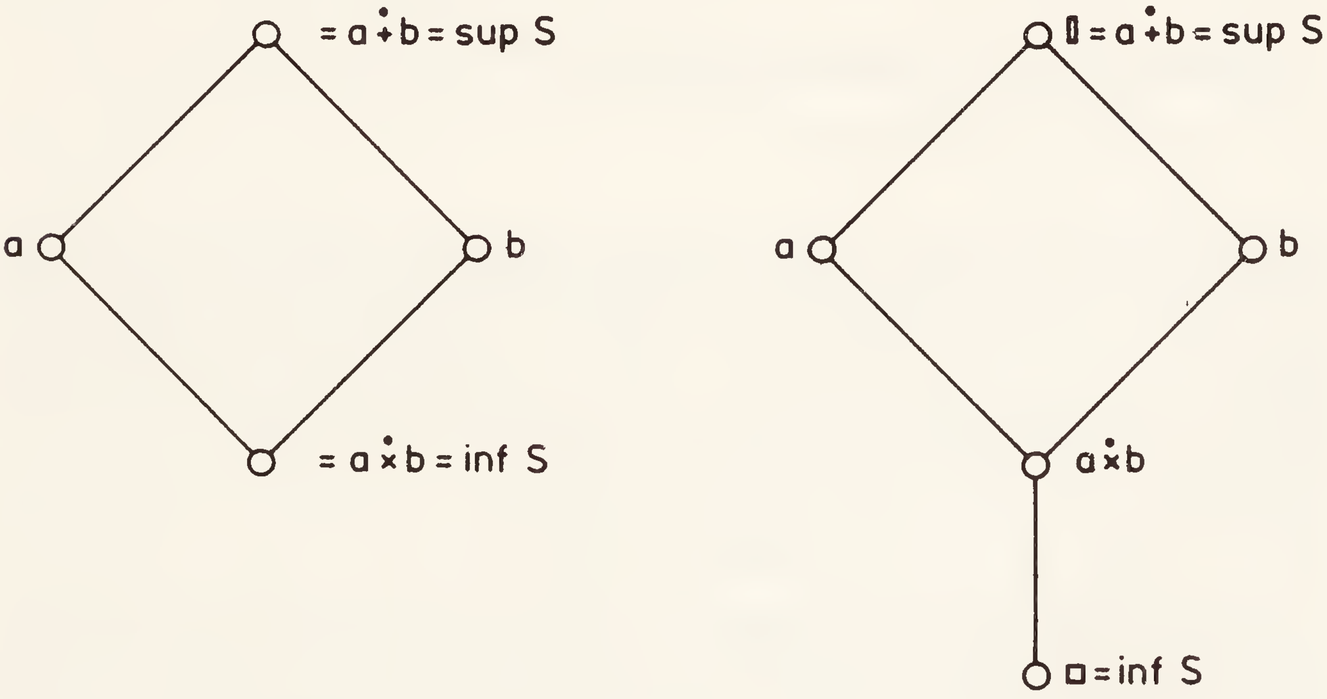
Our association theory bears a superficial resemblance to the ontology proposed by Lesniewski in 1916 (see Sobociński, 1954–55) and worked out in different directions by Tarski (1927), Leonard and Goodman (1940), Lejewski (1967), and a few others. The main differences are these: (a) our theory is much simpler than the others, if only because it adopts a standard mathematical formalism (namely semigroup theory) and does not eschew the language of set theory – which Lesniewski was careful to avoid; (b) whereas the Lesniewski theory (called *mereology*) and its offspring form the totality of contemporary nominalist ontology, our association theory constitutes only the foundation stone of a vast edifice containing items such as properties and kinds, which are anathema to the nominalist; (*c*) our association theory, and the assembly theory to follow, have been conceived not only as philosophical theories but also as theories utilizable in the foundations of science, as we shall explain in Sec. 4.

2. ASSEMBLY

2.1. *Juxtaposition and Superposition: Intuitive Idea*

The notion of association, elucidated in the previous section, is extremely general: there are many ways in which two substantial individuals can associate. We shall presently introduce two specific concepts of association: those of juxtaposition or physical sum, and of superposition or physical product. Two things placed side by side add or juxtapose, while two fluids, when mixed, superpose. We shall formalize these modes of association as so many binary operations in the set S of substantial individuals, designating juxtaposition by '$\dot{+}$' and superposition by '$\dot{\times}$'.

Example 1. Let the universe be cut into two mutually detached parts named a and b, i.e. ▯ $= a \dot{+} b$, with $a \dot{\times} b = \square$. The set $S = \{a, b, \square,$ ▯$\}$ is a complete lattice, since all the members of S can join pairwise in two ways without enlarging S: look at Figure 1.3(*a*).



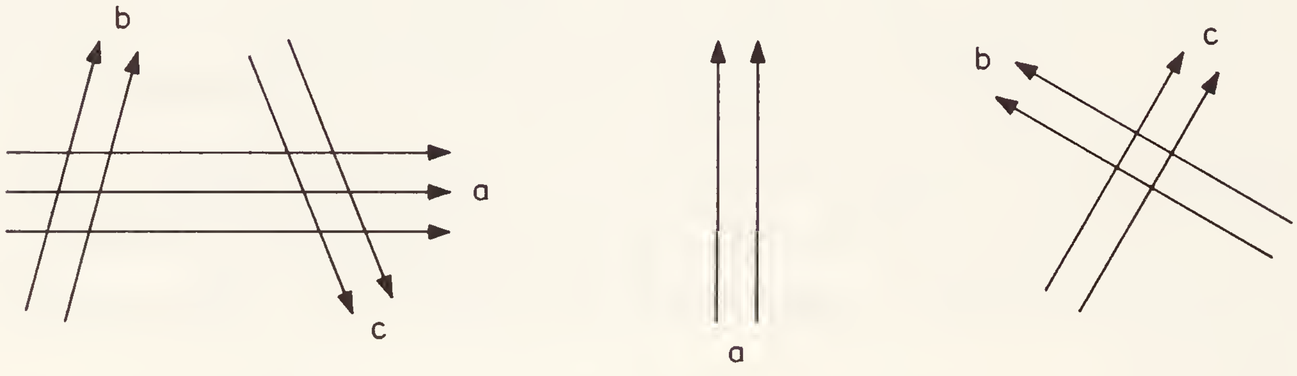
(a) (b)

Fig. 1.3. Two examples of juxtaposition and superposition.

Example 2 Let the universe consist of two superposed things, i.e. ▯ $= a \dot{+} b$, with $a \dot{\times} b \neq \square$. The set $S = \{a, b, a \dot{\times} b, \square,$ ▯$\}$, which includes the previous set, has the lattice structure too: look at Figure 1.3(*b*).

Example 3 Consider three individuals a, b, c, such that a superposes with both b and c. Suppose furthermore that the individuals are fields: look at Figure 1.4(*a*). It is seen that superposition distributes over juxtaposition.

Example 4 Juxtapose a field a and a field $b \dot{\times} c$. The result is that juxtaposition distributes over superposition. See Figure 1.4(*b*).



(a) (b)

Fig. 1.4. (*a*) The total entity is $a \dot{\times} (b \dot{+} c) = (a \dot{\times} b) \dot{+} (a \dot{\times} c)$. (*b*) The total entity is $a \dot{+} (b \dot{\times} c) = (a \dot{+} b) \dot{\times} (a \dot{+} c)$.

So much for the intuitive background.

2.2. *Formalization*

The examples discussed in the previous subsection suggest that we rope in the algebraic concept of a complemented distributive lattice. (Cf. Rutherford, 1965.) A lattice is a set S equipped with two binary associative operations, $\vee$ and $\wedge$, that are commutative and tied together by the so-called absorption laws

$$x \wedge (x \vee y) = x \vee (x \wedge y) = x.$$

A uniquely complemented lattice is a lattice with universal bounds $\square$ and ▯ and such that every element x of S has a single complement x' such that $x \vee x' =$ ▯ and $x \wedge x' = \square$. And a distributive lattice is one in which every operation distributes over the other. Finally a Boolean lattice is a lattice of idempotents which is both complemented and distributive.

More explicitly: the structure $\mathscr{L}=\langle S, \vee, \wedge, ', \square, ▯\rangle$ is a *Boolean lattice* iff, for all x, y and z in S, the following equalities hold:
Associativity $x \vee (y \vee z)=(x \vee y) \vee z, \quad x \wedge (y \wedge z)=(x \wedge y) \wedge z$
Commutativity $x \vee y=y \vee x, \quad x \wedge y=y \wedge x$
Absorption $x \vee (x \wedge y)=x, \quad x \wedge (x \vee y)=x$
Distributivity $x \vee (y \wedge z)=(x \vee y) \wedge (x \vee z), x \wedge (y \vee z)= =(x \wedge y) \vee (x \wedge z)$
Least element $x \vee \square=x, x \wedge \square=\square$
Last element $x \vee ▯=▯, x \wedge ▯=x$
Inverse $x \vee x'=▯, x \wedge x'=\square$.

Lattice theory together with the ontological interpretation we sketched in the previous subsection constitutes the ontological theory to be called *assembly theory*. The foundation of this theory is

POSTULATE 1.5 The structure $\mathscr{L}=\langle S, \dot{+}, \dot{\times}, ', \square, ▯\rangle$, where S is a non-empty set, $\square$ and $▯$ selected elements of S, $\dot{+}$ and $\dot{\times}$ binary operations in S, and $'$ a unary operation in S, is a uniquely complemented and distributive lattice of idempotents obeying the following additional conditions:

(i) S is the set of all substantial individuals;

(ii) $\square$ is the null individual and $▯$ represents the world;

(iii) for any individuals x and y, $x \dot{+} y$ represents the juxtaposition (physical addition) of x and y, whereas $x \dot{\times} y$ represents the superposition (physical product) of x and y;

(iv) the inverse (complement) of an individual x, i.e. the individual x' such that $x' \dot{+} x=▯$ and $x \dot{\times} x'=\square$, represents the environment or external world of x.

Remark 1 The unary operation (inversion or complementation) is defined for every individual entity. The world and the null individual are the inverses of one another. (The world, then, has no environment.) Needless to say, x' is not the opposite of x but just its complement to the world. *Remark 2* The two binary operations are defined for every pair of individuals. But whereas the juxtaposition of any two non-null entities is a third non-null individual, their superposition may be null – in which case they are detached, as we shall see in Definition 1.8. *Remark 3* At first sight superposition can result in annihilation, and wave interference would seem to illustrate this process. This is not so: two fields can superpose destructively over part of the region where they exist but not over the whole of it – otherwise there would be no conservation of energy and angular momentum. *Remark 4* When two or more individuals associate additively to form a whole they retain their identities. Consequently an aggregate, as treated by the present theory, is fully characterized by its composition. *Remark 5* By distinguishing two modes of association, i.e. juxtaposition and superposition, assembly theory allows us to perform a finer analysis of wholes than association theory did. Even so, $\dot{+}$ and $\dot{\times}$ are insufficient for scientific purposes, as things are endowed with a number of properties that determine their mode of coupling, which can be extremely complex. Just think of chemical and social bonds.

The preceding axiom will allow us to refine a few interesting notions.

2.3. *Definitions*

Since we now distinguish two modes of association we may expect roughly twice as many derived concepts as in association theory. Here are some.

DEFINITION 1.8 Let x and y be two distinct individuals. Then

(i) x and y are *detached* (or *separate*) iff their superposition is nought:

$$x \mathrel{\rceil\!\lfloor} y =_{df} x \dot{\times} y = \Box;$$

(ii) x and y *intersect* iff they are not detached:

$$\underset{\smile}{\overset{\frown}{x\ \ y}} =_{df} x \dot{\times} y \neq \Box.$$

Remark No spatiotemporal notions are involved in these definitions. On the contrary, the above notion of separateness will occur in the definitions of spatial concepts in Ch. 6.

DEFINITION 1.9 An individual $z \in S$, other than $\Box$,

(i) is *composed additively* of the individuals x and y iff $z = x \dot{+} y$;

(ii) is *composed multiplicatively* of the individuals x and y iff $z = x \dot{\times} y$.

Examples The contents of a room is composed additively of all the pieces of furniture in it. The gravitational field in a room is composed multiplicatively of the terrestrial field and the fields attached to the house.

DEFINITION 1.10 A substantial individual is *composite* (or *complex*) iff it is composed additively of individuals other than itself and the null individual. Otherwise it is *simple* (or atomic or basic).

DEFINITION 1.11 If x and y are substantial individuals, then x is a *part* of y iff x adds nothing to y:

$$x \sqsubset y =_{df} x \dot{+} y = y.$$

Justification The part-whole relation $\sqsubset$ has the desired properties: reflexivity, asymmetry, and transitivity. It is then a partial order relation. If a and b are additive components of c, they are also parts of c, i.e. they precede c in the order generated by $\sqsubset$. On the other hand if a and b are multiplicative components of c, they follow the individual $c = a \dot{\times} b$.

As in Sec. 1.2, we define the composition of a substantial individual as the collection of its parts: we just copy Definition 1.6. The complexity of an individual may be defined as the numerosity of its composition, i.e.

$$\text{For any } x \in S, \text{ the } \textit{complexity} \text{ of } x =_{df} |\mathscr{C}(x)|,$$

where $|S|$ stands for the cardinality of S. However, this is a coarse measure of ontic (nonconceptual) complexity, as it accounts only for the number of components or parts not for the manner of their coupling. But since we do not yet have the concept of coupling this is all we can do for the moment.

Concerning the complexity of the world we are faced with a choice among the following hypotheses:

H1 *Finitism*: The complexity of $\Box$ is finite.
H2 *Denumerable infinitism*: The complexity of $\Box$ = aleph zero.
H3 *Infinitism*: The complexity of $\Box$ = the power of the continuum.

However, we need not make any such choice at this point.

We now have two different concepts of aggregation:

DEFINITION 1.12 Let $T \subseteq S$ be a set of substantial individuals. Then

(i) the *additive assemblage* of T, or $[T]$ for short, is the supremum (l.u.b.) of T: $[T] = sup\, T$;

(ii) the *multiplicative assemblage* of T, or (T) for short, is the infimum (g.l.b.) of T: $(T) = inf\, T$.

Remark 1 Actually we have just introduced two different assemblage functions :[ ], ( ): $2^S \to S$, each of which takes a set of entities into an individual entity. By assuming Postulate 1.4 we need only the restrictions of these functions to the power set of the set of basics.

Remark 2 The two bounds, *sup T* and *inf T*, are of course defined with respect to the part-whole relation. They are such that, for all $x \in T$,

$x \sqsubset [T]$ and $(T) \sqsubset x$. Besides, if $x \sqsubset y$ for all $x \in T$, then $[T] \sqsubset y$. And, if $y \sqsubset x$ for all $x \in T$, then $y \sqsubset (T)$. *Remark 3* If $T \subset S$ is a finite set of substantial individuals then its additive aggregation is the juxtaposition of its members, whereas its multiplicative assemblage is their superposition. I.e., if $T = \{x_1, x_2, \ldots, x_n\}$, then

$$[T] = x_1 \dotplus x_2 \dotplus \ldots \dotplus x_n, \quad \text{and} \quad (T) = x_1 \dot{\times} x_2 \dot{\times} \ldots \dot{\times} x_n.$$

Remark 4 If T happens to contain a pair of detached entities, then its multiplicative aggregation is null, i.e. $(T) = \Box$. This holds, in particular, for any set of individuals containing the complement of one of them.

Finally we introduce a notion of decomposability. The intuitive idea is this. Let z be a substantial individual composed, no matter how, of two or more individuals. The composite individual will be said to be decomposable into x and y if these are different individuals such that $z = x \dotplus y$ and $x \rceil y$. The components x and y need not be those that make up the original whole z before disintegrating into the separate entities x and y. Nor need they coexist with z: they may emerge in the act of decomposition. The exact and general notion of decomposability is this:

DEFINITION 1.13 Let x be a substantial individual. Then x is *decomposable* iff there is a set $T \subset S$ such that $[T] = x$ and $(T) = \Box$.

Remark From an operationist point of view only effective decomposition counts as an indicator of structure: if no way is known of actually splitting an entity then the latter is declared simple. Counterexample: current particle theory assigns the neutron a structure, hence a composition, but so far the neutron has withstood all efforts at decomposing it. Only the converse of the operationist thesis holds, namely: Anything effectively decomposable has a structure.

DEFINITION 1.14 A substantial individual is *uniquely decomposable* iff it is decomposable in but one way – i.e. if there is a single set $T \subset S$ such that $[T]$ equals the individual concerned and $(T) = \Box$.

Remark Here again unique decomposability is not to be mistaken for the single known way of effectively decomposing a thing. For example, so far the deuteron has been decomposed only into a neutron and a proton; but this does not exclude the possibility of decomposing it into a different set of products.

2.4. *Some Consequences*

We can retrieve a number of results obtained in association theory, since $\dotplus$ and $\circ$ are practically the same. In addition we can obtain a number of new theorems. But we shall exhibit only a few. Firstly

THEOREM 1.7 Every substantial individual is the additive aggregation of its parts. I.e., for every $x \in S$,

$$x = [\mathscr{C}(x)] = sup\{y \in S \mid y \sqsubset x\}.$$

COROLLARY 1.8 Every substantial individual with a finite composition is the juxtaposition of its parts. I.e., for any $x \in S$,

$$\text{If } \mathscr{C}(x) = T \equiv \{x_1, x_2, \ldots, x_n\} \quad \text{then}$$

$$x = [T] = x_1 \dotplus x_2 \dotplus \ldots \dotplus x_n.$$

COROLLARY 1.9 The world is the additive assemblage of all substantial individuals: $\Box = [S] = sup\, S$.

THEOREM 1.8 Every entity is part of some substantial individual: If $x \in S$ then there is at least one $y \in S$ such that $x \sqsubset y$.

Proof Take an arbitrary pair $a, b \in S$ and form the third individual $c = a \dotplus b$. This individual exists and is unique since, by hypothesis (Postulate 1.5), S forms a lattice. And, by definition of the part-whole relation, $a, b \sqsubset a \dotplus b$.

COROLLARY 1.10 Every entity is composite either properly or improperly. I.e., for every $x \in S$, $(\exists y)(y \in S \;\&\; y \sqsubset x)$.

Proof Follows from Theorem 1.8.

Remark 1 That an individual is improperly (or trivially) composite means of course that it consists just of itself. The assumption that every individual we might stumble upon might prove to be properly composite, is a powerful heuristic assumption that must not be confused with the preceding corollary. *Remark 2* Nor should the previous result be mistaken for the statement that S has a least element other than the null element and that would be part of every other individual.

We shall now use the notions of decomposability (Definition 1.13) and unique decomposability (Definition 1.14) to obtain a couple of interesting results.

THEOREM 1.9 All substantial individuals are decomposable. Decomposition includes the trivial decomposition of an individual into itself and the null entity $\square$.

Proof Let y be a part of $x \in S$ and take the environment y' of y: $y \dotplus y' = \square$ and $y' \dot{\times} y = \square$. Call $z = y' \dot{\times} x$ the superposition of y' with x. This is what completes y to form x: $y \dotplus z = x$, with $y \dot{\times} z = \square$. We have effected the decomposition of an arbitrary entity x into y and z.

THEOREM 1.10 No composite individual is uniquely decomposable. Equivalently: For all $x \in S$ other than $\square$, x is uniquely decomposable iff x is simple (i.e. decomposable only trivially: $x = x \dotplus \square$).

Proof (i) The *only if* part: let $y \sqsubset x$. Then $x = y \dotplus (y' \dot{\times} x)$ is a decomposition. In order to be unique, this must be $x = x \dotplus \square$ or $x = \square \dotplus x$. Thus either $y = x$ or $y = \square$. (ii) The *if* part: if $x = y \dotplus z$ and x is simple, then $y = \square$ or $y = x$ and also $z = \square$ or $z = x$. There are two possibilities: if $y = \square$ then $z = x$ and we have the decomposition $x = \square \dotplus x$. And if $y = x$ and also $z = x$ then $y \dot{\times} z = x \neq \square$. But this is a contradiction, so we must have $z = \square$ and thus the decomposition $x = x \dotplus \square$.

Now the conservation law or Epicurus'

THEOREM 1.11 If $x, y \in S$ are not the null individual, then

(i) their juxtaposition does not end up in nought: $x \dotplus y \neq \square$;

(ii) provided they are not detached their superposition does not ensue in nought either: $x \dot{\times} y \neq \square$;

(iii) no being comes out of nonbeing either by juxtaposition or by superposition: $[\square] = \square$ and $(\square) = \square$.

Finally a couple of theorems concerning separation or detachment (Definition 1.8).

THEOREM 1.12 Separation is hereditary, i.e. the parts of detached entities are detached. That is, for any substantial individuals x and y,

$$x \lfloor y \,\&\, u \sqsubset x \,\&\, v \sqsubset y \Rightarrow u \lfloor v.$$

Proof By definition of detachment and of part,

$$x \dot{\times} y = (x \dotplus u) \dot{\times} (y \dotplus v) = \square.$$

Performing the indicated operations and recalling the distributivity of $\dotplus$ over $\dot{\times}$,

$$x \dot{\times} y = (x \dot{\times} y) \dotplus (x \dot{\times} v) \dotplus (u \dot{\times} y) \dotplus (u \dot{\times} v) = \square.$$

By Theorem 1.11 every addend must be null. In particular, $u \dot{\times} v = \Box$, which amounts to $u \lfloor v$.

Remark This theorem shows that our detachment relation $\lfloor$ for entities is analogous to the separation relation for sets (Wallace, 1941).

THEOREM 1.13 Detachment is additive. I.e., if two substantial individuals are detached from a third so is their juxtaposition: for any three entities $x, y, z \in S$,

$$x \lfloor z \;\&\; y \lfloor z \Rightarrow (x \dotplus y) \lfloor z.$$

Proof Suppose the consequent is false. This assumption is equivalent to $(x \dotplus y) \dot{\times} z \neq \Box$, which expands into $(x \dot{\times} z) \dotplus (y \dot{\times} z) \neq \Box$. In turn the last statement amounts to $x \dot{\times} z \neq \Box \vee y \dot{\times} z \neq \Box$. But the first disjunct amounts to $\neg(x \lfloor z)$ and the second to $\neg(y \lfloor z)$, contrary to hypothesis. So, the consequent is true.

Remark In the theory of the Wallace separation spaces (Wallace 1941) additivity is postulated not demonstrated.

2.5. *Atoms and Levels*

The general notion of composition (Definition 1.6) has got to be supplemented with another, more specific notion, which will prove to be more useful than the former, namely that of composition relative to a certain set or level of entities. Thus in the case of an animal society regarded as a whole, we are interested in the set of its components not in the full set of its parts, such as the cells of the animals, even less the atomic components of their cells. That is, we want to know what the "relative" atoms of the whole are. The idea we want is this:

DEFINITION 1.15 Let $A \subset S$ be a set of entities. Then the *A-composition* (or *composition at the A level*) of a substantial individual $x \in S$ is the set of parts of x belonging to A:

$$\mathscr{C}_A(x) = \mathscr{C}(x) \cap A = \{y \in A \mid y \sqsubset x\}.$$

Example The molecular composition of a body of water is the set of its H_2O molecules. On the other hand the atomic composition of the same body is the set of H and O atoms that compose it.

We shall make ample use of this notion in Vol. 4, Ch. 7 on systems, where the composition of a system will be taken to be a certain

A-composition. We shall want the composition of a system to equal the union of the compositions of its subsystems. However, in general the composition of a complex individual is not equal to the union of the compositions of its components: see Figure 1.5. On the other hand the

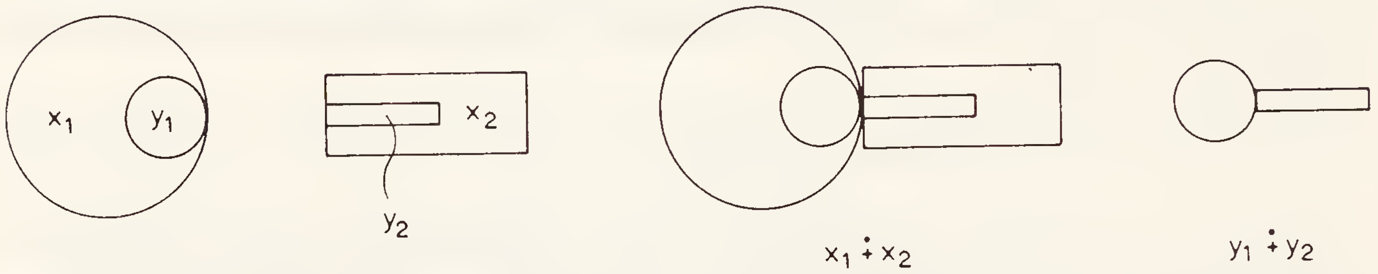


Fig. 1.5. The composite individual $x_1 \dotplus x_2$ has a part, namely $y_1 \dotplus y_2$, which is neither a part of x_1 nor a part of x_2. In general $\mathscr{C}(x_1) \cup \mathscr{C}(x_2)$ is a proper part of $\mathscr{C}(x_1 \dotplus x_2)$. Not so with the A-composition of a compound individual: see Theorem 1.14.

A-composition does have the desired property and this is one reason for preferring it over the general notion of composition. Indeed, we have

THEOREM 1.14 Let $A \subset S$ be a set of substantial individuals (level A atoms), and $x_1, x_2 \in S$ two substantial individuals. Then

$$\mathscr{C}_A(x_1 \dotplus x_2) = \mathscr{C}_A(x_1) \cup \mathscr{C}_A(x_2).$$

Proof If $x \in \mathscr{C}_A(x_1)$ then x is an A-atom (a member of A) and therefore $x \sqsubset x_1 \sqsubset x_1 \dotplus x_2$. Therefore $x \in \mathscr{C}_A(x_1 \dotplus x_2)$. Similarly $x \in \mathscr{C}_A(x_2) \Rightarrow x \in \mathscr{C}_A(x_1 \dotplus x_2)$. Thus $\mathscr{C}_A(x_1) \cup \mathscr{C}_A(x_2) \subseteq \mathscr{C}_A(x_1 \dotplus x_2)$. Now the converse implication. If $x \in \mathscr{C}_A(x_1 \dotplus x_2)$ then $x \sqsubset x_1 \dotplus x_2$, which is equivalent to $x \dot{\times} (x_1 \dotplus x_2) = x$. By distributivity it follows that $x \dot{\times} x_1 \dotplus x \dot{\times} x_2 = x$. But x is an A-atom and therefore we must have $x \dot{\times} x_1 = x$ or $x \dot{\times} x_2 = x$, i.e. $x \sqsubset x_1$ or $x \sqsubset x_2$. We have just shown that $\mathscr{C}_A(x_1 \dotplus x_2) \subseteq \mathscr{C}_A(x_1) \cup \mathscr{C}_A(x_2)$. This, conjoined with the previous result, yields the desired proof.

The entities of kind A, or A-atoms, may be simple (i.e. members of the set B of basics) or complex. To qualify as a member of a given set A, an entity must be able to associate with similar entities to form complex entities of a different kind. But we do not have yet the notion of a natural kind, which will be introduced in Ch. 4, Sec. 3.3. Therefore for the time being we shall have to make do with a presystematic or intuitive notion of an A-atom. The same holds *a fortiori* for the notion of a level. All we can say at this time is that we may split the totality S of entities into a certain number n of disjoint sets A_i, each member of which is composed – additively or multiplicatively – by entities of the next lower level A_{i-1}. The levels hypothesis may then be formulated as follows:

$$S = \bigcup_{i=1}^{n} A_i, \quad \bigcap_{i=1}^{n} A_i = \varnothing, \text{ with } A_i = \{a_i^n \mid n \in \mathbb{N}\}$$

and

$$a_i^n = [\alpha_{i-1}^n] \quad \text{or} \quad (\alpha_{i-1}^n), \quad \text{where } \alpha_{i-1}^n \subseteq A_{i-1}.$$

The matter of (relative) atoms and levels of organization will be taken up again in Vol. 4, Ch. 8.

2.6. *Alternative Formalizations*

Alternative formalizations of the notions of juxtaposition and superposition have been explored. One of them is in terms of ring theory, i.e. it consists in assuming that $\langle S, \dot{+}, \dot{\times}, \square, \text{▯}\rangle$ constitutes a ring of idempotents (Bunge, 1971a, 1973a). In this construal one must abstain from interpreting the unit element of the ring as the world, for in this case the unit is not the last element. This is not a fatal flaw: the defect consists in leaving one primitive devoid of ontological interpretation. What may constitute a defect is that in ring theory $\dot{\times}$ distributes over $\dot{+}$ but not conversely. As a compensation the absorption laws, which seem idle in the ontological interpretation of lattice theory, do not occur in ring theory.

A second alternative formalization consists in a certain interpretation of Boolean algebra (Bunge, 1967b). The two formalizations, though different, are equivalent. In fact by a famous theorem of Stone's, a commutative Boolean ring $\langle S, +, \cdot, 0, 1\rangle$ determines a Boolean algebra $\langle S, \cup, \cap, 0, 1\rangle$ with meets and joins defined as follows:

$$x \cup y = x + y + x \cdot y, \qquad x \cap y = x \cdot y.$$

We may adopt either of these alternative formalizations in the case where the reference class is a proper subset of the total set S of substantial individuals. In this case the unit will not be interpreted as the world. The ring theoretic construal may be preferred when this condition is fulfilled and superposition is not required to be commutative, as is often the case with two parts of a machine.

Needless to say a third alternative, having none of the defects of the preceding ones, should be welcome. The same applies to every one of our ontological theories: different formalizations of the same intuitions, as well as alternative intuitions, should be explored.

2.7. *Concluding Remarks*

Our two theories of substance – namely association theory and assembly theory – systematize the intuitive ideas of a physical object and of the association of concrete individuals. We have not called any of our theories *mereology* – as we should if we had followed in Lesniewski's path – because they achieve more than an elucidation of the part-whole relation. If we were interested just in the latter concept we could adopt a simpler theory, namely that of partially ordered sets. Indeed, assuming that the structure $\langle S, \sqsubset \rangle$ is a poset and adding the obvious interpretations of S and $\sqsubset$, we would get an exact characterization of the notion of a part. And the latter would in turn allow us to define a few other concepts, notably those of detachment and composition. However, such a theory would be too poor: for one thing it would not clarify any notion of association – and this is what our theories of substance are all about.

Nor have we called our theories *calculi of individuals* – as Leonard and Goodman (1940) called their version of Lesniewski's mereology. One reason is that every first order mathematical theory is a calculus of individuals: whether it is a calculus of physical individuals is another matter. Another reason is that, unlike Lesniewski and his fellow nominalists, we draw a radical distinction between physical and conceptual individuals and reject the thesis that a single theory should be able to account for both kinds of individual. In particular our part-whole relation applies only to ontic individuals, i.e. $\sqsubset$ is defined on $S \times S$. More on this matter in the next section.

3. ENTITIES AND SETS

3.1. *The Null Individual and the World*

Both association theory and assembly theory involve the greatest fiction (□) as well as the greatest reality (▯). The null individual has been considered by Carnap (1947), Martin (1965) and a few others. It has usually been characterized by analogy with the empty set, namely as "that thing which is a part of every thing". This characterization is not quite correct. Firstly $\square$ is not a thing but a concept. Secondly the characterization is deficient: the null body is also the null non-body. (Besides, according to the aether theories, the aether, though not null, was supposed to be part of every thing.)

The null individual, or nonbeing, is best characterized in terms of either association or assembly, i.e. either as (i) that which, associated with any substantial individual, yields the latter, or as (ii) that which, juxtaposed to any thing leaves it unchanged and, superposed to it, annuls it. In either case $\square$ is in S and is part of every member of S. (The claim that $\square$ belongs to every set, even the empty set, leads to contradiction.) All these are definite properties of $\square$. That is, according to the theories formulated in the previous sections, it is false to say that the null individual has no properties – as false as to say that it has substantial (physical, nonconceptual) properties. Which reminds one of Lucy's verdict: "For a nothing, Charlie Brown, you're really something" (Schulz, 1967).

What is true is that the null individual simply does not exist physically: it is a fiction introduced to get a smooth theory. We need this pretence not only in ontology but also in the foundations of science – which is not surprising because the two intersect. Thus the vacuum, i.e. the null field, is assigned a number of properties in field theories – such as a refractive power equal to unity. Moreover it is convenient to introduce several null individuals, one for every natural class. For example, in optics we need the void, or null body b_0, and darkness, or the null light field l_0. The reference class of a statement about a light beam l in vacuum is $\{l, b_0\}$, while a statement about a body b in darkness is about $\{l_0, b\}$, and one about the dark void concerns $\{b_0, l_0\}$ (Bunge, 1966).

We need the null entity to think about real entities but we cannot use it to build the latter. Indeed, unlike the empty set in von Neumann's reconstruction of number theory, the null individual is not the point of departure of our cosmology but only a very modest component of it, which discharges a theoretical function but has no counterpart in reality. In other words, entities are not constructible out of the nonentity. This is in sharp contrast with the central role Hegel (1812, 1816), Peirce (1892–93, 6.217) and Heidegger (1927) have assigned nonbeing. (Incidentally none of them seems to have distinguished the nonentity, or nonbeing, i.e. $\square$, from nothingness or the empty set $\varnothing$. Yet $\square$ and $\varnothing$ are radically different, i.e. they have different properties even though none of them is substantial or real.) Far from taking nonbeing as our point of departure, our theories of substance involve the theses of Epicurus (*apud* DeWitt 1955) and Lucretius (55 B.C.?) (*a*) that no thing emerges *ex nihilo* and (*b*) that no thing goes over into nought (Theorem 1.11). Our point of departure is the real world as known to the science of the day: wishing to understand the world we dismantle it in thought and oversimplify its ingredients as well as the manner in which they are actually assembled. We thus obtain a concept of substance, or matter, which, when enriched with properties, will ensue in the concept of a concrete thing (Ch. 3).

3.2. *Entities and Concepts*

While the null individual, a concept, *is* (identical with) □, the world (or reality) is said to be *denoted by* the symbol '▯'. In our theories of substance the world is an individual but not just one more individual: it is the entity that contains as components all other entities. But this is as far as our theories of substance go: they give no details about the structure of ▯. On the other hand they do assign definite structures (semilattice in one case, lattice in the other) to the furniture of the world, i.e. S.

We emphasize that S, the set of all entities, is not the same as the aggregate or whole $[S]$ composed of all physical objects. The difference between the concept S and the entity denoted by $[S] = ▯$ illustrates the construct/thing dichotomy. To us the basic dichotomy in any set of objects is not that between individuals and sets but that between physical objects and conceptual ones. That is, we assume that every class O of objects is split into a class C of constructs and a class $T \subseteq S$ of substantial individuals:

$$O = C \cup T, \quad \text{with} \quad C \cap T = \varnothing.$$

Sets, relations and functions, as well as algebraic and topological structures, rank as constructs in our philosophy and, as such, they do not satisfy any theory of substance.

Whether an object is an individual or a set is of interest to ontology: if the former then it may be either physical or conceptual, if a set it can only be a concept. But whether a *conceptual* object (a construct) is an individual or a set is metaphysically and even mathematically relatively unimportant. This is for the following reasons. First, what is a (conceptual) individual in one theoretical context may become a set in another and conversely: it all depends on the fineness of our analysis. Second, some set theories draw hardly any distinction between sets and individuals. Nevertheless there is one assumption (von Neumann's D axiom) that does draw the line between the two categories by stipulating that every chain of the form ... $x \in y \in z$ has a stop. (For every nonempty set there is a member none of whose members is a member of the given set. Such a member may be regarded as an individual with respect to the given set. For example, in $A = \{\{a\}\}$ the element a is such an individual, the ascending chain being $a \in \{a\} \in A$.) Even if this axiom is not accepted, the individual/set distinction is kept in everyday mathematics. We shall keep it.

We are now in a position to clarify the difference between our ontology and Platonism with regard to individuals. (The difference with respect to properties will be discussed in Ch. 2, Sec. 5.) Suppose we agree to consider, or rather toy with, a universe composed of a finite number of atoms, or simple individuals. We start by inquiring whether these individuals are conceptual or concrete. (On the other hand Goodman, 1956, p. 16 regards this distinction to be "vague and capricious".) If they are conceptual then we let the Platonist take over, for that is his field, though where he believes in the autonomous existence of such ideas we just pretend that to be so for the sake of expediency. He should feel free to build not just the power set of the given set but also any powers of that power set if he needs them. On the other hand if the individuals are concrete then we give the Platonist a push and do our own reckoning. The upshot is this: in addition to the original atoms we get all their partial (binary, ternary, etc.) associations. And on top of these we shall have all the novel things that may ensue from such combinations, since we know from high energy physics that a couple of elementary particles may collide to produce a large number of new individuals. Thus we come up with a universe that, in numerosity, is infinitely smaller than the Platonic universe though appreciably larger than the universe of unchangeable and unreactive atoms envisaged by mechanism.

3.3. *Existence and Individuation*

Russell taught us that the existential quantifier ∃ cannot occur by itself but must be applied to "something described" such as Ax, where A is a unary predicate. Hence at first sight it would seem that our substantial individuals do not exist, for they have no peculiarities. However, they do share the definite property of associating with one another. That is, every member of $\langle S, \circ, \square \rangle$ is characterized by the predicate A defined by

$$Ax =_{df} (\exists y)(\exists z)(y \in S \;\&\; z \in S \;\&\; x = y \circ z \vee y = x \circ z \vee z = x \circ y).$$

Hence we may prefix (x) to this propositional schema, obtaining the proposition "All individuals associate".

Moreover we can individuate those entities with a known composition. That is, we can form definite descriptions of the form

"The member x of S with composition $\mathscr{C}(x)$".

In traditional terms: our *principium individuationis*, at this early stage, is composition. Obviously this principle fails us for simples since, with the exception of $\square$, they are devoid of peculiarities other than that they can associate. (Therefore we cannot use Quine's method of treating all singular terms as definite descriptions: Quine (1950, Sec. 37). In order to use this method we must have stock of predicates large enough to uniquely characterize every individual, and this will have to wait till next chapter.) Besides, the above principle does not even allow us to distinguish between two molecules with the same composition. But this is only a temporary difficulty, as a much finer *principium individuationis* will be adopted in Ch. 2, Sec. 3.2.

Finally a word or two about substantial existence as distinct from existence in general. The existence of simple individuals can be ascertained only by scanning the entire set S. If a belongs to S and is not the null individual we say that a exists. That is, we explicate "a exists" as "$a \neq \square \;\&\; a \in S$". This concept of existence can be called *bare substantial existence.* It suffices in the theory of substance, where the only individuating property is composition. (More on physical existence in Ch. 3, Sec. 4.4.) Note that this is a notion of ontic or physical existence to be distinguished from that of conceptual existence. In formal science to say that an individual a exists it suffices to assume or to prove that a belongs to some set that has been satisfactorily characterized. In ontology we have no use for arbitrary sets except perhaps as auxiliaries devoid of ontological import: here to exist (substantially, physically) is to have a number of substantial properties, among them that of associating with other nonconceptual objects. So, *pace* Wittgenstein (1969, Sec. 35), it makes perfectly good sense to state that there are substantial (physical) objects. Moreover ontology happens to be concerned precisely with such objects. (Recall Introduction, Sec. 2.)

4. CONCLUDING REMARKS

One of the necessary conditions for an ontological theory to qualify as scientific is its relevance to science. (Cf. Introduction.) Association theory and assembly theory comply with this condition: they are relevant to any scientific or technological theory concerned with complex systems such as atoms, cells, machines, brains, or organizations. In particular any such theory employs a concept of association and therefore should welcome an elucidation of the latter. However, in the vast majority of scientific writings only an intuitive concept of association is employed. It is only when the foundations of a scientific theory are carefully laid down that $\circ$, $\dot{+}$ or $\dot{\times}$ are apt to occur explicitly, because they are needed. For example, the very statement of the hypothesis that the electric charge Q is additive involves $\dot{+}$:

If x and y are bodies, and $x \neq y$,
then $Q(x \dot{+} y) = Q(x) + Q(y)$.

Similarly with the intensity E of the superposition of two electric fields:

If x and y are fields, and $x \neq y$,
then $E(x \dot{\times} y) = E(x) + E(y)$.

If only for this reason, i.e. because it is needed, it is mandatory to include some version of assembly theory among the ontological presuppositions of any scientific theory referring to complex systems (Bunge, 1967b, 1973b, 1974d).

Although the scientific method is analytic, from time to time the scientific community is swept by holistic winds – particularly when science fails to disclose the actual composition and inner workings of certain things. At such times the black box theories come in vogue and the mechanistic approach is decried or at least shelved. A characteristic of the black box approach is that it makes little or no use of the very concept of composition: it treats every component of a system, and occasionally even the whole system, as a structureless box. No doubt this strategy is wise as long as little is known, or need be known, about the components and their mode of association. But to advertise this *pis aller* strategy as optimal (as e.g. Chew, 1966, does) is suicidal. Indeed, it amounts to obliterating the difference between simple and composite, hence between microphysical and macrophysical, and it renounces the ideal of the most complete possible account of things. Worse: the strategy ignores whatever complexity has already been disclosed. Far worse: such a drastic reduction in our cognitive goals cannot be implemented in microphysics except by borrowing from translucid box theories such as field theory and ordinary quantum mechanics (Bunge, 1964; Regge, 1967). In short, the idea of composition, and the goal of finding out the precise composition and manner of association, are not "out": at most some grapes are still sour.

So much for the concept of substance or matter. Let us now tackle the problem of characterizing the concept of a property.

CHAPTER 2

FORM

The next step in our conceptual reconstruction of the notion of a real thing is to introduce the concept of a property, trait, or character. Every real thing has a number of properties: there is no formless substance except as a useful fiction. Nor are there pure forms hovering above matter. Every concrete or substantial property, such as moving, reacting, or remembering, is the property of some thing or other – bodies, reactants, brains, or what have you. Were this not so, science would not seek to find and interrelate properties of things, much less the patterns of the associations and changes of properties – i.e. the laws.

We cannot take the notion of a property for granted because it is far from clear. In any event no discipline other than ontology attempts to clarify the notion of a property as distinct from the various specific notions of property. Logic is certainly concerned with the notion of an attribute or predicate. But, as we shall see in Sec. 1, properties should be distinguished from the attributes representing them – except of course in the context of philosophical idealism, where they are conflated.

Nor can we accept uncritically the hypothesis that things have properties, particularly since it has been challenged by nominalist philosophers. In fact the latter wish to dispense with properties, which they regard as Platonic fictions, and attempt to reduce everything to things, their names, and collections of such (see e.g. Woodger (1951) and Cocchiarella (1972)). At the very least the nominalist will want to construe every property as a class of individuals, or of n-tuples of individuals – i.e. he will adopt an ontological interpretation of the semantic doctrine called *extensionalism*, which equates predicates with their extensions. But we have seen (Volume 1, Ch. 5, and Vol. 2, Ch. 10) that extensionalism is indefensible even in mathematics, if for no other reasons than that (*a*) some of the basic mathematical predicates, notably the membership relation, are not defined as sets, and (*b*) coextensive predicates need not be cointensive or have the same meaning. Therefore extensionalists can "deplore the notion of attribute" (Quine, 1963) without being able to dispense with it, much as the Victorians deplored sex while engaging in it.

If extensionalism fails so does its ontological interpretation, namely the reduction of the world to a collection of individuals devoid of properties. For one thing this ontology is incapable of explaining what makes a given individual different from any others: it has no *principium individuationis*. For another, nominalism commits the sin of reification, or the transformation of everything into things or collections of things. (Reification, a constant of archaic thinking, is occasionally found among scientists and philosophers. Thus the vulgar materialists of the 19th century held the world to consist of things of two sorts, *Stoff* or substance and *Kraft* or force. Later on the energeticists, wishing to dematerialize the world, proclaimed that everything is a manifestation of energy. And nowadays the followers of Whitehead maintain that there are no things but just events.) For those two reasons nominalism does not tie in with science, which regards things as individuals possessing properties, and handles the notion of a property as basic – so much so that every law statement is deemed to represent an invariant relation among properties of things.

We shall propose a construal of the notion of property that avoids the extremes of nominalism (or substantialism) and Platonism (or formism), and squares with the scientific conception.

1. PROPERTY AND ATTRIBUTE

1.1. *Difference between Property and Attribute*

All objects have properties. If the objects are conceptual or formal, their properties will be called *formal properties*, or *attributes* or *predicates* for short. If the objects are substantial individuals, their properties will be called *substantial properties*, or *properties* for short. Because every model of a substantial individual is built with concepts, it contains attributes or predicates; and insofar as the model represents a substantial individual, some of those attributes or predicates represent substantial properties.

In the case of a conceptual object, such as a set or a theory, the words 'attribute' and 'property' are exchangeable because a conceptual object has all the properties we consistently attribute to it. But in the case of a substantial individual we must distinguish a substantial property or objective trait from the corresponding attribute(s) if any. A substantial property is a feature that some substantial individual possesses even if we are ignorant of this fact. On the other hand an attribute or predicate is a feature we assign or attribute to some object: it is a concept. A predicate may conceptualize or represent a substantial property; but then it may not or it may do so poorly, i.e. with a large margin of error. On the other hand the possessing of a property is not a matter of truth or falsity; only our knowledge of properties can be more or less true or adequate. For this reason we distinguish

$\ulcorner$Substantial individual b *possesses* property $P\urcorner$.

from

$\ulcorner$Attribute A *holds* for $b\urcorner$,

or $\ulcorner A$ is *true* of $b\urcorner$, or $\ulcorner\mathscr{V}(Ab)=1\urcorner$,

where A is taken to represent P. Again: whereas the possessing (or the acquiring or the losing) of a property by a substantial individual is a fact often beyond our reach, our attribution of a property (via some predicate) is a cognitive act. In other words, whereas we control all predicates because we make them, we control only some properties.

Needless to say, no such difference between attributes and substantial properties is admitted by idealism: in such a philosophy the acquiring of a property coincides with its attribution. (Which is why the inadequacies of this philosophy are hardly realized in the realm of formal science.) Oddly enough naive realism, while recognizing the difference between attributes and substantial properties, asserts their one-to-one correspondence. Therefore the stand of those two poles of philosophy with respect to the theory of properties is rather close: whereas idealism asserts that the theory is the logic of predicates, naive realism is committed to the claim that the theory of substantial predicates is an ontological interpretation or model of the predicate calculus.

We proceed to approaching this matter from the vantage point of our semantics (Vols. 1 and 2).

1.2. *Attribute-Property Correspondence*

Surely we know properties only as attributes or predicates, i.e. as components of our views of things. Still, we must distinguish the object represented from its representations if we wish to account for discovery (or invention) and ignorance, truth and error. We do that by making statements of the form

$\ulcorner$Attribute A *represents* substantial property $P\urcorner$,

or $\ulcorner A \triangleq P\urcorner$ for short.

For example, in certain contexts angles represent inclinations, probabilities tendencies, densities crowdings, and so on. The attribute-property correspondence is a particular case of the knowledge-reality, or mind-world relation. This correspondence is not isomorphic because some attributes represent no substantial properties, others represent several properties, and finally some properties are represented by no attributes (because we ignore either or both) or by several predicates (often belonging to different theories of the same kind of thing).

The relation between properties and attributes may be construed as follows. Let $\mathbb{P}$ be the set of substantial properties and $\mathbb{A}$ that of attributes or predicates. Then the representation of properties by attributes is a function $\rho : \mathbb{P} \to 2^{\mathbb{A}}$ that assigns each property P in $\mathbb{P}$ a collection $\rho(P) \in 2^{\mathbb{A}}$ of attributes, so that the formula '$A \in \rho(P)$', for A in $\mathbb{A}$ and P in $\mathbb{P}$, is interpreted as *attribute A represents property P*, or $A \triangleq P$ for short. Details on the concepts of attribute (or predicate) and representation are found in Vol. 1, Ch. 3 and Vol. 2, Ch. 6.

The representation function is a correspondence between a proper subset of all the conceivable attributes (predicates) and the ill-defined set of all (known and unknown) substantial properties. That is, there are attributes with no ontic correlate. Among them we find membership in a set, the negative attributes, and the disjunctive ones. Let us discuss the three because they will show what a substantial property is not. First the matter of membership. In mathematics every member of an arbitrary (but well defined) set may be assigned the attribute of membership in that set. However, being an element of an arbitrary set does not count as a substantial property. For example, although I may decide to group my shoes together with President X's latest statement, such a common membership does not constitute an objective property shared by the two items. In short, not all sets are kinds.

Nor, *pace* a few distinguished philosophers (e.g. Bolzano (1851), Sec. 39 and Russell (1918), Secs. I and III), are "negative" properties possessed by factual items such as things or events. These have only "positive" properties (Bunge, 1974g). In the statement ⌜Neutrons are not electrically charged⌝ the negation affects the entire proposition ⌜Neutrons are electrically charged⌝: it denies the latter statement instead of attributing neutrons the negative property of not being charged, let alone that of being anticharged. We certainly need negation to understand reality and argue about it or anything else, but external reality wears only positive traits. In other words, even though a proposition of the form $\ulcorner \neg Ab \urcorner$ be true and indistinguishable from the proposition $\ulcorner (\neg A)b \urcorner$, there may not exist any real or substantial property represented by the negative attribute $\neg A$ and exemplified by the individual b. Consequently if attribute A represents substantial property P(i.e. $A \triangleq P$), then we can accept the truth condition (sufficient for qualitative attributes)

$\ulcorner \neg Ab \urcorner$ is true if and only if b fails to possess P.

but not

$\ulcorner \neg Ab \urcorner$ is true if and only if b possesses $\neg P$.

In short, negation is *de dicto* not *de re*: it is defined on the set $\mathbb{A}$ of attributes not on the set $\mathbb{P}$ of properties. And because there are no negative properties there are neither tautological nor contradictory substantial properties corresponding to tautological and contradictory attributes such as $A \vee \neg A$ and $A \;\&\; \neg A$ respectively.

Likewise there are no disjunctive attributes with ontic correlates. For example, there is no substantial individual possessing the property of being heavy *or* translucid, even though the proposition ⌜Lucite front doors are heavy or translucid⌝ is true. (In other words, we employ the disjunctive attribute "heavy or translucid" but do not have it represent a property possessed by any substantial individual.) On the other hand certain properties can conjoin. For example there are things both heavy and capable of synthesizing chlorophyll. (But of course other properties are mutually incompatible, i.e. cannot conjoin.) What the expression 'conjunction of properties' signifies will be seen in Sec. 3.4.

The preceding considerations, Byzantine though they may look, are necessary for building a theory of properties and they have far reaching philosophical consequences. A first consequence of the lack of isomorphism between properties and attributes is the ruin of naive realism, both in the form of the reflection theory of knowledge and of the picture theory of language. According to these views every factually true proposition depicts a fact. But if we admit just "positive" properties then we must rule out negative facts. And if we do not admit disjunctive properties then we must write off disjunctive facts, and *a fortiori* general facts. Of course we accept negative and disjunctive propositions as long as they are sufficiently true or at least promising, but that has nothing to do with accepting negative facts and disjunctive facts. Thus "There are no elephants in your pocket." is true precisely because this proposition fails to represent a situation in which there are elephants in your pocket. (On the other hand naive realism would have us interpret that statement as "Everything is either a nonelephant or unlocated-in-your-pocket".) Last, but not least, the attribute-property gap bars any attempt to read the predicate calculus in ontological terms, i.e. to get a theory of properties without tears. Therefore we must try and build a property calculus as distinct from the predicate calculus. To work.

2. ANALYSIS

2.1. *Property in General and Property of a Particular*

The expressions 'pure form', 'system of qualities in themselves', and even 'property' make no sense except as abbreviations or abstractions. In fact, a mathematical and semantical analysis of the concept of a property will show us shortly that every property – except of course the null property, which is a fiction – is possessed by some individual or other: there are no properties that fail to be paired to any individuals. In particular, substantial properties are properties of substantial individuals.

In other words, an attribute can only be attributed to, or predicated of, some subject or other. A snowball is white: whiteness can be predicated of snowballs and other things but it does not exist separately any more than snowballs failing to "participate" in whiteness – to lapse into Platonic jargon. In other words there are no universals in themselves but only properties that are universal in a given set of individuals, i.e. that are shared by all the members of the set. (More on universals in Sec. 5.3.) All this is rather obvious from the way properties are handled in science and predicates are analyzed in semantics. In both cases every property is represented by a function mapping individuals (or n-tuples of individuals) into statements of the form ⌜Individual (or n-tuple) x is assigned attribute A⌝. Such propositional functions, or proposition-valued functions, will be called *attributes* or *predicates*.

Example 1 The property of being able to read is representable as a function R_1 from the set H of humans into the set P_1 of propositions containing the predicate R_1:

$R_1: H \rightarrow P_1$, where $R_1(b)$, for $b \in H$, abbreviates "b can read", a member of the set P_1.

Example 2 The property of being able to read books can be represented by a function R_2 from the set of couples $\langle x, y \rangle$, with $x \in H$ and $y \in B$, where $H =$ Humans and $B =$ Books:

$R_2: H \times B \to P_2$, where $R_2(b, c)$, for $b \in H$ and $c \in B$, abbreviates "b can read c", a member of P_2.

Example 3 An arbitrary mathematical function f with domain D and range R can be associated the propositional function

$F: D \times R \to P_3$ such that $F(x, y) = (f(x) = y) \in P_3$ for $x \in D$ and $y \in R$.

In ontology we are concerned with properties of entities, i.e. members of the set S of substantial individuals characterized in Ch. 1. A substantial property must then be representable as a propositional function, or predicate, on a domain that somehow includes S. The function will represent the property in general, e.g. age; and its value for a particular individual, the given property of the individual concerned, e.g. its age. But sets other than S are likely to occur as well in the domain of the predicate. For example, mass is representable by a certain real valued function M on the set of quadruples ⟨body, reference frame, time, mass unit⟩. In symbols,

$$\ulcorner M: B \times F \times T \times U_M \times \mathbb{R} \to \text{Propositions containing } M \urcorner$$

represents the mass of entities $B \subset S$, whereas the value $\ulcorner M(b, f, t, u, r) \urcorner$ represents the mass $r \in \mathbb{R}$ of a particular body $b \in B$ relative to a given frame $f \in F$ at time $t \in T$, reckoned or measured in mass units $u \in U_M$ (e.g. grams or pounds).

We generalize the preceding considerations by introducing the following axiom of a methodological nature:

POSTULATE 2.1 Let S be the set of substantial individuals or some subset thereof, and let T to Z be arbitrary nonempty sets, equal to or different from S. Then

(i) any *substantial property in general* is representable as a predicate (or propositional function) of the form

$$A: S \times T \times \ldots \times Z \to \text{Propositions including } A;$$

(ii) any *individual substantial property*, or property of a particular substantial individual $s \in S$, is representable as the value of an attribute at s, i.e. as $A(s, t, \ldots, z)$, where $t \in T, \ldots, z \in Z$.

Every individual property, or property of a particular, is *dichotomic* in the sense that the individual either has it or fails to possess it. This holds not only for qualities and for quantitative properties that take on definite numerical values but also for any quantity the range of which is a family of intervals, as is the case with quantum theoretic dynamical variables. Therefore in an expression of the form $\ulcorner A(s, t, \ldots y) = z \urcorner$ it is irrelevant, for our present purposes, whether z is a single number (or an n-tuple of numbers) or a whole set of numbers (or an n-tuple of numerical intervals). In either case, whether sharp or extended, an individual or a set, z will represent a property of individual s.

Properties are then attributable to, or predicable of, individuals of some kind or other. There is no substantial property apart from entities, let alone prior to them and dwelling in a separate Realm of Forms: a form is a form (property) of a chunk of substance, a universal is a property possessed by all the substantial individuals in a given subset of S. Substrate free forms, or Platonic universals, are just as imaginary as formless substances. But at least the fiction of the bare individual makes mathematical sense while that of a pure form does not. (The barest of individuals is characterizable as the member of some set, but the simplest of forms requires a support or domain, because it is a function.)

An entity possesses certain properties but *is* not a bundle of properties. That entity b possesses properties $P_1, P_2, \ldots, P_n, \ldots$ does not entail that $b = \{P_1, P_2, \ldots, P_n, \ldots\}$. If it did we would have to define properties independently of any individuals, and condone absurd expressions such as '$\{P_1, P_2, \ldots, P_n, \ldots\}$ possesses P_1'.

Example 1 A corpuscle is not a mass-position-velocity compound but an entity possessing definite mass values, position values, and velocity values. (Such a triple is only a schema of such an entity. Recall Vol. 1, Ch. 3, Sec. 3.1.) *Example 2* Having a certain thought is a property of some animals at certain times, and as such is representable by a function on the cartesian product of the set of animals of a certain kind by the set of instants. Put another way: that thinking is a function of certain brains entails that neither thoughts nor brains of certain kinds exist separately. What do exist are brains capable of thinking. (More on the mind-body problem in Vol. 4, Ch. 10.)

The functional construal of properties solves a number of problems, among them the ancient biological conundrum: Which is prior, the organ or the function – e.g. the brain or ideation, feeling, etc.? Answer: neither, for the function is just what the organ does. Take for instance the proposition ⌜The function of organelles of kind A is to synthesize proteins of kind B⌝. This statement can be compressed into ⌜All organelles A synthesize some protein B⌝. The latter does not contain the suspect notion of biological function, which smacks of purposiveness, nor does it state that the synthesis of B is the sole function of an A. The second statement exhibits clearly the idea that the function concerned is a relation between organelles and proteins, namely the relation of synthesizing, which can be construed as a function from the set $A \times B$ of organelle-protein pairs into certain propositions. In this way the quaint idea that there could be a biological function independent of either an organ or its output vanishes.

2.2. *Intrinsic and Mutual, Primary and Secondary*

Some properties, such as radioactivity and intelligence, are inherent properties of individuals. Therefore we can sometimes represent them by unary attributes:

$$Rad: \text{Atoms} \rightarrow \text{Propositions involving } Rad$$

$$Int: \text{People} \rightarrow \text{Propositions involving } Int.$$

We call such properties *intrinsic*. Other properties, such as solubility and performance, are properties of pairs or, in general, n-tuples of substantial individuals. Accordingly we represent them by predicates of rank 2 or higher, such as

$$Sol: \text{Solutes} \times \text{Solvents} \rightarrow \text{Propositions involving } Sol$$

$$Per: \text{People} \times \text{Circumstances} \rightarrow \text{Propositions involving } Per.$$

Such properties will be called *mutual* or *relational*.

All mutual properties must be represented by predicates of rank higher than one but the converse is false. That is, some n-ary predicates, with $n > 1$, represent intrinsic properties. For example, the gross national product, which is an intrinsic property, is representable by a predicate of the form

$$GNP: N \times T \times U \times Q^{+} \rightarrow \text{Propositions involving } GNP,$$

where N is the family of nations, T the set of years, U the set of units of production (e.g. dollars), and Q^{+} the set of positive fractions. In the determination of the n-arity of a property,what counts is the number of sets of substantial individuals occurring in the domain of the corresponding predicate.

A mutual or relational property of an entity may or may not depend causally upon some other individual. For example velocity is a mutual property since it depends on both the moving entity and the reference frame, but it is not caused by the latter. The same holds for distance, duration, frequency, mass, temperature, electric field strength and many other properties in relativistic physics: they are frame-dependent but not causally dependent upon the reference frame, which is assumed to be passive. On the other hand certain mutual properties are environment-dependent. This is the case with the force on a body, the position and momentum distribution of a microsystem, solubility, the frequency of the cricket chirping, the performance of a student, and the rate of production of manufactured goods: in all these cases the environment exerts an influence on the entity of interest. All the phenomenal properties, such as color and perceived loudness, are mutual properties of this kind, i.e. they depend not only upon the object-in-the-environment but also upon the subject or perceiver. More on this presently.

(The way to find out whether a given property is absolute (or invariant or frame-independent) is to investigate its behavior under changes in the reference frame – e.g. under displacements or under rotations. If the corresponding attribute does not change under the given transformation then it is declared to be *invariant* under the latter (or an invariant of the entire group of transformations). This procedure establishes or refutes the hypotheses of relative invariance, i.e. absoluteness with respect to a given group of transformations. Since there is no way of finding out whether a given property is invariant with respect to an arbitrary group of transformations, there is no such thing as absolute invariance (or absoluteness). That is, *all invariance is relative.*)

Since phenomenal properties are subject-dependent they are, a fortiori, frame-dependent. (Indeed, a sentient being may be regarded as a reference frame.) The converse is not true, i.e. not every frame-dependent property is subject-dependent or subjective. For example, the frequency of an oscillation is frame-dependent but not subject-dependent. In case of doubt concerning the objective character of a property, swap subjects (observers) either experimentally or in the theoretical formulas, and see whether the values of the property change. If they do not then the property is objective on top of being relational. Outside psychology all properties, whether intrinsic or mutual, are supposed to be objective, i.e. observer-independent. This alone, and in particular the existence of invariant properties (such as electric charge, entropy, and number of entities), disqualifies any subjectivistic ontology in the eye of science. In other words, a scientific metaphysics must be just as objectivistic as science itself, i.e. thoroughly.

A scientific ontology will not discard phenomenal or secondary properties, such as color and loudness, but will attempt to account for them in terms of nonphenomenal or primary qualities. Whatever the precise account may turn out to be, it must rest on the construal of a secondary property as a mutual property at least one of whose legs is a set of sentient organisms. For example, color is wavelength as perceived by some subject, loudness felt acoustic intensity, and warmth felt heat. No sentient organism, no secondary properties. Hence color predicates are representable as certain functions on the cartesian product of the set of light signals by the set of organisms endowed with sight. The other phenomenal predicates (i.e. predicates representing secondary qualities) are similar.

The physicist assumes that there are sound waves that go unheard and light waves that are unseen. And the psychologist knows that there can be acoustic and visual sensations in the absence of concurrent physical inputs. Therefore it would seem that neither primary qualities are necessary for the corresponding secondary qualities nor conversely. However, there would be no perceptual hallucinations if there were no normal perceptions: psychologists assume tacitly that an organism deprived of every trace of a hearing system experiences no sound hallucinations, and similarly for the other kinds of sensation. Hence sound waves are necessary for hearing – normally as immediate causes, abnormally, as stimuli for past experiences (ontogenetically, phylogenetically, or both). We shall accordingly say that acoustic volume *supports* loudness, luminosity *supports* brightness, and so on, even though not every sensation is caused in an immediate fashion by a physical stimulus endowed with the corresponding supporting ability. This view goes back to Locke (1689 Bk. II, Ch. VIII).

The preceding considerations make no sense to phenomenalism, operationism, and subjectivism: according to these philosophies all properties are secondary. But of course natural science since Galilei recognizes only primary properties, and its progress has partly consisted in shoving secondary qualities to the field of psychology. Note finally that in our view secondary qualities are neither purely objective nor purely subjective, for they are possessed by the subject/object interface rather than by either component separately. This is why a secondary quality is construed as a mutual property of entities and sentient organisms.

We may summarize this subsection in the following methodological axiom, which spells out Postulate 2.1:

POSTULATE 2.2 Let $\{S_i \subseteq S | 1 \leqslant i \leqslant n\}$ be a family of nonempty subsets of substantial individuals not including the null individual. Further, let T to Z be arbitrary nonempty sets [of e.g. units], the same as or different from any of the S_i. Finally, let $\mathbb{R}$ be a set of numbers or of sets of numbers [such as the power set of the real line] and p a natural number. Then

(i) every *qualitative intrinsic property* (quality) of the S_i is representable by attributes of the form

$$A: S_i \times T \times \ldots \times Z \to \text{Propositions containing } A;$$

(ii) every *qualitative mutual property* of the S_i, for $1 \leqslant i \leqslant m \leqslant n$, is representable by attributes of the form

$$A: S_1 \times S_2 \times \ldots \times S_m \times T \times \ldots \times Z \to \text{Propositions containing } A;$$

(iii) every *qualitative phenomenal* (secondary) *property* is a qualitative mutual property representable as a predicate of type (ii) where $T =$ Set of sentient organisms;

(iv) every *quantitative intrinsic property* of the S_i is representable by attributes (magnitudes, quantities, variables) of type (i) where $Z = \mathbb{R}^p$;

(v) every *quantitative mutual property* of the S_i for $1 \leqslant i \leqslant m \leqslant n$ is representable by attributes (magnitudes, quantities, variables) of type (ii) where $Z = \mathbb{R}^p$;

(vi) every *quantitative phenomenal* (secondary) property is a quantitative mutual property representable by a predicate of type (v) with $T =$ Set of sentient organisms;

(vii) every *property of an individual* (or individual property) ${}^i b$ of kind S_i is representable by the value of the corresponding attribute at ${}^i b$, and every *property of an aggregation of m individuals* ${}^1 b \dotplus {}^2 b \dotplus \ldots \dotplus {}^m b$, where ${}^i b \in S_i$, is representable by the value of the corresponding n-ary attribute at $\langle {}^1 b, {}^2 b, \ldots, {}^m b \rangle$.

It might be thought that some if not all of the above distinctions are shallow or arbitrary. In particular, it might be claimed that all individual properties, whether qualitative or quantitative, can be represented by dichotomic (or presence-absence) attributes. Thus both "is married" and "is 25 years old" are dichotomic attributes in the sense that they are either true or false of a given individual. But the point is that, whereas being married is a qualitative property that admits of no degrees, age does come in degrees. What is true is that the progress of science carries with it the quantitation of a number of attributes that had previously been regarded as being inherently dichotomous.

Likewise it might be thought that, since all relations can be reduced to binary relations (Quine, 1954), the n-arity of a predicate is unimportant. This may well be so, but such a logical reduction need not be construed as mirroring anything in reality. Our planet did not cease to revolve around the Sun between Mercury and Saturn the moment ternary relations were shown to be reducible. Besides, the said reduction does not hold for the most useful of all relations, namely functions. Thus a function of two variables is not generally reducible to two functions of one variable each (i.e. two dyadic relations).

Nor does the opposite move work, viz., that of augmenting the degree of predicates on philosophical grounds. This gambit was tried by Helmholtz (1873, p. 260), who held that "each quality or property of a thing is, in reality, nothing else but its capability of exercising certain effects upon other things". Likewise Ducasse (1968) maintained that every property is a causal power to produce some effects. This view rests on the operationist confusion between a property and the way of testing for it. Surely a property that does not affect anything cannot be observed even indirectly and therefore can hardly be said to be possessed by the entity of interest. But if scientific theory construes a given property as an n-ary predicate, our metaphysics has no right to "interpret" it as an $(n+1)$-ary property.

3. THEORY

3.1. *Unarization and Dichotomization*

Thus far we have made only a few rather informal remarks on properties and have analyzed the way they are representable by predicates. In the present section we shall make definite ontological assumptions embodied in a general theory of properties and their scopes, i.e. kinds. Given the variety of properties (intrinsic and mutual, qualitative and quantitative, primary and secondary) it may well be wondered whether the task is feasible. Fortunately we can introduce a remarkable uniformity, and thus pave the way for the search for structure, by using two devices. One is to replace every mutual property by a bunch of intrinsic properties, the other is to concentrate on individual intrinsic properties. The end result is in each case a set of unary dichotomic predicates every one of which is either true or false of a given substantial individual. A couple of examples will show how to proceed in general.

Consider the property of falling. In ordinary knowledge this is represented by a unary predicate. In science, falling is analyzed as a binary predicate F such that 'Fxy' is interpreted as "x falls on y". We can now freeze the second argument, i.e. take it for granted that whatever falls does so on a fixed body b such as our planet. That is, we can form the *pseudo-unary* predicate F_b such that

$$F_b x = x \text{ falls on } b.$$

If now we change the value of the parameter, say to $c \neq b$, we obtain another predicate, namely F_c, such that $F_c y = y$ falls on c. In this way *the single binary predicate F is replaced by an infinite set of unary predicates* F_z. (No return then to the original innocence of ordinary knowledge.) There is of course no economy at all in the unarization procedure: this is just a trick allowing one to speak, though at greater length, of any property of an individual *as if* it were intrinsic. Therefore it has nothing to do with either Bradley's attempt to eliminate relations in favor of monadic predicates or "internal relations" (Bradley, 1893). Nor is it related to the even more quaint claim that a binary relation can be construed as composed of three separate parts: an outgoing arrow, an incoming arrow, and the glue between them (Harary, 1971).

The unarization procedure can be generalized to cover not only mutual properties of n-tuples of individuals but all kinds of complex properties. Consider the statement

> ⌜Body a pulls body b, at time t, relative to reference frame f, with force p in force units u⌝.,

or ⌜$P(a, b, t, f, u, p)$⌝ for short. The 6th rank quantitative predicate P represents the property of pulling, and any of its values represents the individual property of a given thing pulling another with a fixed force relative to some frame at some instant. By focusing on the agent a we manufacture one predicate P_{btfup} for each circumstance $\langle b, t, f, u, p\rangle$, such that

$$P_{btfup}(a) = a \text{ pulls } [b \text{ at time } t \text{ relative to frame } f \text{ with force } p \text{ in units } u].$$

Every one of these predicates may be taken to represent an intrinsic property and moreover an individual one, for it is either possessed or not possessed by the corresponding substantial individual, in this case a. Since the sets of instants, frames, force units, and force values are infinite, the number of such artificial unary predicates is infinite as well. This is a high price to pay and for this reason the transaction is not performed in science. But it is the price to pay if we want a general theory of properties and kinds. Let us then proceed to make

DEFINITION 2.1 Let $S_1, S_2, \ldots, S_n \subseteq S$, with $n > 1$, be n nonempty sets of substantial individuals and let $T_1, T_2, \ldots, T_m$, with $m \geqslant 0$, be m arbitrary nonempty sets. Furthermore let

$$A : S_1 \times S_2 \times \ldots \times S_n \times T_1 \times T_2 \times \ldots \times T_m \to \text{Propositions involving } A$$

be an attribute representing an n-ary substantial mutual property of such individuals. Then for each $1 \leqslant i \leqslant n$ and for each $(n+m-1)$-tuple

$$\langle x_1, x_2, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n, t_1, t_2, \ldots, t_m \rangle$$
$$\in S_1 \times S_2 \times \ldots S_{i-1} \times S_{i+1} \times \ldots \times S_n \times T_1 \times T_2 \times \ldots \times T_m,$$

the *i-th unary attributes associated to A* are the functions

$$A x_1 x_2 \ldots x_{i-1} x_{i+1} \ldots x_n t_1 t_2 \ldots t_m(x) =$$
$$=_{df} A(x_1, x_2, \ldots, x_{i-1}, x, x_{i+1}, t_1, t_2, \ldots, t_m).$$

We shall henceforth take this unarization for granted throughout the remainder of this chapter. And we shall also take it for granted that, when dealing with a property, we actually handle an individual property, i.e. a property of some substantial individual. These two conventions allow us to introduce

DEFINITION 2.2 P is a *substantial property* (or a member of the set $\mathbb{P}$ of substantial properties) iff some substantial individuals possess P:

$$P \in \mathbb{P} =_{df} (\exists x)(x \in S \ \& \ x \text{ possesses } P).$$

In what follows we shall investigate the structure of the set $\mathbb{P}$ of substantial properties. That such an investigation is called for is obvious from the result of Sec. 1, namely that although all properties may be representable by attributes, not all attributes represent substantial properties.

3.2. *Basic Assumptions and Conventions*

We proceed to formulate a handful of assumptions and conventions that will allow us to lay bare the structure of the set of all substantial (intrinsic and dichotomic) properties. (The formal treatment from Definition 2.5 on follows closely Bunge and Sangalli (1977).)

The collection of properties of an individual, and that of a set of individuals, deserve special names that will be used frequently in the sequel:

DEFINITION 2.3 Let $T \subseteq S$ be a nonempty set of substantial individuals and $\mathbb{P}$ the set of (unarized dichotomic) substantial properties. Then

(i) the set of (unarized dichotomic) *properties of individual* $x \in T$ is called

$$p(x) = \{P \in \mathbb{P} \mid x \text{ possesses } P\};$$

(ii) the set of (unarized dichotomic) substantial *properties of the* T's is called

$$p(T) = \{P \in \mathbb{P} \mid \text{For all } x \in T, x \text{ possesses } P\}.$$

Consider for a moment the set $p(x)$ of (unarized dichotomic) properties of an entity x. Since every one of these properties is taken at a given time and relative to a given reference frame, when reckoning with all the possible instants and frames we end up with a nondenumerable infinity of (potential) properties of x, no matter how modest this individual may be. (Recall Sec. 3.1.) On the other hand it seems reasonable (and comforting) to assume that the set of substantial properties in general, though extremely numerous, is finite. Thus one thinks of an animal as having different weights, metabolic rates, and ages at different times; yet all these are just different values of only three general properties – weight, metabolic rate, and age at different times and relative to different frames. In any case we stick our neck out and assume

POSTULATE 2.3 The set of general substantial properties is finite, and that of substantial individual (unarized and dichotomized) properties, i.e. $\mathbb{P}$, is nondenumerable.

Next we accept Aristotle's ontological axiom that every individual either possesses a given property (in a given respect at some time) or not:

POSTULATE 2.4 For every $x \in S$ and every $P \in \mathbb{P}$,

$$x \text{ possesses } P \vee \neg x \text{ possesses } P.$$

This axiom must not be mistaken for the excluded middle principle, which concerns predicates. Hence a mathematical intuitionist can accept the former. By logic, whether ordinary or intuitionistic, it follows immediately that no individual has a given property and fails to possess it. That is, there are no inherently contradictory things: contradiction proper is always *de dicto* never *de re*. What there can be is of course mutually opposing properties, such as excitation and inhibition, but these do not illustrate contradiction. Also, by adopting Postulate 2.4 or its corollary, one does not rule out change, in particular the acquisition or loss of a property, because every property occurring in the postulate is taken at a given time under given circumstances. Which leads us to

DEFINITION 2.4 Two properties are *incompatible* over a set $T \subseteq S$ of substantial individuals iff possessing one of them precludes having the other: If $P_1, P_2 \in \mathbb{P}$, then

(i) P_1 is *incompatible* with P_2 over $T =_{df} (x)(x \in T \Rightarrow (x \text{ possesses } P_1 \Rightarrow \neg x \text{ possesses } P_2))$;

(ii) P_1 and P_2 are mutually *compatible* over T iff they are not incompatible over T.

Note that two properties may be compatible yet not both actually possessed by a given entity. For instance honesty and wealth are compatible even though rarely concomitant. (Compatibilities are dispositional properties.)

An interesting case of property incompatibility is that of microsystems. According to the quantum theory a microsystem does not have both a sharp spatial localization and a precise velocity value. (What are compatible, moreover concomitant, are the probability distributions of position and of momentum.) In this theory several properties (the dynamical variables) are represented by operators, some of which fail to commute pairwise. If A_1 and A_2 are operators representing mutually incompatible properties, then $A_1A_2 \neq A_2A_1$ and conversely. When this is the case then, whenever A_1 takes on a precise (eigen)value, its partner A_2 exhibits a whole range of values and conversely. That is, noncommuting variables do not have joint sharp values: they have only distributions of values, each with a given probability. Operationism notwithstanding this – insofar as quantum mechanics is true – is an objective trait of nature not a feature of measurement. In other words the incompatibility between properties represented by noncommuting operators is verified in experiment not caused by the latter (Bunge, 1967b).

We adopt next a *principium individuationis*:

POSTULATE 2.5 No two substantial individuals have exactly the same properties:

$$\text{For all} \quad x, y \in S, \quad \text{if} \quad x \neq y \quad \text{then} \quad p(x) \neq p(y).$$

By contraposition it follows that, if two entities have exactly the same properties, then they are one:

COROLLARY 2.1 For all $x, y \in S$,

$$\text{if} \quad p(x) = p(y), \quad \text{then} \quad x = y.$$

Either of these hypotheses may be called *Leibniz' law* (Leibniz, third and fourth letter to Clarke, in Alexander, Ed., 1956). They take identity seriously without mistaking it for mere similarity: the slightest difference between two entities – such as a difference in relative position with respect to a third entity – results in difference. It is only in the realm of constructs that there can be several identical copies of one and the same object, as with the cases of $a + a$ and $A \times A$. But even here one may argue that there is a single object taken repeatedly.

It is usually maintained that the concept of identity occurring in Leibniz' law is that of *contingent identity* as opposed to formal identity. Thus a living brain is said to be contingently identical with the interior of the skull of a living animal, and gene duplication contingently identical with the uncoiling of the double helix. I do not understand the alleged difference between contingent and formal identity: since both concepts have exactly the same properties they must be identical and must fall under the theory of identity.

Because the relation of identity is reflexive, we retrieve a famous statement sometimes regarded as a basic principle of both logic and ontology, at other times decried as absurd or, even worse, as trivial, namely

COROLLARY 2.2 Every entity is identical to itself (i.e. self identical).

Some philosophers have held that this statement is incompatible with change. Nothing of the sort. If an entity changes then it becomes a different entity – or an entity in a different state – even though we may go on calling it by the same name. All that Corollary 2.2 asserts is that every entity preserves whatever "identity" it may have – until it loses it and acquires another. (Caution: in the last sentence 'identity' signifies "collection of peculiarities".)

Note that identity, therefore also difference, are relations, hence concepts not facts. Even though it is true that a dog is not the same as a star, there is no connection or coupling between the two – i.e. "$\neq$" mirrors no such relationship or link. In other words both identity and difference are *de dicto*. This is one of the crucial places at which naive realism (i.e. the fact-thought isomorphism thesis) fails.

One last caution concerning identity: this concept must not – *pace* Strawson (1959) – be mistaken for the pragmatic concept of *identification*. One may by mistake identify two things that are actually different; or one may "identify" an object *qua* member of a certain class, thereby failing to use the concept of identity. For this reason we cannot adopt the operationist claim that "the relation of identity or distinctness has no other meaning than that two objects have been identified or distinguished" (Yessenin-Volpin, 1970, p. 7). Whether or not an identity statement has been put to the test, it should be meaningful to begin with. (For the relation between meaning and testability see Vol. 2, Ch. 7, Sec. 5.1.)

Finally we reach a central convention in our theory:

DEFINITION 2.5 The *scope* of a substantial property is the collection of entities possessing it. In other words, the scope $\mathcal{S}$ is the function $\mathcal{S}\colon \mathbb{P} \to 2^S$ from the set of all substantial properties to the set of all the subsets of substantial individuals, such that "$x \in \mathcal{S}(P)$", for $x \in S$, is interpreted as "*Individual x possesses property P*".

For example, the scope of the mass property is the set of all bodies, and that of the social mobility property is the set of all human societies.

A first, surely modest use of $\mathcal{S}$ is in defining the fiction called *null property*: N is a null property iff $\mathcal{S}(N) = \varnothing$.

Note the difference between the scope of a property and the extension of a predicate or attribute (cf. Vol. 2, Ch. 9, Sec. 1). For one thing $\mathcal{S}$ is defined on properties not on predicates; for another $\mathcal{S}$ is not defined for negation and disjunction.

Note also that some of the ideas handled in the preceding can be reformulated in terms of scopes. For example the Definition 2.4(i) of property incompatibility becomes

$$\begin{aligned}&P_1 \text{ and } P_2 \text{ are } \textit{mutually incompatible} \text{ over}\\ &T =_{df} \mathcal{S}(P_1) \cap \mathcal{S}(P_2) \cap T = \varnothing.\end{aligned}$$

Given a property other than a null property, there is always a nonempty set of individuals that possess it since, by Definition 2.2, a substantial property is one possessed by at least one substantial individual. See Figure 2.1. But the converse is false: an arbitrary collection of objects need not share a given property. When they do, and no object outside the collection has the property of interest, the set is called a class:

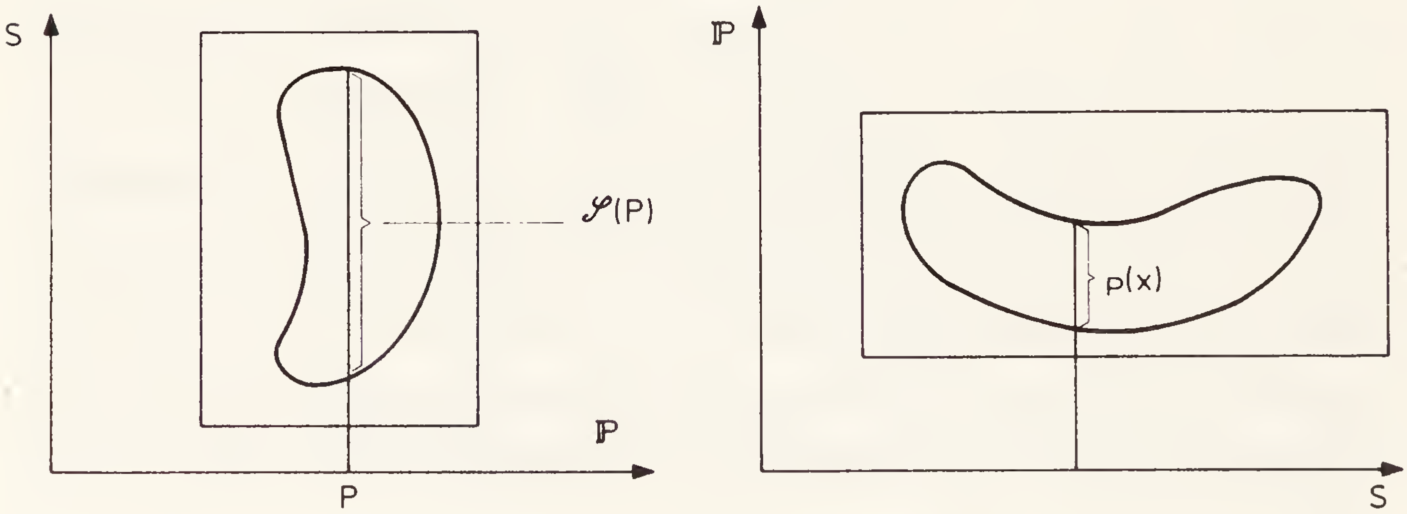

Fig. 2.1. Two complementary concepts: the scope of a property and the set of properties of an individual.

DEFINITION 2.6 A subset X of S is called a *class* (of substantial individuals) iff there exists a substantial property $P \in \mathbb{P}$ such that $X = \mathcal{S}(P) \in 2^S$.

Since all substantial individuals can associate (Ch. 1), S forms a class – in fact the largest of all classes studied by ontology, i.e. the universe of discourse of the latter.

Our next assumption is

POSTULATE 2.6 The intersection of any two classes is a class: For any two compatible substantial properties $P, Q \in \mathbb{P}$, there is at least one other property $R \in \mathbb{P}$ such that $\mathscr{S}(R) = \mathscr{S}(P) \cap \mathscr{S}(Q)$.

Note that the third property determined by any two given properties need not be unique. In fact there might be a fourth property with the same scope as R. Secondly, if P and Q are mutually incompatible over some domain of individuals, then they determine an empty class. Thirdly, the above assumption is not necessary for attributes or predicates because, if A and B are attributes with overlapping domains, then their conjunction $A \& B$ exists on their overlap and it determines a set, namely the extension of the composite predicate $A \& B$. But we still do not know what the conjunction of properties might be, so the above postulate is nontrivial. Fourthly, we are not asserting that the union of two classes is a class, for this would be definitely false in the particular case when the classes are natural kinds: think of the set (not the class) equal to the union of the class of clouds and the class of flies.

So much for properties in general. Let us now study a particular class of properties, namely laws.

3.3. *Laws as Properties*

So far as Postulate 2.6 is concerned, all the classes could be pairwise disjoint. Our final assumption will deny this possibility, i.e. it will assert that some pairs of classes overlap and, moreover, that some are contained in others. In other words, we shall assume that all entities satisfy some laws – or, what amounts to the same, that every substantial property is lawfully related to some other substantial property. To formulate this idea with precision we need

DEFINITION 2.7 If $P, Q \in \mathbb{P}$ are substantial properties, then the statement $\ulcorner \mathscr{S}(P) \subseteq \mathscr{S}(Q) \urcorner$ or its converse or, equivalently,

> $(x)Lx$ with $Lx = \ulcorner x$ possesses $P \Rightarrow x$ possesses $Q \urcorner$ or its converse

is called a *law statement* relating P to Q.

If the scope of a property is included in that of another, the two properties are said to be *lawfully related*. A property not so related to any other property is said to be *stray* or *lawless*.

This notion of a law will be considerably refined in Ch. 3, Sec. 2.3. Note that we have not defined laws, or objective patterns, but law statements, or conceptual reconstructions of objective patterns. The relation between the two categories is an instance of the property-attribute relation discussed in Sec. 1.2.

It might be objected that there are single property laws, such as the law of inertia, which can be abbreviated to "$V = \text{const.}$" This would be mistaken, for the preceding formula is a poor rendering of the correct statement, which involves further variables. Firstly there is the property of being a free body (predicate B). Secondly, there is a tacit reference to a frame (predicate F) as well as to time (T). Indeed, the complete formulation is: "If x is a free body (B) and y a reference frame (F) and t an instant of time (T), then the velocity of x relative to y is constant for all t in T". The function V represents then a mutual property (of body and frame) and the last statement makes no sense without the antecedent, which contains the predicates B and F. True, time (T) looks external to things – common to all hence the property of none. But it actually summarizes the state of the reference frame. (See Ch. 5, Sec. 3.2.) In fact t can be replaced by the phase of some process occurring in a frame $y \in F$. (For example t could be the angular position of the pointer of a chronometer attached to y, or the mass of water flowing in a clepsydra.) This renders it a property of entities. In any event the initial simplicity of the law of inertia was deceptive.

We can now formulate the hypothesis that there are no stray or lawless properties:

POSTULATE 2.7 Every substantial property is lawfully related to some other substantial property. I.e., if $P \in \mathbb{P}$, then there exists a $Q \in \mathbb{P}$ such that either $\mathscr{S}(P) \subseteq \mathscr{S}(Q)$ or $\mathscr{S}(Q) \subseteq \mathscr{S}(P)$.

This ontological principle underlies all science and all technology. (Recall Introduction, Sec. 7, principle *M8*.)

Note that, since laws interrelate substantial properties and the latter are properties, *laws themselves are properties of entities*. So much so that they can be expressed by formulas of the basic form $\ulcorner (x)Lx \urcorner$. Thus it is a property of a free body that it satisfies the law of inertia. Like every other property, it is represented by a predicate analyzable in the manner prescribed by Postulate 2.2. However, laws are properties *lato sensu*, not in the strict sense we have been considering heretofore. For, if every law were to belong to $\mathbb{P}$, then by Postulate 2.7 it would occur in some other law – and so on *ad infinitum*. But this would contradict the Postulate 2.3 that $\mathbb{P}$ is finite. Hence when claiming that laws are properties we use the term 'property' in a broader sense than when we state that laws relate properties. More in a while.

Postulate 2.7 is our present version of the *principle of lawfulness*. (For a discussion of the latter see Bunge (1959).) It will play a decisive role in Ch. 3, Sec. 3.3, in helping us define the notion of a natural kind as distinct from a mere class. And it provides the following propertyhood

CRITERION 2.1 P is a property iff P occurs in at least one law.

By this criterion predicates such as "non-smoker", "fast or thinking", and "green before AD 2000 and blue thereafter" (the infamous "grue") do not represent any substantial properties. This is of course in agreement with Sec. 1. Moreover we are now in a better position to distinguish an arbitrary function from one representing a substantial property:

CRITERION 2.2 A function F represents a property of substantial individuals of class $T \subseteq S$ iff

(i) T^n, with $n \geqslant 1$, occurs in the domain of F;

(ii) F occurs in at least one law statement referring to T.

By this criterion "differentiable" (in the mathematical sense) does not represent a substantial property because its domain is the set of functions. On the other hand "differentiable function" can be made to represent properties that happen to be smooth.

Finally we introduce a useful convention:

DEFINITION 2.8 The totality of laws possessed by substantial individuals is denoted by $\mathbb{L}$.

Remark 1 The ontological concept of a law can be illustrated. On the other hand it is not ostensive: it is impossible to point to a law – as different from a sentence expressing a law statement conceptualizing a law. Furthermore nobody could possibly exhibit or even mention the set of all laws. (At most one could try to list the known law statements in a given field of research – or rather a subset of standard law statements with neglect of their innumerable instances.) Thus $\mathbb{L}$ is a nonconstructive set and is, if anything, even more metaphysical than its members. It is one of those ontological notions used, though not elucidated, in the everyday metascientific discourse of scientists. *Remark 2* Since laws are properties in a broad sense, we can form the totality $\mathbb{P} \cup \mathbb{L}$ of properties *lato sensu*, where $\mathbb{P}$ is the set of properties *sensu stricto* (those occurring in the members of $\mathbb{L}$). *Remark 3* Because laws are properties, they can be assigned scopes – provided we agree to introduce a new scope function defined on $\mathbb{P} \cup \mathbb{L}$, not just on $\mathbb{P}$. The scope of a law would then be the set of entities possessing ("obeying") the law. This set is the same as the reference class of the law statement representing the objective law – not however the same as its extension; which is the set of entities for which the law statement holds exactly. *Remark 4* Another consequence of construing laws as properties (in a broad sense) is that the scope of a law may include or be included in that of some other property, in particular that of another law. Hence the set $\mathbb{L}$ of laws, far from being amorphous, is partially ordered in respect of breadth of scope. However, in the technical developments to follow we shall keep to the narrow construal of 'property'.

So much for our main assumptions and definitions. Let us now proceed to make the most of them.

3.4. *Precedence and Conjunction of Properties*

The concept of a law introduced by Definition 2.7 and occurring in Postulate 2.7 suggests the formation of the following preordering relation:

DEFINITION 2.9 If P and Q are substantial properties (i.e. members of $\mathbb{P}$) then *P precedes Q* iff P is more common than Q, i.e.

$$P \preccurlyeq Q =_{df} \mathscr{S}(Q) \subseteq \mathscr{S}(P).$$

Since in turn inclusion is defined in terms of implication, the previous definition is equivalent to

DEFINITION 2.10 If P and Q are substantial properties, then *P precedes Q* iff P is necessary for Q, i.e.

$$P \preccurlyeq Q =_{df} (x)(x \in S \Rightarrow (x \text{ possesses } Q \Rightarrow x \text{ possesses } P)).$$

In other words, "precedes", "is more common than", and "is necessary for" are coextensive. Equivalently: "follows", "is rarer than", and "is sufficient for" are coextensive. Example: the property of thinking follows that of being alive, which in turn follows that of containing genetic material.

Warning: the preceding definitions should not be read in terms of attributes or predicates, if only for the following reason. Let A and B be two attributes with the same referents and the same rank, and assume that B is necessary for A, i.e. $A \Rightarrow B$. Then by Craig's interpolation theorem there exists at least one other attribute C with the same referents and the same rank that mediates between A and B, i.e. such that $A \Rightarrow C \,\&\, C \Rightarrow B$. This, which is a theorem in logic, does not guarantee the existence of a substantial property represented by the interpolated predicate. Such an existence hypothesis, if made, would give us a different theory of properties.

The precedence relation is reflexive and transitive, i.e. it is a preorder relation. In fact it is not antisymmetric, i.e. $P \preccurlyeq Q$ and $Q \preccurlyeq P$ does not imply $P = Q$. Indeed different properties may have the same scope – just as two attributes can have the same extension without being identical. In order to obtain an order and thus uncover richer structures we must shift attention from properties to classes (or scopes of properties). To begin with we make

DEFINITION 2.11 If P and Q are any two substantial properties, then they are *concomitant* iff they have the same scope:

$$P \sim Q =_{df} \mathscr{S}(P) = \mathscr{S}(Q).$$

In other words, two properties are concomitant if the corresponding attributes are equivalent. Or also:

$$P \sim Q =_{df} (x)(x \in S \Rightarrow (x \text{ possesses } P \Leftrightarrow x \text{ possesses } Q)).$$

The concomitance of properties is what Hume called 'constant conjunction of properties' (Hume, 1739–40). In our ontology, by virtue of Definition 2.7, *the concomitance of properties is not coincidental but lawful*; or, if preferred, it is nomically necessary rather than accidental.

The relation $\sim$ of concomitance is important because it is an equivalence relation on $\mathbb{P}$, i.e. it splits $\mathbb{P}$ into disjoint sets (equivalence classes), namely of those properties that happen to come together. To investigate the structure of the resulting sets we need some further notation:

DEFINITION 2.12 Let $\mathbb{P}$ be the collection of substantial properties and $\sim$ the relation of property concomitance defined on $\mathbb{P}$. Then for any $P \in \mathbb{P}$:

(i) the *totality of concomitants* of P: $[P] =_{df} \{Q \in \mathbb{P} \mid Q \sim P\}$;

(ii) the *family of sets of concomitants*: $[\mathbb{P}] =_{df} \{[P] \mid P \in \mathbb{P}\}$;

(iii) the *scope of sets of concomitants*: $[\mathscr{S}]: [\mathbb{P}] \to \mathscr{P}(S)$.

Clearly, for any substantial property P, $[\mathscr{S}]([P]) = \mathscr{S}(P)$ is the class of entities that possess P and all the other properties concomitant with P.

The preorder relation $\leqslant$ on $\mathbb{P}$ induces a partial order relation $[\leqslant]$ on $[\mathbb{P}]$ according to

DEFINITION 2.13 Let $[\mathbb{P}]$ be the collection of all equivalence classes of properties. Then, for any two $[P], [Q] \in [\mathbb{P}]$,

$$[P][\leqslant][Q] =_{df} \mathscr{S}[Q] \subseteq \mathscr{S}[P].$$

This new precedence relation has all the formal properties of the inclusion relation. It enables us to compare not properties but their scopes – thus obliterating any difference among properties with the same scope. Hence $\langle [\mathbb{P}], [\leqslant] \rangle$ is a partially ordered set. Actually $[\mathbb{P}]$ has a richer structure, as shown by

THEOREM 2.1 The family of sets of concomitant properties has the sup-semilattice structure, where the supremum of $[P]$ and $[Q]$ is defined as

$$[P] \sqcup [Q] =_{df} \{R \in \mathbb{P} \mid \mathscr{S}(R) = \mathscr{S}(P) \cap \mathscr{S}(Q)\}.$$

Proof It is easily verified that $[P] \sqcup [Q]$ is a set of concomitants and the least (in the sense of $[\leqslant]$) upper bound of $\{[P], [Q]\}$, i.e. $[P], [Q][\leqslant]([P] \sqcup [Q])$.

COROLLARY 2.1 If a substantial property R belongs to the supremum of two sets $[P]$ and $[Q]$ of concomitant properties, i.e. $R \in [P] \sqcup [Q]$, then an entity possesses R just in case it possesses both P and Q: $(x)(x \in S \Rightarrow (x \text{ possesses } R \Leftrightarrow x \text{ possesses } P \,\&\, x \text{ possesses } Q))$.

We shall shorten "x possesses P & x possesses Q" to "x possesses $P \wedge Q$", where the complex property $P \wedge Q$ is characterized, albeit not defined, by

$$\mathscr{S}(P \wedge Q) = \mathscr{S}(P) \cap \mathscr{S}(Q).$$

$P \wedge Q$ will be called the *conjunction* of P and Q, or the *complex property* composed of P and Q. This is not a definition proper because equality of scope (which is all we are requiring) is necessary but not sufficient for identity of properties. (Caution: property conjunction should not be mistaken for property concomitance or "constant conjunction".)

Properties then may be simple (or basic) or complex (or derivative). For example in contemporary physics mass, charge, spin and strangeness are regarded as basic (simple) properties in the sense that they are not reducible to any other properties. On the other hand weight is a derivative (complex) property, as it consists in an entity's having a mass *and* being placed in a gravitational field. That is, weight is the conjunction of two properties.

Only a scientific theory can say whether a given property is basic or derivative. But such a dichotomy holds only for the proper subset $\mathbb{T}$ of $\mathbb{P}$ represented in the theory, so the most one can venture is to say that a certain property P is simple, or else complex, *in* $\mathbb{T}$. Alternative theories dealing with the same properties may decide differently. For example energy and momentum, which are simple in certain theories, are treated as complex in others. Therefore we cannot pass final judgment on the degree of complexity of a property on the basis of an analysis of the corresponding attributes. Nevertheless such indications, ambiguous and fickle as they are, are the only ones we have.

It seems reasonable to assume that, even though we often find it difficult if not impossible to ascertain whether a given property is basic, reality has no such problem and builds complex properties out of simple ones – or rather complex entities out of simpler ones. It is therefore worth while to state that assumption in exact terms. But to this end we first have to introduce an exact concept of a basic property. And this in turn calls for the explicit introduction of the concept of a universal property, i.e. one possessed by all entities. More precisely, we form the equivalence class of all universal properties and call it

$$[U] =_{df} \{P \in \mathbb{P} \mid \text{For all } x \in S : x \text{ possesses } P\}.$$

Clearly, $[U]$ precedes every other set of concomitant properties in the sup semilattice $\langle [\mathbb{P}], \sqcup \rangle$, hence it is the smallest element of it, i.e. its zero. In other words $[U]$ is the root of the tree of (sets of concomitant) properties: see Figure 2.2. Note that there is no top element formed by the properties that no entity possesses because, by Definition 2.2, a substantial property is possessed by at least one entity.

We are now ready to elucidate the notion of a basic (or generating) property. We stipulate it to be a property occurring as a conjunct in some other (complex) property. More exactly, we adopt

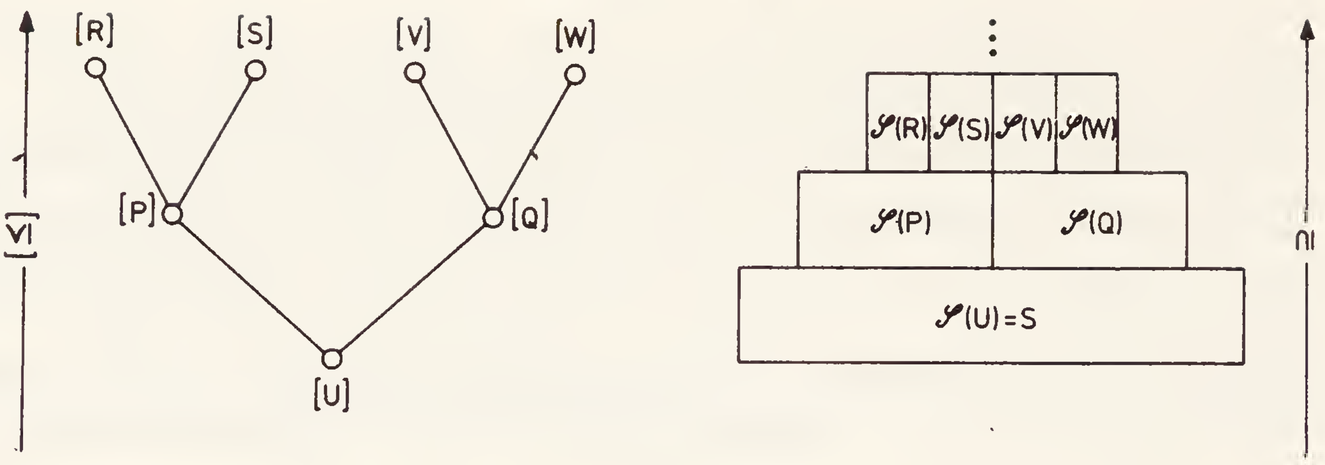

Fig. 2.2. The tree of (sets of concomitant) properties and the pyramid of classes of entities with the same properties. The more basic a property the more common it is.

DEFINITION 2.14 A subset $\mathbb{B}$ of $\mathbb{P}$ is called a set of *independent generators* of $\mathbb{P}$ iff

(i) for every $P \in \mathbb{P}$ there exist $B_1, B_2, \ldots, B_n \in \mathbb{B}$, $n \geqslant 1$, such that $P = B_1 \wedge B_2 \wedge \ldots \wedge B_n$;

(ii) for all $n > 1$ and all $B_1, B_2, \ldots, B_n \in \mathbb{B}$, if $B_1 = B_2 \wedge \ldots \wedge B_n$ then either $B_i = B_1$ or $B_i = U$ (a universal property) for $i = 2, 3, \ldots, n$.

Every set $\mathbb{B}$ of independent generators splits into a set of universal properties and another of *atomic* properties, i.e. properties which are basic (or generating) but not universal:

$$\mathbb{B} \subseteq At(\mathbb{P}) \cup [U].$$

If there are such atomic properties then this is a trait of reality not a mathematical "fact". And if we do assume their existence then we must suppose that they are infinitely many. In fact a finitely generated semi-lattice is finite but, by Postulate 2.3, $\mathbb{P}$ is infinite. Therefore the assumption that there are basic properties that determine all others reads:

POSTULATE 2.8 The set of atoms of $\mathbb{P}$ is infinite and it generates $\mathbb{P}$.

An immediate consequence is that each property is of either of the following types:

(i) *basic* properties (i.e. members of some $\mathbb{B} \subseteq At(\mathbb{P}) \cup [U]$);

(ii) properties that are *finite conjunctions* of two or more basic properties;

(iii) properties that are *infinite conjunctions* of basic properties (in the sense that their scopes are infinite intersections).

Infinite conjunctions of properties are not ghostly or even exceptional. Thus the trajectory of a particle relative to some reference frame may be construed as the conjunction of its (nondenumerably many) successive positions.

The epistemological consequence of Postulate 2.8 is this. For any class $T \subset S$ of entities, in order to know all the properties in $p(T)$ it suffices to know the atomic properties of the T's, i.e. the atoms of $\mathbb{P}$ belonging to $p(T)$.

We close this section with an algebraic note showing that the collection of substantial individuals, far from being an amorphous set, has a definite structure. Consider the family $\mathbb{K}$ of all classes of substantial individuals. Since by Postulate 2.6 the intersection of any two classes is a class, $\mathbb{K}$ has the semilattice structure. In other words, we have proved

THEOREM 2.2 The system $\langle \mathbb{K}, \cap \rangle$, where

$$\mathbb{K} = \{\mathscr{S}(P) \in 2^S \mid P \in \mathbb{P}\}$$

is the family of all classes of substantial individuals, is an inf-semilattice.

We shall have much more to say on the algebra of classes of substantial individuals in Ch. 3, Sec. 3.

3.5. *Similarity*

Knowing that two given concrete objects are different is not enough: we should know what their degree of difference is – or, which amounts to the same, in which respects they are the same. To be the same in some respects is to be similar. Now, similarity can be weak or strong, superficial or deep, according as the overlap in properties is slight or large. Most assertions of identity with reference to concrete objects are actually statements of strong similarity (or equality) not of strict identity. For example the statement that all the atoms of a given kind in a certain state are identical means that they are the same barring certain extrinsic differences – e.g. in position relative to other things.

We must therefore investigate the concept of degree of similarity and its dual, degree of dissimilarity. We start with the convention that the similarity between two things is the collection of their shared properties. More precisely, we make

DEFINITION 2.15 Let $\sigma: S \times S \to 2^{\mathbb{P}}$ be the function such that $\sigma(x, y) = p(x) \cap p(y)$ for any $x, y \in S$. Then

(i) $\sigma(x, y)$ is called the *similarity* between x and y, and

(ii) two entities are said to be *similar* ($\sim$) iff their similarity is not nought:

$$\text{If } x, y \in S \quad \text{then} \quad x \sim y =_{df} \sigma(x, y) \neq \varnothing .$$

Note that $\sim$ is a similarity relation, not an equivalence relation, because it is reflexive and symmetric but not transitive. (One entity may resemble another and the latter a third while the former does not resemble the third. Just think of face similarity.)

By Postulate 1.1 in Ch. 1, Sec. 1.2, all substantial individuals have the property of associating. (Besides, we know from physics that all entities have energy, are capable of moving, etc.) Hence

THEOREM 2.3 All entities are similar [or equal in some respect]: If $x, y \in S$, then $x \sim y$.

In other words, no matter how dissimilar two things may be in most respects, they share some property or other – in fact a number of properties. This is one of the reasons that all things can be studied scientifically (with the help of the scientific method) – the other reason being that they are all studied by beings equipped with similar neurosystems. Caution: this is not to conclude, with mechanism and animism alike, that all things have the same properties, only in varying degrees – as Whitehead (1929) and Teilhard de Chardin (1964) believed.

If, for the sake of expediency rather than truth and depth, we assign all properties the same weight, then we can define a quantitative concept of degree of similarity provided we restrict ourselves to the subset of the known properties of a thing (to avoid division by infinity):

DEFINITION 2.16 The *degree of similarity* between two entities $x, y \in S$ relative to a finite subset $\mathbb{B}$ of $\mathbb{P}$ [such as, e.g., the genetic similarity or the cultural similarity of two human populations] is

$$s(x, y) = \frac{|\sigma(x, y) \cap \mathbb{B}|}{|(p(x) \cup p(y)) \cap \mathbb{B}|}.$$

This is none other than the simple matching coefficient used in numerical taxonomy to estimate the distance between biological species (Sneath and Sokal, 1973). Because $\mathbb{B}$ is a finite set, $s(x, y)$ can be zero or it can be equal to unity. For example, the degree of genetic similarity between any two cells of a single organism equals 1. But by taking $\mathbb{B}$ to be a big enough set of properties we obtain a smaller value of s.

The above concepts of similarity can be generalized to whole sets of entities, namely as follows. Let $x_1, x_2, \ldots, x_n$ be the members of a finite set T of entities. Then the *similarity among the members of* T is defined as

$$\sigma(x_1, x_2, \ldots, x_n) = \bigcap_{x_j \in T} p(x_j)$$

and the corresponding degree of similarity as

$$s(x_1, x_2, \ldots, x_n) = \frac{|\sigma(x_1, x_2, \ldots, x_n)|}{\left|\bigcup_{x_j \in T} p(x_j)\right|}.$$

However, we shall not employ the last two concepts.

The notion of dissimilarity is mathematically more interesting than its dual. We define it thus:

DEFINITION 2.17 Let $\delta: S \times S \to 2^{\mathbb{P}}$ be the function such that

$$\delta(x, y) = p(x) \mathbin{\Delta} p(y) \quad \text{for any} \quad x, y \in S,$$

where 'Δ' designates the symmetric or Boolean difference. $\delta(x, y)$ is called the *dissimilarity* between x and y.

By Definitions 2.15 and 2.17, the relation between δ and σ is

$$\delta(x, y) = p(x) \cup p(y) - \sigma(x, y).$$

The function δ is a set valued distance function, hence $\delta(x, y)$ should be a good measure of the "distance" between x and y in the space of properties. More precisely, we have

THEOREM 2.4 The dissimilarity function δ is a set valued distance function in a one dimensional space: for all $x, y, z \in S$,

(i) $\varnothing \subseteq \delta(x, y) \subset \mathbb{P}$;
(ii) δ is symmetric: $\delta(x, y) = \delta(y, x)$;
(iii) $\delta(x, y) = \varnothing$ iff $x = y$;
(iv) $\delta(x, y) \mathbin{\Delta} \delta(y, z) = \delta(x, z)$.

Proof The first part is obvious from the definition. (ii) is a consequence of the symmetry of Δ. (iii) follows from $p(x) \mathbin{\Delta} p(x) = \varnothing$. Conversely, by

Postulate 2.5 if $p(x)\,\Delta p(y)=\varnothing$ then $x=y$. (iv) follows upon replacing the LHS of (iv) by the definiens:

$$(p(x)\,\Delta\, p(y))\,\Delta\,(p(y)\,\Delta\, p(z))=p(x)\,\Delta\, p(y)\,\Delta\, p(y)\,\Delta\, p(z)=$$
$$=p(x)\,\Delta\, p(z).$$

By taking the cardinality of the dissimilarity and normalizing it to unity we obtain a quantitative concept of dissimilarity:

DEFINITION 2.18 Take a finite subset of the set of all the properties of two entities $x, y \in S$. Then their *degree of dissimilarity* is

$$d(x, y)=\frac{|\delta(x, y)|}{|p(x)\cup p(y)|}.$$

The values of d, just as those of the degree of similarity s, are bounded by 0 and 1. It can be shown that d is a metric, hence a good measure of the distance between entities in respect of their properties. (Needless to say, there is no relation, other than a mathematical similarity, between this distance and a spatial distance.) That is, one can prove

THEOREM 2.5 The structure $\langle S, d\rangle$, where d is the degree of dissimilarity, is a metric space.

Extreme difference is sometimes called *opposition*. This concept is elucidated by

DEFINITION 2.19 Two entities are *opposite* to one another iff their similarity is nil.

But, according to Theorem 2.3, all things share some properties. Hence we have

THEOREM 2.6 There are no opposite entities.

Opposition, when it exists, is relative to a proper subset of properties. Moreover only "positive" properties should count: the mere absence of a property is not to be equated with the opposite of that property. For instance dark is not the opposite of illuminated, as the former is nothing but the absence of illumination. Real opposition, when it exists, is active and consists in having contrary effects. Moreover real opposition does not exist between utterly different entities. For example two animals of the same species may fight over the same pool of water, or the same prey, or the same female, precisely because they have similar drives.

This point deserves a few more examples. In an electric circuit the self-inductance initially opposes the action of the impressed electromotive force, so that the two aspects are mutually opposed in their effects on the overall current. Likewise if a substance A promotes the synthesis of a protein while A' inhibits it, then A and A' may rightfully be regarded as opposites with regard to protein synthesis no matter how much they resemble in other respects – and they do since both can act on the given protein. Likewise in a mammal the sympathetic and the parasympathetic systems oppose one another in the sense that they check each other: when one of them excites a given organ the other inhibits the latter. But even this opposition is not complete, as there is also some cooperation between the two systems. And in any case this interaction ensues in homoeostasis or equilibrium not in qualitative change (such as the breakdown of the main system) – whence it does not illustrate dialectics.

In sum, although *some* pairs of things do have parts and features that are mutually opposed in *limited* respects, no thing is composed of absolute opposites. Consequently the thesis of dialectical ontologies, that *every* thing is a synthesis or unity of opposites (in what respects?) is, if intelligible at all, false. Moreover the assumption that there are absolute opposites contradicts the materialist thesis, incorporated into our system, that all things – no matter how different – share some properties precisely by virtue of being entities. Besides, the thesis that all things are unities of opposites entails the infinite divisibility of every single entity into two mutually opposed entities, since every part should in turn be a synthesis of opposites – and there is no empirical evidence for this consequence. The most we can assert is that there are relative opposites, i.e. things with features that oppose one another in their effects. But this timid thesis can hardly serve as a cornerstone of a philosophical cosmology. (More on dialectics in Bunge, 1975.)

The upshot of this subsection is this. Although by Postulate 2.5 every entity is unique in some respect(s), all entities are similar in some other respect(s). Shall we then say that all entities are alike and aren't? Not at all: 'alike' (or 'similar') is a syncategorematic term or, if preferred, a vague notion that should be qualified by the expression 'in the respect(s) P'. The complete expression 'x and y are alike (similar) in the respect(s) P' is no longer vague, hence it does not lead us to contradiction. It is moreover compatible with 'x and y are dissimilar in the respect(s) Q, where $Q \neq P$'. In other words 'similar' is not an attribute word on the same footing as 'alive': it is an incomplete or partial attribute word – though not more so than 'blue' or 'heavy'. Hence the need for replacing wherever possible the relation $\sim$ of similarity by the function σ or by the function d.

3.6. *Indiscernibility*

We hold that there are no two identical entities – yet it is common experience that some things are indiscernible or indistinguishable. There is no contradiction here, as two different concepts of difference are involved: the *ontological* concept of (objective) difference on the one hand, and the *epistemological* (or pragmatic or psychological) concept of (subjective) differentiability, or discernibility, or ability of somebody to distinguish empirically, e.g. by observation. Two entities may be indistinguishable to a given subject equipped with certain means of observation but may become discernible to the same subject using improved equipment. (The concept of resolving power of a microscope or of a telescope presupposes the difference between objective difference and perceived difference.)

We must therefore distinguish between factual difference and empirical difference or discernibility. This will require roping in a notion that, strictly speaking, we have no right to use systematically since it will be introduced in Volume 4, Ch. 10, namely that of a cognitive subject. Therefore we shall not number the definitions that follow.

DEFINITION. Let $\mathbb{P}_s \subset \mathbb{P}$ be a proper subset of the totality of substantial properties, and s a cognitive subject in a given state and equipped with certain cognitive means (instruments, theories, etc.). Then for $x, y \in S$, x and y are *indiscernible* (indistinguishable) *to* s iff x and y are the same in every respect $P \in \mathbb{P}_s$ known to s. Notation: $x \sim_s y$.

The terms 'indiscernibility' and 'indistinguishability' have been misused at several critical points. *Example 1* Leibniz himself stated his principle (our Postulate 2.5) in an equivocal manner, namely by writing that "il n'y a point dans la nature deux êtres réels absolus indiscernables", and calling this the *principium identitatis indiscernibilius*. As Russell (1900) saw, all Leibniz intended to affirm is "that any two substances [things] differ as to their predicates [properties]". Leibniz cannot have intended to state that if two things are indiscernible then they are identical, for he was well aware of the marvels of microscopy.

Example 2 The logical principle of substitutivity is sometimes called the *principle of the indiscernibility of identicals* – another obvious mistake. Consider: the principle holds that if b has P, and if $b = c$, then P is true of c as well. It has become fashionable to claim that this principle fails in the so-called "intensional contexts" and thus doubts are cast on the truth of Leibniz' ontological principle (our Postulate 2.5). For example, it is clear that "Smith doubts that $x = y$" does not entail "Smith doubts that $x = x$". The rejoinder is that, if Smith doubts that $x = y$, then he will be well advised to abstain from applying it the principle of substitutivity. And, if a principle is not applied, it runs no risks. Anyway this has nothing to do with indiscernibility. *Example 3* In microphysics one assumes that particles of the same kind and in the same state (i.e. with no intrinsic differences) count as equal or equivalent and so can be exchanged both in fact and in the calculations. This assumption is usually cast with the term 'indistinguishable' replacing 'equal' or 'equivalent' – as if the particles could care about our ability to discern among them. The fact is that we do distinguish among them by their extrinsic (spatiotemporal) properties and so are able to count them. See Figure 2.3. In other words, the truth of the matter is that the "elementary particles" are distinct and often distinguishable in practice, but (a) they can be counted as equal or equivalent and (b) when constituting certain wholes they surrender part of their individuality. (See Ch. 5, Sec. 4.2 for the partial loss of "identity" of things when they become components of a system.) In short, Postulate 2.5 is confirmed by microphysics. Plato (*Phaedo* 74a–75c), Leibniz (1704, Ch. XXVII), and Bolzano (1851, Sec. 50) were right in assuming it.

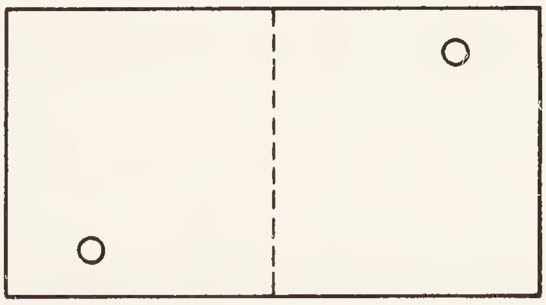

Fig. 2.3. Two electrons in a box: exchangeable if in the same state, yet distinct and distinguishable (discernible). I.e. their exchange has no effect on the states of the system as a whole. But it can happen precisely because the particles are distinct.

Indiscernibility is a special kind of similarity (see Sec. 3.5). Hence, unlike identity, indiscernibility is not transitive. Therefore it does not generate equivalence classes. Instead, indiscernibility generates indiscernibility spaces, also called tolerance spaces (Zeeman, 1962; Schreider, 1975). These spaces have interesting topological properties and occur in the study of perception. We shall take a quick look at them, starting with

DEFINITION A *tolerance space* $\langle T, \sim_s \rangle$ is a set $T \subset S$ of entities together with an indistinguishability (indiscernibility) relation $\sim_s$ on T.

Example Let T be the collection of entities in the visual field of a subject s (in a given state) and let $\sim_s$ be the visual acuity tolerance for the same subject, i.e. (extensionally) the collection of pairs of entities that s cannot distinguish visually from one another. The structure $\langle T, \sim_s \rangle$ is a tolerance space.

The topology of a tolerance space is determined by the collection of neighborhoods defined by

DEFINITION The *vicinity* of an entity $x \in S$ is the collection of entities indistinguishable from x:

$$N(x) = \{ y \in S | y \sim_s x \}$$

Any given set of entities can be covered by such neighborhoods. (Clearly no topology generated in this way is Hausdorff. Hence it has little if any interest in the study of physical space.) What holds for individual entities holds for aggregates of such since these, too, are entities. That is, we could define tolerance spaces for sets of aggregates of entities. But we cannot define indistinguishability between sets of things, except of course conceptual indistinguishability which is the same as identity. Hence most of the results on tolerance spaces obtained by Zeeman (1962) have no application to reality. A case in point is the theorem according to which if $\langle T, \sim_s \rangle$ is an indistinguishability space so is $\langle 2^T, \sim_s \rangle$. In fact we do not perceive or fail to perceive the elements of 2^T, for they are sets.

4. PROPERTIES OF PROPERTIES

4.1. *Identity and Difference of Properties*

How can property identity be characterized, i.e. under what conditions can two properties be said to be the same? We shall begin by examining, and eventually rejecting, two seemingly natural solutions to this problem – only to end up by declaring the problem itself to be ill conceived.

Suppose properties were conceived of in a nominalistic fashion, i.e. as collections of individuals, or of n-tuples of such (recall the Introduction). Then identical properties would be those possessed by exactly the same individuals (cf. Wilson, 1955). That is, every equivalence class $[P]$ of concomitant properties (Definition 2.11) would be just a singleton. But this proposal is not viable, for it obliterates the difference between properties with equal scope, hence between coextensive though not cointensive attributes, such as "fluid" and "viscous", or "living" and "mortal". Hence here as elsewhere nominalism is a failure.

A second possibility that suggests itself is to adopt a paraphrase of Leibniz' law of individual identity (Postulate 2.5), namely this: "Two properties are the same just in case they have the same (second order) properties". Unfortunately we do not know exactly what a second order property might be. We know only what a second order *attribute* or predicate is – namely one that applies to first order predicates and obeys some system of second order predicate logic. Therefore the logical criterion of attribute identity does not help us out.

Our theory of properties concerns only properties of individuals, hence it does not contain a definition, let alone a criterion, of property identity. This is just as well, for nobody needs such a definition and such a criterion. In science, as in everyday life, one uses properties to individuate entities, not the other way around. Therefore one characterizes the identity (or the difference) of things, namely by Postulate 2.5.

For the above reasons the discussions on property identity in the current philosophical literature are wrong headed hence sterile. Moreover they are sloppy because they are not conducted in the context of a full fledged theory of properties. Let us therefore turn to some genuine problems, and in the first place to the problem of the identity of attributes.

The latter problem is genuine and manageable, if only because we manufacture attributes ourselves. Roughly, the criterion of attribute identity is this: "Two attributes are the same iff they are the same (propositional) function and are assigned the same interpretation". Function identity is not enough because one and the same function may be assigned any number of inequivalent interpretations. To obtain a full characterization of an attribute representing a given substantial property we must append the semantic assumption (or "correspondence rule") telling us what property of which entities the given predicate represents.

A more precise characterization of attribute identity is obtained with the help of our theory of meaning (Vol. 2, Ch. 7). In the latter two predicates are the same just in case they have the same sense and the same reference class. If the predicate happens to belong to a definite closed context, such as a scientific theory, then its sense is defined as the union of its principal ideal and its principal filter. And in any case the reference class of a predicate equals the union of the sets occurring in its domain. Therefore two predicates are the same just in case (*a*) the unions of their respective principal ideals and filters coincide, and (*b*) their domains are the same. In sum, we have

CRITERION 2.3 Two attributes (predicates) are the same iff they have the same sense and the same referents.

Needless to say, two predicates are different just in case they are not the same. Moreover their precise difference can be computed with the help of Definition 7.13 in Vol. 2, Ch. 7.

So much for the pseudoproblem of the identity of properties.

4.2. *Property Weight*

Aristotle saw that not all properties are equally weighty and classed them into essences and accidents. He erred of course in reducing essences to the four basic elements, in regarding them as absolute and unchanging, and in believing change (in particular motion) to be just as accidental as location. Galilei discarded the Aristotelian essences for being unknowable and, by investigating the modest but knowable *accidentia* and their lawful interrelations, changed the face of science. (See Shea, 1972, pp. 70–72.)

Although modern science rejects the essence/accident dichotomy it does not brush aside the very distinction between essential and accidental properties. Far from levelling properties it recognizes that some are necessary for others (Sec. 3.3); moreover, it assumes that there are, as it were, degrees of necessity. So much so that, whenever one sets up a theoretical model of a concrete entity, he tries to seize on its salient properties discarding all others as inessential – at least until further notice. Thus the ontological hypothesis that properties have different weights underlies the strategy of model building.

Where theories are scarce but data plentiful, statistical measures of property weight can be used. The most obvious candidate is of course the coefficient of linear correlation. With its help the following measure of relative property weight can be defined. (Cf. Blalock, 1961.) Let P, Q, and R be properties such that R depends (statistically) upon P and Q. Then

$$P \text{ is } \textit{weightier} \text{ than } Q \text{ for } R \text{ iff } |r_{PR}| > |r_{QR}|,$$

where r_{AB} is the linear correlation coefficient between A and B.

As soon as precise functional dependences among variables can be assumed, a more precise and stable measure of relative property weight can be established. Thus if F is a differentiable function of n variables x_i, where $1 \leqslant i \leqslant n$, each of these "independent" variables contributes its own share to F. An obvious measure of the contributions of x_i to F (or of the weight of x_i relative to F) is

$$w(x_i, F) = \int_{D_i} dx_i \left| \frac{\partial F}{\partial x_i} \right|$$

where D_i is the domain of x_i.

Regardless of the precise mode of computation of property weights, they fall under

DEFINITION 2.15 Any function $w: \mathbb{P} \times \mathbb{P} \to [0, 1]$ such that, for all P, Q, $R \in p[T]$, where $T \subset S$,

(i) $w(P, P) = 1$ for all P;

(ii) if P precedes (is necessary for) Q, then $w(P, Q) \geqslant w(Q, P)$;

(iii) if P and Q are incompatible [by Definition 2.4], then $w(P, Q) = = w(Q, P) = 0$;

(iv) if P and Q are concomitant [by Definition 2.11], then $w(P, Q) = = w(Q, P) \neq 0$;

(v) for any given $P \neq Q$, $\sum_{Q \in \mathbb{P}} w(P, Q) = 1$;

(vi) $\ulcorner w(P, R) > w(Q, R) \urcorner$ is interpreted as P being weightier than Q for R,

is called a *property weight*, and its value $w(P, Q) \in [0, 1]$ the *weight* of P relative to Q.

What about essential properties? The traditional answers are:

(i) *nominalism and conventionalism*: there are no essential properties;

(ii) *essentialism*: every entity has some properties which are essential, all others being accidental.

The former doctrine is at odds with the practice of science, where one does not assign all properties the same weight but regards some of them as basic and the others as derived. (For example, some chemical properties are steric, i.e. shape-dependent. And some biological properties depend upon the chemical composition.) As for classical essentialism, it contains a grain of truth – namely the recognition that not all properties are removable tags – but it fails in conceiving of accidents as unimportant and lawless. And the latest version of essentialism, namely modal essentialism (cf. Teller, 1975), is useless because it revolves around the vague notion of necessity elucidated in modal logic – the metaphysical inanity of which will be shown in Ch. 4.

Our own brand of essentialism, which may be called *nomological essentialism*, boils down to the following points:

(i) An essential property is, by definition, one that, far from being stray, participates in some law. (On the other hand an accidental property is a nonessential property.) Now, by Postulate 2.7, all properties participate in some laws. Hence *all properties are essential* – which is to say lawful. In other words there are no accidental properties.

(ii) Although there are no accidental properties, there are *attributes* accidental in a given context. Thus the price of gold is accidental from a chemical point of view, not so from a financial point of view.

(iii) Every law of an entity is a property of it (in the extended sense clarified in Sec. 3.3), hence it is an essential property of the entity.

(iv) The real divide is not the nonexisting distinction between *essentia* and *accidentia* but that between *basic* and *derived* properties. This distinction is inherent in the very notion of property precedence: P is *basic to* Q iff $P \preccurlyeq Q$, or $\mathscr{S}(Q) \subseteq \mathscr{S}(P)$. But if P is basic to Q then P is also basic to the law $\ulcorner \mathscr{S}(Q) \subseteq \mathscr{S}(P) \urcorner$.

Nomological essentialism has the following advantages over its rivals: (*a*) it is consistent with a full fledged theory of properties; (*b*) it fits in with the practice of science; (*c*) it discourages the popular view that the essence of a thing is a part of it, namely its unchanging inner core – which core proves in most cases to be imaginary; and (*d*) it puts an end to the medieval dispute (revived by existentialism) concerning whether essence is prior to existence or conversely.

4.3. *Resultants and Emergents*

Let us return to a consideration of properties in general, such as having red blood cells, rather than individual properties, such as having so many red blood cells at a given moment. Some properties may be called *bulk* or *global* properties because they characterize an entity as a whole. Bulk properties are of two kinds: resultant and emergent (Lewes, 1879). Energy is a resultant or hereditary property in the sense that it is possessed by every part of a thing. On the other hand being stable, being alive, having a certain structure, and undergoing a social revolution, are emergent or nonhereditary properties because they are not possessed by every component of the whole: see Figure 2.4. Accordingly we are justified in proposing

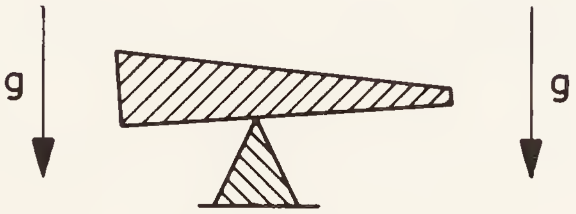

Fig. 2.4. A lever supported by a wedge in equilibrium in a gravitational field. Being in equilibrium is a property of the system as a whole.

DEFINITION 2.16 Let $P \in p(x)$ be a property of an entity $x \in S$ with composition $\mathscr{C}(x) \supset \{x\}$. Then P is a *resultant* or *hereditary property* of x iff P is a property of some components $y \in \mathscr{C}(x)$ of x other than x; otherwise P is an *emergent* or *gestalt property* of x. That is,

(i) P is a *resultant* or *hereditary* property of $x =_{df} P \in p(x) \;\&\; (\exists y)(y \in \mathscr{C}(x) \;\&\; y \neq x \;\&\; P \in p(y))$;

(ii) P is an *emergent* or *gestalt property* of $x =_{df} P \in p(x) \;\&\; (y)\neg(y \in \mathscr{C}(x) \;\&\; y \neq x \;\&\; P \in p(y))$.

Mechanism and individualism assume all properties to be hereditary or resultant, hence explainable by reduction, as is the case with the total charge on a body or the total consumption of goods in a society. We follow instead the tradition of the Greek atomists in recognizing the existence of emergent properties. But, unlike holism, we regard emergents as rooted in the properties of the components, hence as explainable in terms of the latter, though not by reduction to them. For example, temperature is explainable as average kinetic energy of the molecules, but this does not exemplify reduction because averages, though *computed* from individual values alone, are collective properties. Were this not so it would make sense to attribute a temperature value to an individual molecule and a social structure to a person – but it does not. Likewise the cohesiveness of a society can be explained in terms of the participation of its members in a number of social cells but it is societal property not an individual one. These remarks can be generalized into

POSTULATE 2.9 Some of the substantial properties of all composite things are emergent, and all of the emergent properties of a whole are preceded by properties of some of its parts:

(i) $(x)(x \in S \ \& \ \mathscr{C}(x) \supset \{x\} \Rightarrow (\exists P)(P \in p(x) \ \& \ P \text{ is emergent}))$

(ii) $(x)(x \in S \ \& \ \mathscr{C}(x) \supset \{x\} \Rightarrow (P)((P \in p(x) \ \& \ P \text{ is emergent}) \Rightarrow (\exists y)(\exists Q)(y \in \mathscr{C}(x) \ \& \ Q \neq P \ \& \ Q \in p(y) \ \& \ Q \preccurlyeq P)))$.

Whereas the first clause should warm the hearts of holists, the second should cool it. In fact, whereas (i) asserts that some bulk properties are emergent, (ii) suggests that emergents are analyzable – though not reducible. In other words, whereas some bulk properties (the hereditary or resultant ones) are eliminable (definable) in favor of microproperties, others are not – yet in either case they are analyzable or explainable. Let us emphasize that, whereas (ontological) reducibility entails (epistemological) analyzability, the converse is false. There is epistemic novelty in the formation of attributes representing emergent (ontological) novelty. Nor does the explanation of emergence involve the elimination of ontological novelty: a mountain is not explained away when explained as composed of atoms. Explained emergence is still emergence.

4.4. *Properties of Properties*

Every predicate has a number of properties – second order predicates. The n-arity of a predicate is such a second order predicate. Properties such as this one belong in the very definition of the predicate. A second order property of a different kind is that exemplified by the predicate "mechanical predicate". By this one means a predicate, such as the mechanical stress tensor, occurring exclusively in mechanical theories. Such properties are then dependent upon the mode of division of intellectual work. In either case a property of a predicate is a construct not a property of a concrete object.

What about substantial properties: does every such property have properties, and do the latter represent features of a concrete individual? Consider a couple of examples. First: the weight of an organism has the property that it varies in time. But this is just a way of saying that organisms have a *variable weight*, and this is a property of theirs not a second order property. Second: the specificity peculiar to enzymes is (believed to be) a steric property, i.e. one deriving from the shape of the enzyme molecule. But this is just to say that molecule *shape precedes specificity* – and this is a law concerning enzymes, i.e. a first order property.

We make bold and generalize: While every predicate has some (second order) predicates, there is no such thing as a second order substantial property. Whatever we predicate of substantial properties is a predicate – a construct or artifact. (Of course some such predicates are attributed truly and others not, but this is a different story.) This is just as well, for otherwise the symbol '$p(x)$' could not designate the set of *all* properties of x.

5. STATUS OF PROPERTIES

5.1. *The Reality of Properties*

We have tacitly regarded all substantial properties as real, though not as autonomously real, or real in themselves, i.e. apart from the individuals possessing them. More precisely, we have implicitly employed

DEFINITION 2.17 A property P is *real* $=_{df}$ There is at least one individual $x \in S$, other than the null individual, that possesses P (equivalently: $\mathscr{S}(P) \neq \varnothing$).

This definition applies not only to intrinsic properties (represented by unary predicates) but also to mutual properties (represented by n-ary predicates). Thus to say that a certain relation R is real amounts to saying that there are R-related entities or substantial individuals. (Cf. Bolzano, 1837, Sec. 80.5.) We do not assign intrinsic properties a greater ontological weight, or a higher degree of reality, than mutual properties. Thus a mutual property like gravitational interaction (or a certain parent-child mutual action) is just as real as an intrinsic property such as composition (whether chemical or social).

Surely the above view is not the only possible one. Essentially the following doctrines concerning the reality of properties have been put forth:

(ia) *Properties, whether intrinsic or mutual, are real, nay supremely real, and individuals only exemplify them.* (This generalizes Plato's original doctrine of forms, all of which were unary.) This view is untenable, as a property is null unless it is possessed by some individual. Consider in particular a mutual property represented by a binary predicate R. The extension of R is the set of ordered pairs $\langle x, y\rangle$ such that x bears R to y. If the extension is empty, i.e. if R has no examples, then R happens to be the null relation – the one that fails to hold.

(ib) *Whereas intrinsic properties are real, mutual properties are not.* This thesis seems to find support in ancient logic and ancient grammar, with their insistence that all predicates are unary. In turn, this view may spring from a spontaneous tendency to deal with things separately rather than in their mutual relations. It was vehemently defended by Bradley (1893) and still has defenders among those philosophers who regard, say, "South of the Canadian border" as a "spurious property". The thesis has recently been revived in the proposal to split a relation, or arc of a graph, into two demiarcs and a junction or glue – without of course any attempt at characterizing mathematically either of these alleged components (Harary, 1971). Needless to say, the thesis is indefensible and, if adopted, would kill science, which consists largely in an endeavour to disclose connections. And it would render metaphysics quite uninteresting, as it would force us to conceive of reality not as an aggregate of systems but as a mere collection of disconnected individuals. This borders on

(ii) *All properties, whether intrinsic or mutual, are unreal: only individuals are real.* This is of course the nominalist thesis and the exact dual of the generalized Platonist thesis (ia). According to it a property, if intrinsic, is identical with a collection of individuals and, if mutual, is nothing but a collection of ordered n-tuples. This view is muddled: the examples of a relation, i.e. the individual n-tuples, are characterized by their being related. The relata constitute the extension or graph of the relation, not the relation itself. (More against the extensionalist identification of predicates with sets in Vol. 1, Ch. 4, Sec. 1.2, and Vol. 2, Ch. 10, Sec. 1.2.)

(iii) *Neither properties nor individuals are independently real.* Some individuals and some properties constitute things, their states and their changes of state – the only realities. In the fact that *thing b pulls thing c* what is real is neither of the three items separately but the fact as a whole. Only in pure mathematics does one find (or rather create) individuals bereft of all relations, namely the members of structureless sets. And again only in pure mathematics can one maintain that either the individuals or the relations (in particular the functions) constitute the basic objects out of which everything else can be built. Thus set theory takes the view that individuals and collections of such are basic, everything else being reducible to them; and category theory starts on the other hand from the functions which the individuals happen to satisfy. Neither point of view carries over to ontology: here we must regard individuals as well as their properties as so many abstractions. The real thing is the substantial individual with all its intrinsic and mutual properties. Everything else is fiction. Needless to say we champion this third position and do it on the strength of its being inherent in science. Indeed, science has no use for either propertiless individuals or properties that happen not to be properties of substantial individuals.

What holds in general for relations holds in particular for polarities, or relations among polar opposites such as source and sink. A pole is a constituent of a polarity, which in turn is an even degree relation such as a binary interaction between particles differing only in the sign of their electric charge. By definition then poles come in pairs or, generally, in 2 n-tuples: there are no monopoles. (The expression 'electrical monopole', applied to an electrically charged body, is a misnomer.) Therefore it is mistaken to claim that the existence of any one pole renders its partner possible (Stiehler, 1967, pp. 15, 17). However, we shall not set much store by polarity – a pitfall of archaic metaphysics – since most polarities are imaginary: in fact most of them are just not pairs of opposites and others arise from reifying negation. Thus quantity-quality, one-many, subject-object, appearance-reality, and mind-body are not pairs of opposites but of differents. Others, like being-nothingness, identity-difference and the like are genuine pairs of opposites but have no ontic status. Indeed nonbeing does not oppose being except logically, hence they cannot fight except metaphorically. Likewise the opposition between identity and difference is conceptual not a "struggle of opposites". In both cases the confrontation is strictly logical: A "versus" non-A. Which brings us to the important difference between two kinds of relation: binding and nonbinding.

The relation of being greater (or older or richer or worse) than is "external" to its relata in the sense that it does not alter them and does nothing to keep them together or even apart. Similarly with all the spatiotemporal relations such as those of contiguity, betweenness, precedence, and simultaneity: they do not affect their relata. In general, all comparative (order) relations and all equivalence relations are of this kind, i.e. nonbinding. Not so the hydrogen bond or a relation of economic bondage or of cultural influence: these "make a difference" to the individuals so related: they are in a way "internal" to them. This distinction, ignored by Hume and his followers, was pointed out by Peirce (c. 1909, 6.318), who wrote of "existential relations" or relationships in contrast to mere relations. It was also a favorite with Whitehead (1929) and Woodger (1929) who called them 'organic relations' although they also hold among parts of a machine.

Binding relations, i.e. those that "make a difference" to the relata, may be characterized as follows. Two entities $x, y \in S$ are *bound* (or *connected* or *coupled*) iff some changes in x are accompanied (or preceded or followed) by some changes in y. This must be considered a preliminary elucidation, since we do not yet have any exact concept of change. (See Ch. 5, Sec. 4.1.) Nevertheless the previous characterization should suffice to draw the attention to the two main types of substantial mutual property and to avoid some mistakes.

One mistake stemming from overlooking the above distinction concerns the relation between being connected and being a part. Clearly any two things with a common part are connected. But this is a very special kind of connection: overlapping is sufficient but not necessary for connection. Hence, *pace* Leonard and Goodman (1940), and Feibleman and Friend (1945), things need not overlap in order to be coupled. For example, the feudal baron and his serf are connected without having any common part. Another mistake worth warning against is the belief that, since logic does not discriminate between binding relations and nonbinding relations, it ought to be augmented with ontic or physical predicates (Lewis, 1946, pp. 218 ff.). This is not necessary: we may take off the rack any of the n-ary predicates found ready made in logic (and in mathematics) and endow it with the appropriate ontological interpretation. In general it is not advisable to try and supplement logic with ontology: these two disciplines have very different goals and methods, and a single logic should underly all the varieties of ontology.

5.2. *A Critique of Platonism*

The Platonic doctrine of properties is, in a nutshell, the following: (*a*) form is self-existent, ideal, and external to matter, and (*b*) form precedes matter and can take on individuality, or be realized (exemplified) in particulars. Thus a white thing is said to "participate" in the universal Whiteness – or, as logic teachers are still fond of saying, a white individual *instantiates* the predicate Whiteness. (Aristotle corrected this doctrine by denying the autonomy of forms and holding that matter develops form but, to him, the formless substance was real not just a useful fiction as it is for us.) This theory of forms lingers on in a number of contemporary scholars. While only a few (notably Castañeda, 1974) are avowed Platonists most of them would be surprised to learn that they have adopted the least reputable of all of Plato's teachings. Here are a few examples of Platonism picked at random in recent publications.

(*a*) The biologist Paul Weiss (1963) invokes a super-ordinating "principle" hovering above the molecules that make up a cell and regulates it.

(*b*) E. W. Sinnot (1963, p. 194), another biologist, writes that "Form consists of *relations* among particles, or orderly patterns in them. (...) It is a category of being very different from matter, for it is not the nature of the material particles themselves that is involved, but rather how they are related to one another. Form may disappear and appear, as order yields to randomness or comes again, but matter (in its widest sense, as matter-energy) is conservative, moving toward uniformity and maximum entropy".

(*c*) Nobel laureate Werner Heisenberg (1969, pp. 324–325) states: "'In the beginning was Symmetry' – this is surely truer than the Democritean thesis 'In the beginning was the particle'. The elementary particles embody the symmetries, they are the simplest representations of the latter but they are just a consequence of the symmetries".

(*d*) The philosopher U. J. Jensen (1972) has claimed that mental phenomena are not particulars but universals, hence unmeasurable.

A related view is that properties, far from being separate from things, constitute the latter: a thing would be a bundle of qualities – hence a noun could be decomposed into a pack of adjectives. This view, a thoroughly monistic doctrine of form, has been held by the following contemporary thinkers:

(*a*) Russell (1940 p. 98) wrote: "Common sense regards a 'thing' as having qualities, but not as defined by them; it is defined by spatio-temporal position. I wish to suggest that, wherever there is, for common sense, a 'thing' having the quality *C*, we should say, instead, that *C* itself exists in that place, and that the 'thing' is to be replaced by the collection of qualities existing in the place in question. Thus '*C*' becomes a name, not a predicate".

(*b*) A. I. Ujomov (1965, p. 17) states: "The thing is a system of qualities". And the parts of a thing are not parts of space but "parts of a system of qualities" (p. 18).

(*c*) G. Falk (1966, I, p. 77): "A body moving with velocity v is, according to dynamics, nothing but a certain momentum p and a certain amount of energy $\varepsilon = \varepsilon(p)$ that are transported through space with the velocity v". (Disregard the heresy of identifying a function with an arbitrary value of it.)

(*d*) H. Hiż (1971) too has held that any entity can be identified with the set of its properties and moreover that "an individual may be construed as a set of properties of an individual" – pardon the circularity.

Both the Platonic doctrine of forms and the view that things are bundles of qualities are muddled and therefore neither can be formulated exactly. Organic forms are forms *of* organisms; particle and field symmetries are symmetries of properties *of* things (e.g. of their hamiltonians or of their basic laws); a kind of mental phenomena is a class of *individual* mental phenomena; a thing is *characterized* by its properties but not identified with or defined by them, if only because some of its properties are shared by other things; and a set of properties may be used to sketch or model a thing but it does not *replace* the latter. In sum let us heed Ockham's injunction: *Do not detach forms from particulars* – e.g. speak not of Motion but of moving entities. (Or, if you do employ the concept of motion, construe it as the set of moving things.) Likewise let us speak not of Life but of living things, not of Mind but of sensing and thinking things, and so on. Firstly because there is not a shred of empirical evidence for the hypothesis that forms are detachable from their carriers. Secondly because every property is conceptualized as a function defined on some set of entities. (Recall Postulate 2.1 in Sec. 2.1.)

5.3. *The Problem of Universals*

The problem of universals boils down to the questions: What are universals and how do they exist if at all? This problem looks now rather different from what it looked like in the Middle Ages. Indeed we have come to realize that, before rushing to propose an answer such as that universals exist *ante rem* (Platonism), *in re* (Aristotelianism), or *post rem* (nominalism), we should clarify the question itself. To do this we shall define the concept of a universal or rather two radically different concepts of universal in tune with the methodological dualism we adopted in Ch. 1, consisting in splitting every set of objects into entities (S) and constructs (C). Indeed we shall distinguish the *substantial universals*, or widespread properties of entities, from the *conceptual universals* – among them the predicates representing the former. This distinction is introduced explicitly by

DEFINITION 2.18 Let $A \in \mathbb{A}$ be an attribute, $P \in \mathbb{P}$ a property, and T a set. Then

(i) A is a (*conceptual*) *universal* in the set $T \subset C$ of constructs iff the extension of A equals T:

$$A \text{ is } \textit{universal} \text{ in } T =_{df} \mathscr{E}(A) = T,$$

(where the extension function is defined in Vol. 2, Ch. 9 of this *Treatise*);

(ii) P is a (*substantial*) *universal* in the set $T \subset S$ of entities iff the scope of P equals T:

$$P \text{ is } \textit{universal} \text{ in } T =_{df} \mathscr{S}(P) = T.$$

These notions of a universal are then relativized to a set of objects. And since nothing is said about the cardinality of this set, the above definition does not allow one to distinguish a "genuine" universal such as womanhood from an idiosyncrasy such as being the 20th president of México. One might of course try to improve on this situation by introducing a quantitative concept of degree of universality. A suitable candidate for finite sets would be the function characterized by

DEFINITION 2.19 Let $P \in \mathbb{P}$ be a substantial property and $T \in \mathscr{P}(S)$ a nonempty finite set of substantial individuals. Then the *degree of universality* of P in T is the value of the function

$$u\colon \mathbb{P} \times \mathscr{P}(S) \to [0, 1] \text{ such that } u(P, T) = \frac{|\mathscr{S}(P)|}{|T|},$$

where $|A|$ designates the numerosity of A.

This concept would allow one to overcome the primitive dichotomy of the universal and the particular. Still, this more refined concept does by itself not solve the ontological and epistemological problem of universals. To begin with the so called *formal properties of things*, such as number and shape, appear to be full fledged conceptual universals inherent in concrete entities and thus defy the substantial/conceptual dichotomy assumed in Definition 2.18. Thus numerosity is a property of any collection whatever the nature of its components. True, but then a set is a concept. Surely dogs are normally four legged, this being a substantial property of theirs. The corresponding mathematical property is the cardinality of the set of legs of a dog. In other words four leggedness is a substantial property to be distinguished from the mathematical property of the set of legs of a quadruped. The relation between the predicate and the corresponding property is that of representation: the former represents the latter in the case we are considering. Likewise when we say that the history of a person is uninterrupted we do not assign the person a formal property but choose the mathematical property of continuity (a conceptual universal) to represent the smoothness (or absence of gaps) in a sequence of states of an entity. To sum up: not things but our models of them have mathematical properties, and this because we conceptualize substantial properties as functions. This mode of representation is so deeply ingrained in our habits of thought that we often mistake the deputy for his constituency.

In the medieval dispute about universals only conceptual universals seem to have been considered by both the "realists" (Platonists) and the nominalists. In that context we would have sided with Ockham (ca. 1320 I, C.xvi): "nothing is universal except by signification, by being a sign of several things". The conceptual universal "humanity" is not in the individual Socrates but in our idea of him. Of course Socrates is human: he has a property that is universal in the class of humans. This is what the Aristotelians replied: humanness, as a substantial universal, "inheres" in every human being. (In our terminology: the scope of the substantial property of humanness is mankind.) In sum substantial universals (properties and in particular laws) are *in re*. On the other hand conceptual universals (predicates) are *entia rationis*: they are *post rem* if they happen to represent substantial universals preexisting knowledge, and *ante rem* if they anticipate experience or action.

Our theories of substance (Ch. 1) and form (present chapter) allow us to see a further aspect of the problem of universals in a different light, namely the particular/universal dichotomy. First of all this dichotomy, when legitimate, is conceptual not real: the world contains neither bare particulars nor pure forms. Substance and form, individual and universal, are distinct aspects of our conceptual analysis and theoretical modelling of things and facts. Lacking an independent existence, they are not mutually reducible. That is, universals are not collections of particulars (nominalist reduction) and particulars are not bundles of universals ("realist" reduction). The nominalism-"realism" issue, though *de facto* not dead, is finished *de jure*: neither contender was completely right because each focused on just one aspect of the situation while ignoring the other. And each side is done justice by our representing every substantial property by a predicate, and construing the latter as a function from individuals to statements.

Moreover the individual/universal dichotomy, valid and so useful in first order logic, may collapse elsewhere. *Example 1* Sets are neither individuals nor universals – unless they occur as members of a collection of sets, in which case they become individuals, without however the family being a universal. (A nonempty set is constituted by individuals but this does not make it into a universal, much less an individual.) However, some sets are determined or defined by universals (predicates) via the scope function or the principle of abstraction. *Example 2* Some "universals", such as "the set contained in every set", are instantiated by a single object (in this case the empty set). Why call them 'universals' if they are unique? *Example 3* One and the same object can now be regarded as an individual, now as a set (or as a concrete collection). There is nothing final about being an individual. *Example 4* To say that b is an individual is saying too little: what are the properties of b? And saying that P is a property is just as little: what individuals does P apply to, i.e. what is its scope?

The upshot of the preceding discussion is this: Platonism is not a viable metaphysics any more than nominalism is. It might be contended that, though unsuitable as an ontology of substantial individuals, Platonism is the correct philosophy of mathematics because "mathematics has no need for non-classes, like cows or molecules; all mathematical objects and relations can be formulated in terms of classes alone" (Mendelson, 1963, p. 160). This, it is sometimes claimed, is why the von Neumann–Bernays–Gödel version of set theory deals only in classes and sets. Yet (a) the basic predicate of this theory, namely the membership relation, is not construed as a class, and (b) the individuals of the theory are, precisely, sets and classes (as pointed out by Bernays, 1937). Moreover one needs properties even in pure mathematics as soon as one becomes interested in particular sets, i.e. in characterizing them rather than in handling them indiscriminately (i.e. in general) as set theory does. Just think of characterizing, say, the interior of a circle of a given radius without using any predicate. Finally, even if mathematicians one day succeed in producing a mathematics using only classes, metaphysics is likely to continue using the notions of individual and of property if only because both are essential to science: scientific research involves finding out the properties of individuals. Not even the most sophisticated reconstruction of a scientific theory could eliminate properties in favor of classes if only because distinct properties can have the same scope. Nor could it succeed in eliminating individuals, because properties are properties of individuals or of sets of such.

6. CONCLUDING REMARKS

To summarize. There is but one world, denoted □, and it is composed of entities or substantial individuals, i.e. members of the set *S* introduced at the outset (Ch. 1). Every entity is either simple or composite. And every entity has a certain number of properties in addition to its composition. For example a lump of copper, i.e. an entity composed of Cu atoms, is malleable, shiny, melts at 1083 °C, is a good conductor of electricity, is rather scarce, its ore is coveted by all industrial powers, and so on. These are systemic properties of the nonhereditary or emergent kind; on the other hand having a mass and being capable of moving are hereditary properties of a lump of copper, i.e. properties shared by its atomic components.

A substantial property may also be called a *physical* property, in the largest possible sense of 'physical', and in contrast to a conceptual item such as an attribute or predicate. Thus being feathery must be distinguished from the attribute(s) or concept(s) representing featherhood or denying it (e.g. 'featherless'). Firstly because every property is representable by at least one attribute. Secondly because some attributes (in particular the negative and the disjunctive ones) represent no substantial property at all.

Further, there are no properties or forms fluttering over substantial individuals: there are only propertied entities, such as feathery animals. And properties, far from coming either in isolation or in amorphous droves, form clusters and drag one another. That is, every property is either necessary or sufficient for some other properties of the same entity. I.e., there are laws. And these laws are complex properties of entities or, rather, of entire kinds. So much so that they determine the natural kinds. But this is a subject for the next chapter.

CHAPTER 3

THING

So far we have dealt largely with fictions: entities deprived of most of their properties, and forms without a definite stuff. However, we warned that these are fictions and anticipated that they would enable us to construct the notion of a real thing as a fully qualitied individual. This is indeed what a concrete or material object, such as a radio wave or a person or a society is: namely an entity endowed with all its properties, both intrinsic and mutual, permanent and transient.

In the present chapter we shall deepen our study of the concept of a substantial individual and shall investigate in particular the following problems. One of them concerns the characterization of the states of a thing. We shall use the results of this investigation in our treatment of the problem of change in general, to be tackled in Ch. 5. Another question to be dealt with in this chapter is this: What groups different things into natural kinds or species?

Surely the objects we are concerned with "exist in space and time", as the obsolete formula has it. (We shall argue in Ch. 6 that concrete things constitute space and time.) However, we shall still disregard all of the spatiotemporal characteristics of things, characteristics which will be taken up in Ch. 6. Moreover we shall not particularize any properties: that is, our concept of a concrete object, or thing, will apply to a community just as well as to an electron. Finally we shall defer to Vol. 4, Ch. 7 the study of the particular things known as systems. In fact our definition of the system concept will employ the notion of a thing we proceed to elucidate.

1. THING AND MODEL THING

1.1. *Thing*: *Definition*

We stipulate that a thing is an entity or substantial individual (Ch. 1) endowed with all its (substantial) properties (Ch. 2). As may be recalled (Definition 2.3 in Ch. 2, Sec. 3.2) the totality of properties of a substantial individual $x \in S$ was called

$$p(x) = \{P \in \mathbb{P} | x \text{ possesses } P\},$$

where $\mathbb{P}$ is the collection of substantial (nonconceptual) unarized properties.

It may also be remembered that, although we identify or spot any concrete individual by its properties, it is impossible to define an entity as the set of its properties, if only because the expression 'Entity $p(x)$ possesses property P which is a member of $p(x)$' makes no sense. A final caution: although usually a proper subset of $p(x)$ will suffice to *distinguish* x from other entities, nothing short of the totality $p(x)$ of properties of x will *constitute* and *individuate* it, i.e. render it ontically distinct from every other entity. In fact by Postulate 2.5 and its corollary in Ch. 2, Sec. 3.2, what makes a thing what it is, i.e. a distinct individual, is the totality of its properties: different individuals fail to share some of their properties.

The preceding considerations suggest introducing

DEFINITION 3.1 Let $x \in S$ be a substantial individual and call $p(x) \subset \mathbb{P}$ the collection of its (unarized) properties. Then the individual together with its properties is called the *thing* (or *concrete object*) X:

$$X =_{df} \langle x, p(x) \rangle.$$

When referring to a fully qualitied entity, i.e. a thing, we shall often write '$X \in \Theta$' or simply '$x \in \Theta$', where Θ is characterized by

DEFINITION 3.2 The *totality of things* is called Θ:

$$\Theta =_{df} \{\langle x, p(x) \rangle | x \in S \ \& \ p(x) \subset \mathbb{P}\}.$$

This concept of a thing synthesizes the notions of substance and of form studied in Chs. 1 and 2 respectively. We might of course have proceeded the other way around, i.e. starting from things and analyzing them into bare individuals and bunches of properties. But this alternative would have violated the norm that enjoins us to build out of simple units and it would have broken the line of progress we intend to follow.

It might be objected that, since an ordered pair is often defined as a set of sets, namely thus: $\langle a, b \rangle = \{\{a\}, \{a, b\}\}$, our definition of a thing does not retrieve the idea that a thing is a particular. However, it is well known that an ordered pair need not be analyzed and defined as a set but may be characterized as an individual satisfying the single axiom:

$$\langle a, b\rangle = \langle a', b'\rangle \text{ if and only if } a = a' \text{ and } b = b'.$$

Besides, there need be no similitude between a definition and the thing defined. After all, Definition 3.1 characterizes a concept of a thing rather than being the "real definition" of a thing. More on this in Sec. 1.3. And now we turn to some assumptions and a few more definitions.

1.2. *Assumptions*

Our first assumption will be that there are things and indeed infinitely many and moreover a whole continuum of them:

POSTULATE 3.1 The totality Θ of things is an uncountable set.

Remark 1 From a mathematical point of view it would have been more natural to postulate the cardinality of the set S of bare individuals introduced in Ch. 1. That of Θ would have followed because of the one to one correspondence between the two sets. But since bare individuals are fictitious it seemed preferable – from a metaphysical point of view – to assume as little as possible about them. *Remark 2* That an existence hypothesis must be either affirmed or denied explicitly at this point, is shown by the existence of subjective idealism, according to which there are only mental states – or, according to a recent version, just propositions (Fitch, 1971). *Remark 3* Another reason for having to postulate the existence of things is that, if we want to prove anything about existents, we must posit them. We cannot prove the existence of concrete things any more than we can prove the existence of deities or of disembodied minds. What can be proved is that, unless there were things, other items – such as acting on them and investigating them – would be impossible. *Remark 4* That the hypothesis $\ulcorner \Theta \neq \varnothing \urcorner$ is true, is suggested by the fact that all of the factual sciences adopt it tacitly: far from doubting the existence of all things, they take some of them for granted, hypothesize others, and investigate them all. *Remark 5* That the infinity of things is nondenumerable is suggested by the existence of physical continua, such as gravitational fields, all parts of which are fields themselves. Even if the world were to consist of a single particle surrounded by its own gravitational field, it would contain a nondenumerable infinity of things, namely all the parts of the field, which – according to our present knowledge – is infinitely divisible. But of course such a world would contain no detachable parts. *Remark 6* The quantization of a field does not alter the situation: not the field itself but the set of its quanta is denumerable. And even in the absence of quanta a residual or background field remains, namely the one corresponding to the vacuum state. (The latter is not nought.) *Remark 7* The postulated existence of a nondenumerable infinity of things is compatible with the controversial hypothesis that they are organized in a finite number of systems – the only chance for the universe to be spatially finite. But we are not committing ourselves on this point which belongs to Ch. 6 anyhow. In the hypothetical example mentioned in Remark 5 the system is of course the single particle accompanied by its gravitational field.

Having defined the concept of a thing (Definition 3.1) we now define that of the juxtaposition or physical addition of things:

DEFINITION 3.3 Let $X = \langle x, p(x)\rangle$ and $Y = \langle y, p(y)\rangle$ be two things. Then the *juxtaposition* of X and Y is the third thing

$$Z = X \dotplus Y = \langle x \dotplus y, p(x \dotplus y)\rangle.$$

Note that we are not assuming that the properties of the whole are all and only those of the parts, i.e. that $p(x \dotplus y) = p(x) \cup p(y)$. This assumption would be false if only because the compound $x \dotplus y$, for $x \neq y$, has the property of being composed of x and y, which its parts fail to have.

Next we posit that the association theory expounded in Ch. 1, Sec. 1 carries over to things, and we use the symbol '$\dotplus$' to denote the association or juxtaposition of things. More precisely, we lay down

POSTULATE 3.2 Let Θ be the totality of things, $\Box$ a distinguished element of Θ, and $\dotplus$ a binary associative operation in Θ. Then the following holds by stipulation:

(i) $\langle \Theta, \dotplus, \Box\rangle$ is a commutative monoid of idempotents – for any x, y, z in Θ, $x \dotplus y = y \dotplus x$, $x \dotplus (y \dotplus z) = (x \dotplus y) \dotplus z$, $x \dotplus x = x$, and $x \dotplus \Box = \Box \dotplus x = x$;

(ii) $\dotplus$ represents the association or juxtaposition of things;

(iii) the string $x_1 \dotplus x_2 \dotplus \dots \dotplus x_n \in \Theta$, where $n > 1$, represents the concatenate of things x_1 to x_n;

(iv) the neutral element $\square$ of the monoid is the null thing or nonentity – i.e. not a thing proper.

We can retrieve for things everything we defined or proved for bare individuals (or things deprived of their properties other than the property of associating and the properties, such as composition, derived from associability). In particular we can make

DEFINITION 3.4 Let $x, y \in \Theta$ be things. Then x is a *part* of y iff $x \dotplus y = y$. Symbol of the part-whole relation: $\sqsubset$.

Our next assumption is

POSTULATE 3.3 There exists a thing such that every other thing is part of the former. That thing is unique and we call it *the world* or ▯.

Since the world is a thing, and indeed the biggest of all, $x \dotplus \text{▯} = \text{▯} \dotplus x = \text{▯}$.

Because the juxtaposition $x \dotplus y$ includes x and y as parts (by Definition 3.4), the former is the supremum of x and y with respect to $\sqsubset$, i.e., $sup\ \{x, y\} = x \dotplus y$. This remark allows one to prove the analogue for things of Theorem 1.4, namely

THEOREM 3.1 The totality of things has the semilattice structure. More precisely, $\langle \Theta, \dotplus, \square, \text{▯} \rangle$ is a semilattice with least element $\square$ and last element ▯.

The generalization of the notion of concatenation or juxtaposition to an arbitrary set $T \subseteq S$ is that of $sup\ T$. But the existence of this element has got to be assumed:

POSTULATE 3.4 For any subset T of Θ, its supremum $[T]$ exists.

This hypothesis allows us to make

DEFINITION 3.5 The *aggregation* of a set $T \subset \Theta$ of things, or $[T]$ for short, is the supremum of T with respect to the part-whole relation, i.e. the thing such that

(i) $x \sqsubset [T]$ for all $x \in T$;

(ii) if $y \in T$ is an upper bound of T, then $[T]$ precedes y: i.e. if $x \sqsubset y$ for all $x \in T$, then l.u.b. $T \equiv sup\ T = [T] \sqsubset y$.

Remark Just as Postulate 3.2 contained the statement that every finite association of things is a thing (clause (iii)), so the previous definition tells us, among other things, that every association or juxtaposition, whether finite or infinite, yields a thing. This is no ontological triviality: magicians claim to be able to create things out of nothing and to annihilate other things. And some emergentist philosophers believe that certain types of aggregation ensue in objects transcending the realm of things.

The previous assumptions and definitions entail

COROLLARY 3.1 Every part of a thing is a thing:

$$\text{If } x \sqsubset y \text{ and } y \in \Theta, \text{ then } x \in \Theta.$$

Proof The part-whole relation has been defined for things only – not e.g. for concepts – so the assertion that $x \sqsubset y$ is a tacit recognition that both x and y are things.

Remark Nor is this result self evident. Think of the claim that the constituents of ordinary self existents are not things existing autonomously but are the outcome of certain cognitive acts (such as measurements) performed by experimenters with the help of things of a special kind (pieces of apparatus).

Finally we state a consequence of the previous Corollary 3.1 and Postulate 3.3:

COROLLARY 3.2 Every part of the world is a thing:

$$\text{For every } x\text{: If } x \sqsubset \Box \quad \text{then} \quad x \in \Theta.$$

It follows by contraposition that whatever is not a thing fails to be part of the world. But this matter borders on the next subsection.

We close this subsection with two notes of caution. The first is that the world $\Box = [\Theta]$ does not have all the properties of each of its parts: for example, it does not spin, it does not interact with other things, it is not alive, and it has no mind. Indeed, by using Definitions 3.1 to 3.3 we find that

$$\Box = \langle [S], p([S]) \rangle$$

where, in accordance with the warning following Definition 3.3,

$$p([S]) \neq \bigcup_{x \in S} p(x).$$

The second note of caution is that the statement that two or more things form an aggregate satisfying Postulate 3.2, is a factual statement, i.e. one concerning matters of fact. However, this does not render it falsifiable. If any of the clauses of the postulate – e.g. commutativity – should fail, we would conclude not that the postulate has been refuted but that the things of interest have not formed an aggregate. (Equivalently: the resulting thing does not satisfy our axiomatic definition of an aggregate.) For example, if a catalyzer, such as an enzyme, acts on two different reactants, it may happen that it binds faster with one of them than with the other, so that the order in which the three things join does make a difference. But of course this order is temporal, and so has nothing to do with associativity.

1.3. *Thing and Construct*

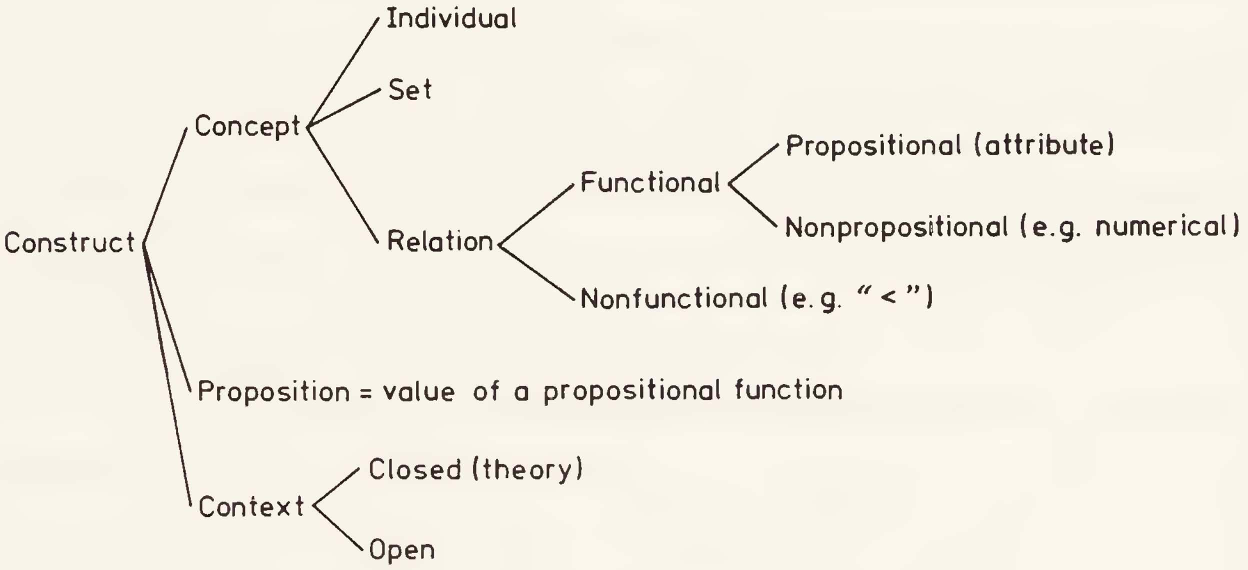
In the previous chapters we have distinguished objects of two kinds: substantial or concrete entities, and constructs. It is now time to sharpen somewhat this distinction – a matter that will be taken up again in Sec. 4.3. To this end we shall start by outlining the concept of a construct, leaving its detailed study to the sciences of constructs, namely logic, semantics, and mathematics.

We feign that there are constructs, i.e. creations of the human mind to be distinguished not only from things (e.g. words) but also from individual brain processes. (Only, we do not assume that constructs exist independently of brain processes.) We distinguish four basic kinds of construct: concepts, propositions, contexts, and theories. Concepts, such as the notion of a thing, are the building blocks of propositions – such as 'All things change' – which are in turn the constituents of contexts – such as the set of all propositions concerning dogs – and of theories.

Basically a concept is either an individual (such as "3" in elementary arithmetic), or a set (such as the set of integers), or a relation (such as "<"). Whether either category is reducible to the other will not concern us here. The most interesting relations are the functions, which are either many-one or one-one relations. We distinguish two kinds of function: propositional and nonpropositional. A propositional function, or predicate, or attribute, is a function that maps some domain of individuals (or n-tuples of such) into some set of propositions. (Recall Ch. 2, Sec. 2.1.) A nonpropositional function takes values in a set other than a set of propositions. (However, every nonpropositional function may be paired off to a propositional function. For example the sine function, which maps reals into reals, is a nonpropositional function that can be assigned the propositional function

$$\begin{aligned}&\text{Sin}: R \times R \to P, \quad \text{where}\\ &\text{Sin}(x, y) = (\sin x = y) \quad \text{for} \quad x, y \in \mathbb{R},\end{aligned}$$

P being the set of all propositions containing the predicate Sin.) Finally, a context is a set of propositions sharing a reference class, and a theory is a context closed under the operation of deduction. In sum we have the following classing:



Individual
Set
Concept
Propositional (attribute)
Functional
Construct
Relation
Nonpropositional (e.g. numerical)
Nonfunctional (e.g. "<")
Proposition = value of a propositional function
Closed (theory)
Context
Open

Constructs do not have all the properties of things. For example sets add and intersect but do not aggregate, do not move around, have no energy and no causal efficacy, etc. Constructs, even those representing things or substantial properties, have a conceptual structure not a material one. In particular, predicates and propositions have semantical properties, such as meaning, which is a nonphysical property. We summarize and extrapolate:

POSTULATE 3.4 Every object is either a thing or a construct, no object is neither and none is both.

Equivalently: Every set O of objects splits into two disjoint sets, one of things, the other of constructs. In the simplest nontrivial case, the set O of objects contains but one thing ϑ and one construct, namely $\{\vartheta\}$. That is, $\Theta = \{\vartheta\}$, $C = \{\{\vartheta\}\}$, $O = \{\vartheta, \{\vartheta\}\}$. Clearly, $\Theta \cap C = \varnothing$.

Substantial individuals devoid of properties, and substantial properties apart from the individual things possessing them, rank as constructs. Likewise a change in properties apart from every changing thing, and a change in an individual apart from a change in its properties, are fictions, i.e. members of some C.

Postulate 3.4 is an axiom of *methodological dualism.* It does not commit us to metaphysical dualism: we are not claiming that there are two kinds of thing, the *res extensa* and the *res cogitans*, or things proper and ideas. We take it that constructs, whether useful or idle, scientific or mythical, are fictions not entities. Hence they are not part of the real world even when they take part in our representations of the latter.

Moreover the preceding postulate entails that each category of objects, Θ and C, has its own peculiarities but does not preclude the possibility that they share some properties. For example some constructs concatenate just like things, and many things are just as thinkable as constructs. However, these two properties are mutual not intrinsic. Intrinsic properties are either of things or of constructs. On the other hand a mutual (e.g. binary) property can link things with constructs. An example of a mutual property of this kind is that of representation, such as it occurs in the statement ⌜Proposition p represents thing b⌝.

The totality of objects has no property other than that of being the union of the class of things and that of constructs. Therefore ontology cannot be construed as the theory of the arbitrary object, or of all objects: there is nothing to be said about O beyond what has just been said. This does not preclude the possibility of making long discourses about the ability to think of all objects, for when so doing we employ binary predicates such as "representing" or "thinking of", which are not subject to the above restriction.

Another obvious consequence of the preceding considerations is that concrete objects (things) have no intrinsic conceptual properties, in particular no mathematical features. This last statement goes against the grain of objective idealism, from Plato through Hegel to Husserl, according to which all objects, in particular material things, have ideal features such as shape and number. What is true is that some of our *ideas* about the world, when detached from their factual reference, can be dealt with by mathematics. (For example, by analysis and abstraction we can extract the constructs "two" and "sphere" from the proposition "That iron sphere is composed of two halves".) In particular, mathematics helps us to study the (mathematical) form of substantial properties. In short, not the world but some of our ideas about the world are mathematical.

Any construct that violates Postulate 3.4 will be declared *metaphysically ill formed.* The attribution of conceptual properties to things, and the attribution of substantial properties to constructs, are in the category of metaphysically ill formed statements. Examples of such metaphysical misfits are ⌜A body is a point set⌝ and ⌜The empty set is grey⌝. Likewise the thesis that a thing is identical with the set of its properties (i.e. $\vartheta = p(\vartheta)$) is metaphysically ill formed because it entails attributing substantial properties to a set, as shown by the following example. Let $p(\vartheta) = \{\text{Drunkard, Cantankerous}, \ldots\}$. Identifying this obnoxious individual with his properties leads to attributing drunkenness, cantankerousness, etc., to the set {Drunkard, Cantankerous, ...}. It could be argued that some metaphysically ill formed statements, such as ⌜Santa Claus has a white beard⌝ and ⌜Number three is perching on a branch⌝ are meaningful in certain contexts. But they do not belong in the body of factual knowledge and it is a matter of indifference whether or not they can be assigned truth values in certain contexts, such as fairy tales – e.g. possible worlds metaphysics.

Let us now turn to a special kind of construct, namely the conceptual sketch or model of a thing.

1.4. *Model Thing*

Theoretical science and ontology handle not concrete things but concepts of such, in particular conceptual schemata sometimes called *model things.* Our construal of a thing as a substantial individual together with the set of all its properties (Definition 3.1) is of course such a model thing – albeit a rather poor one. A richer characterization of a thing is given by a set equipped with specified relations, such as functions or operations. For example, if the thing represented is a force field, then the set will be a portion of a geometrical manifold M – e.g. a region in Euclidean three space – together with a tensor field F on M. Briefly, $\langle M, F\rangle \triangleq$ field. We shall adopt this mode of representation by making

DEFINITION 3.6 Let $X = \langle x, p(x)\rangle$ be a thing of class $T \subseteq \Theta$. A *functional schema* X_m of X is a certain nonempty set M together with a finite sequence $\mathbb{F}$ of nonpropositional functions on M, each of which represents a property of T's. Briefly,

$$X_m =_{df} \langle M, \mathbb{F}\rangle, \text{ where}$$
$$\mathbb{F} = \langle F_i \mid F_i \text{ is a function on } M \;\&\; 1 \leqslant i \leqslant n < \infty\rangle.$$

The base set M will be denumerable or nondenumerable, as the case may be. It may or may not be thought of as mapped on a subset of physical spacetime. (In systems theory M is usually taken to be a set of time instants.) As for the functions F_i in $\mathbb{F}$, every one of them refers to the individual $x \in T$ of interest and is thus evaluated at a fixed x in T even though it may be a function of whatever other variables may be the case. The finiteness of the set of components of $\mathbb{F}$ agrees with the part of Postulate 2.3 specifying that there are finitely many general properties (such as length or longevity). And it does not contradict the second part of that postulate, according to which $p(x)$ is nondenumerable for each $x \in S$. Indeed, recall that a single continuous general property, such as age, gives rise to infinitely many individual properties (such as successive ages) as the property in question takes its values. It might be objected that restricting the number of components of $\mathbb{F}$ is artificial since any function, even the constant function, can be decomposed into infinitely many functions, as is the case with Fourier series expansions. But such mathematical tricks have no ontological significance: they are purely conceptual.

Example 1 The simplest functional model of a corpuscle with variable mass is the classical mass point. Here $M = F \times T$, where F is the set of reference frames and $T = \mathbb{R}$ the real line, every point of which is interpreted as an instant of time. And $\mathbb{F} = \langle \mu, \pi, \varphi \rangle$ is a triple of functions on $M = F \times T$, such that $\mu(f, t)$ represents the mass, $\pi(f, t)$ the position, and $\varphi(f, t)$ the force acting on the corpuscle, relative to frame $f \in F$, at time $t \in T$. This functional schema of a particle is consistent with a number of alternative equations of motion (law statements), i.e. it can be shared by a number of different theories hinging on the same model object. *Example 2* A simple electrical model of the brain consists of a finite region of a four manifold (namely spacetime) together with a single function on it representing the electric potential. And a possible chemical model of the same thing is constituted by the same set together with n functions with domain on it, each of which represents the concentration of a given chemical at a given point in space and time.

Finally we assume that the set of functional schemata is nonempty and can grow indefinitely. That is, we lay down the following methodological

POSTULATE 3.4 Any thing can be modelled as a functional schema: For any $X \in \Theta$ there is at least one $X_m = \langle M, \mathbb{F} \rangle \in C$ such that $X_m \triangleq X$.

Remark 1 The failure to distinguish the thing represented from its model is not just a form of mental derangement: it is also at the root of black magic and subjectivism. The idealist who does not distinguish a thing from any of its models cannot account for the multiplicity of schemata of one and the same thing. Consequently he cannot understand the history of theoretical science, which consists partly in the replacement of some schemata by others. *Remark 2* Our characterization of a functional schema is consistent with current scientific practice. However, two notes of caution are in order. Firstly, more sophisticated modes of representation are conceivable, e.g. with the help of the concept of a category (cf. Padulo and Arbib, 1974). Secondly, sometimes a thing is *defined* as a certain relational structure, i.e. it is identified with one of its model objects. This is mistaken, for only (some) constructs can be defined: things can only be represented (or misrepresented), and occasionally also manipulated. But the mistake is harmless if we are aware of it. *Remark 3* Nominalists are bound to dislike our construal of a sketch or schema of an individual thing as a structured set: they may demand "individualism" for both the world and our conceptual representations of it. Thus Goodman (1956, p. 16): "Nominalism for me consists specifically in the refusal to recognize classes"; it "requires only that whatever is admitted as an entity at all be construed as an individual" (ibid., p. 17). (In particular it does not require the concrete/conceptual distinction (ibid., p. 16).) That demand is not met by science, so we can ignore it. *Remark 4* The set M, if infinite, may represent an actual infinity such as a gravitational field or some other continuum. Such an infinity will be looked at askance by Aristotelians and empiricists alike. On the other hand it will warm the hearts of Leibnizians. Thus Bolzano's *Paradoxien des Unendlichen* (1851) carried as a motto the following quotation from Leibniz: "Je suis tellement pour l'infini actuel, qu'au lieu d'admettre que la nature l'abhorre, comme l'on dit vulgairement, je tiens qu'elle l'affecte partout, pour mieux marquer les perfections de son auteur".

The various functional schemata of a given thing need not be equivalent: for example they may exhibit different amounts of structure. Thus a set whose elements are related pairwise is more structured, integrated, or tightly knit, than one whose elements have only unary properties. Moreover an amorphous set does not become structured by increasing the number of properties of its elements even though it does become more complex. (I.e. the more structured the more complex but not conversely.) This suggests measuring the amount of structure of a relational structure by the number and rank of the predicates included in it. A translation of this idea into our terminology is as follows:

DEFINITION 3.7 Let $X_m = \langle M, \mathbb{F} \rangle$ be a functional schema of a thing X and call the *rank* of $F_i \in \mathbb{F}$ the number of independent variables or argument places of F_i. Then the *amount of structure* of thing X exhibited by its functional schema X_m equals

$$\alpha(X_m) = \sum_k n_k (r_k - 1),$$

where n_k is the number of functions of rank r_k in $\mathbb{F}$.

Now, two relational structures, such as $X_m = \langle M, \mathbb{F} \rangle$ and $X'_m = \langle M', \mathbb{F}' \rangle$, are said to be *similar* iff $\mathbb{F}$ and $\mathbb{F}'$ have the same number of components and their corresponding components are of the same rank (Tarski 1954). In our terminology: two model things X_m and X'_m are *similar* iff their amounts of structure are the same, i.e. if $\alpha(X_m) = \alpha(X'_m)$. This notion suggests attributing the modeled things themselves the property of being similar:

DEFINITION 3.8 Let X and X' be two things modeled as $X_m = \langle M, \mathbb{F} \rangle$ and $X'_m = \langle M', \mathbb{F}' \rangle$ respectively. Then X and X' are *formally* (morphologically) *similar under the same modelings* iff their respective functional schemata X_m and X'_m are similar (i.e. if they exhibit the same amount of structure).

Remark 1 In particular, things described with the help of the same mathematical formalism are modeled similarly and can thus be declared to be similar – under the given modeling! (See Bunge, 1973a, Ch. 5.) However, since morphological similarity as defined above is not an intrinsic property of things but rather a property of pairs thing-model thing, we must be careful not to mistake the above concept for that of objective similarity introduced in Ch. 2, Sec. 3.5. Whereas the latter is an ontological concept the former is an ontological-epistemological one. *Remark 2* It goes without saying that things belonging to the same natural kinds – e.g. electrons, neurons, peasant societies – are represented by the same functional schemata. In particular, indiscernibles are representable by the same model things. In other words, for theoretical purposes we may treat indiscernibles *as if* they were identical – which of course they are not (cf. Ch. 2, Sec. 3.6).

So much for a preliminary characterization of model things, or sketches of things. We proceed to refine the notion of a functional schema of a thing, by taking a closer look at the n-component function $\mathbb{F}$. This will enable us to elucidate the notion of a state of a thing, a notion which will be crucial to our investigation of change in general.

2. STATE

2.1. *Centrality of the State Concept*

Every thing is – at a given time associated with a given reference frame – in some state or other. This is a hypothesis about the furniture of the world and, since it does not specify either the kind of thing or the kind of state, it is ontological. It is not a self evident assumption. For one thing it is rarely if ever formulated explicitly. For another the world might be constituted in such a way that the assumption be false. Moreover according to the classicist interpretations of the quantum theory the latter fails to assign definite states to its referents. But this is mistaken: the truth is that the theory does not assign its referents classical states such as sharp position and velocity values, but quantum states such as position and velocity probability distributions.

The ontological hypothesis that every thing is in some state or other underlies all science, has invaded philosophy, and has spilled over to ordinary knowledge, to the point that statesmen speak of the state of the nation. Each exact scientific theory is of course in a position to give a precise characterization of the concept of a state. But it will be concerned with a particular kind of state, such as the dynamical or the chemical or the physiological or the economic state of its referents, not with the generic concept of state of a thing. To elucidate the latter concept is the business of exact ontology, in particular of systems theory.

Surprisingly enough, systems theory has so far failed to give an exact and general enough analysis of the concept of the state of a system. To begin with the usual accounts (e.g. Zadeh and Desoer, 1963; Mesarović and Takahara, 1975; Padulo and Arbib, 1974) do not apply either to continuous systems such as fields or to quantum-mechanical systems. Moreover the concept of a reference frame has no place in those accounts, probably because it is not needed in automata theory, electrical network theory, and a few other theories. Yet the concept is central to many other theories. (Recall Example 1 in Sec. 1.4.) For example, it occurs in the explanation of the working of an electric motor – not to speak of the underlying theories of mechanics and electrodynamics. The notion of a reference frame is in fact so central in physics that the states of any real physical system are relative to some frame or other: just think of the state of motion of a body, or of the state of an electromagnetic field.

A second concept one misses in systems theory is that of a law. To be sure a general theory of things should neither presuppose nor contain any specific (e.g. thermodynamical or chemical or biological) law, for otherwise it would not be so general. (Equivalently, the systems it describes could not be realized in a number of alternative ways, in particular employing materials of different kinds – hence satisfying different laws.) However, the general concept of a law – the philosophic concept as distinct from a particular law statement such as Ohm's – ought to play some role in systems theory if only for a mathematical reason. Indeed, but for the laws – which place restrictions upon the ranges of the components of the function $\mathbb{F}$ occurring in any functional schema of a thing – we should accept the usual characterization of the collections of possible states (or state spaces) as vector spaces or even as inner product or metric spaces. The existence of laws ruins this characterization. In fact if a law restricts the range of a variable, as it usually does, then it is no longer true that the product of a variable by an arbitrary scalar belongs to the same space. In sum, not even the most general scientific theories – namely those that qualify also as metaphysical theories – have given satisfactory characterizations of the general concept of a state.

Nor have metaphysicians exactified the notion of state – nor, a fortiori, that of change of state. Not even the process metaphysics – such as those of Hegel, Bergson, Whitehead, and their numerous followers – have taken it upon themselves to clarify the notions of state and of change of state – although in science, at least, a process is a sequence of different states. Consequently those philosophers have bequeathed us obscure philosophies of change. Much the same holds for the fashionable possible worlds metaphysics: here the concept of state of a possible world is central, yet it remains undefined. Likewise the various systems of inductive logic employing the concepts of state and of state description fail to analyze them in a manner consistent with the concepts of state occurring in science.

Such a lack of analyses is deplorable if only because the concept of a state, hence the notions of a state description and of a change of state, pose interesting philosophical problems. For example, since every state of a thing is determined by a bunch of state variables for the thing, and since the choice of the latter is partly determined by the state of the art, what right do we have in assigning a thing an objective state portrayed by a state description? Another example: the so-called identity theory (or rather hypothesis) is usually formulated as stating the identity of mind and brain. Would the hypothesis not gain in precision by construing it as stating that mental states are states of the nervous system (or rather of subsystems thereof) and therefore mental events changes in the states of neuron assemblies? These and other philosophical problems call for, even before they are properly stated, an elucidation of the notion of a state of a thing. Let us therefore turn to this task.

2.2. *State Function*

Recall the notion of a functional schema $X_m = \langle M, \mathbb{F} \rangle$ representing a thing X (Definition 3.6). It consists of a set M and a list $\mathbb{F} = \langle F_i | 1 \leq i \leq n \rangle$ of n functions with unspecified domain M and equally unspecified codomains V_i. Each component $F_i : M \to V_i$ of $\mathbb{F}$ is supposed to represent a general property, or property of things of the kind to which X belongs. And each value of F_i for a particular entity at a point $x \in M$ is supposed to represent an individual property, or property of X. In Example 1 of Sec. 1.4 the function $\mu : F \times T \to \mathbb{R}^+$ represents the mass (a general property), and its value $\mu(f, t)$ represents the mass of the given corpuscle, relative to frame f, at time t. Unlike the F_i, which are property-representing "variables" (or rather functions), f and t are not "variables". They are arbitrary members of certain sets (F and T respectively) and they are not possessed by any thing in particular: on the contrary they are rather public in the sense that they can be "used" by a number of things.

The components F_i of the list $\mathbb{F}$ of functions in a functional schema are usually called *state variables* because their values contribute to characterizing or identifying the states the thing of interest can be in. We shall call them *state functions* because this is what they are. And we offer the following preliminary characterization: A function is a *state function* for a thing of a given kind if it represents a property possessed by the thing. Whether this representation is faithful (true) is immaterial to the function's qualifying as a state function. What is decisive is that the function refers to the thing and can be interpreted as representing or conceptualizing the intended property.

A few more examples should give a better feel for the concept of a state function.

Example 1 Qualitative global property: social structure. Let $F_i \triangleq$ social structure in ith respect (occupation, or income, or number of school years, or political power, or whatever). Call Σ the set of all social systems (communities or organizations) and $T \subseteq \mathbb{R}$ the set of instants. Further, call $\mathscr{C}(\sigma)$ the (atomic) composition of system $\sigma \in \Sigma$ at the person level, i.e. the set of individuals composing σ. Define on $\mathscr{C}(\sigma)$ a social equivalence relation $\sim_i$ as that which induces the partition of $\mathscr{C}(\sigma)$ into groups of people that are homogeneous in the ith respect (roughly the same occupation, or the same income, etc.). Call $\mathscr{C}(\sigma)/\sim_i$ such a partition. Then a social structure is a list $\mathbb{F}$ of n state variables of the form

$$F_i: \Sigma \times T \to \{\mathscr{C}(\sigma)/\sim_i | \sigma \in \Sigma\}.$$

Example 2 Population, a conspicuous biological and sociological variable, may be conceptualized as a state function

$$F: \Sigma \times T \to \mathbb{N}$$

from pairs $\langle$community σ of organisms of a kind, instant $t\rangle$ to the natural numbers $\mathbb{N}$. Each value $F(\sigma, t) = n$, for $n \in \mathbb{N}$, represents an individual property of σ, whereas the function F itself represents a general property, or a property of all the members of the set Σ.

Example 3 Quantitative stochastic property. Let $F \triangleq$ Momentum probability distribution. Here $M = \{q\} \times \{f\} \times \mathbb{R}^3 \times T$ and $V = \mathbb{R}$, where $q \in Q$ is a quantum-mechanical entity of kind Q, $f \in F$ a reference frame of kind F, and $\mathbb{R}$ the real line. The function $F: M \to V$ satisfies a certain law statement and '$F(q, f, p, t)\, dp$' is interpreted as "The probability that entity q, relative to frame f, at time t, possesses a momentum comprised between p and $p + dp$". (In rather common notation, $F = |\varphi|^2$, where φ is the Fourier transform of the state function ψ representing the position distribution.)

We are now ready for a general characterization of our concept:

DEFINITION 3.9. Let X be a thing modeled by a functional schema $X_m = \langle M, \mathbb{F}\rangle$, and suppose that each component of the function

$$\mathbb{F} = \langle F_1, F_2, \ldots, F_n\rangle: M \to V_1 \times V_2 \times \ldots \times V_n$$

represents a property of X. Then F_i, for $1 \leqslant i \leqslant n$, is called the *ith state function* for X, $\mathbb{F}$ the *total state function* for X, and its value

$$\mathbb{F}(m) = \langle F_1, F_2, \ldots, F_n \rangle (m) = \langle F_1(m), F_2(m), \ldots, F_n(m) \rangle$$

for $m \in M$ is said to represent the *state of X at m* – all this *in the representation X_m*. Furthermore, if all the V_i for $1 \leqslant i \leqslant n$ happen to be vector spaces, then $\mathbb{F}$ is called a *state vector* for X in the representation X_m.

Notice the cautious expression 'in the representation X_m'. The reason is that there is no such thing as the absolute state function for a given thing: indeed there are as many state functions as functional schemata of the thing can be conceived, i.e. any number of them. (For example, whereas lagrangian theories employ generalized coordinates and velocities as the basic state functions, hamiltonian theories choose generalized coordinates and momenta.) And even one and the same representation is compatible with infinitely many choices of systems of units, every one of which may ensue in a different state function.

The sole test for the adequacy of a choice of state functions is the adequacy (factual truth) of the theory as a whole, in particular that of its key formulas, which are those interrelating the various components of the total state function – namely the law statements and constraint formulas of the theory. Even so there may be alternative though basically equivalent formulations of one and the same theory. (For example, most field theories can be formulated using either field strengths or field potentials, and the latter are mutually equivalent modulo certain arbitrary constants or even functions.) In the case of equivalent theories there are no preference criteria other than those of computational convenience, or else heuristic power, or even sheer beauty or fashion.

To put it negatively: The choice of state functions is not uniquely determined by empirical data but depends partly on our available knowledge, as well as upon our abilities, goals, and even inclinations. This consideration will play an important role in any talk of states and state spaces, of which more in Sec. 2.4. But lest we have given the impression that the choice of state functions is totally arbitrary and a matter of sheer taste, let use hasten to add that whatever set of state functions be chosen, they are supposed to abide by certain law statements – and this is not a matter of convention. More on this in the next section.

Finally a point of mathematical detail. Typically the state functions for a given thing are defined on a single domain M. Think of the mass density, stress tensor, velocity field, entropy density, and the other "variables" concerning a fluid. Likewise the set of dynamical variables ("observables") of a quantum mechanical system are all operators on the Hilbert space associated with the system. However, it might happen that a given set of state functions for things of a given kind fail to be defined on the same domain. In this case a harmless trick will allow us to assign them all the same domain and thus comply with a tacit condition of Definition 3.9. Thus if

$$F_1: A \to B \quad \text{and} \quad F_2: C \to D, \quad \text{where} \quad A \neq C \quad \text{and} \quad B \neq D,$$

we can adopt the new state functions

$$\left.\begin{array}{lll} F_1': A \times C \to V_1 & \text{such that} & F_1'(a, c) = F_1(a) \\ F_2': A \times C \to V_2 & \text{such that} & F_2'(a, c) = F_2(c) \end{array}\right\} \quad \text{for all} \quad a \in A, c \in C.$$

But, as we noted before, it is unlikely that we shall ever have to make use of this artifice.

2.3. *Law Statements as Restrictions on State Functions*

In Ch. 2, Sec. 3.3, we gave an exact but not very illuminating definition of a law. Roughly, we stated that if P and Q are two properties of entities of a kind, then any inclusion relation between the scope of P and Q counts as a law. We are now in a position to offer a deeper analysis of the law concept, namely as a condition on certain state functions for some thing. Such conditions may take a number of forms, depending not only on the things themselves but also on the state of our knowledge. All of the following are conspicuous simple forms:

Example 1 Range of $F = V$, where F is a state function and V some well defined set. (Think of the relativistic restriction on the velocity values.)

Example 2 $\partial F/\partial t \geqslant 0$, where $t \in T$, and $T \subseteq \mathbb{R}$ occurs in the domain of F.

Example 3 Kinematical model of a thing (usually called dynamical system):

$$\frac{d\mathbb{F}}{dt} = \mathbb{G}(\mathbb{F}, t), \text{ with } \mathbb{G} \text{ a specific function.}$$

Example 4 Lagrangian model of a system:

$$\int_{t_1}^{t_2} dt\, F(q, \dot{q}, t) = \text{extremal, with } t_1,\ t_2 \text{ two selected elements of } T \subseteq \mathbb{R}.$$

Example 5 Field theoretic model of a system:

$$F_2(x, y) = \int_V du\, dv\, F_1(u-x, v-y), \text{ with } F_1, F_2\colon E^3 \times E^3 \to \mathbb{C}.$$

Example 6 Another model of the same genus:

$$\nabla^2 F_1 = F_2, \quad \text{with} \quad F_1, F_2\colon E^3 \to \mathbb{R}.$$

The preceding considerations suggest adopting the following characterization:

DEFINITION 3.10 Let $X_m = \langle M, \mathbb{F} \rangle$ be a functional schema for a thing X. Any restriction on the possible values of the components of $\mathbb{F}$ and any relation among two or more such components is called a *law statement* iff (i) it belongs in a consistent theory about the X's and (ii) it has been confirmed empirically to a satisfactory degree.

(It might be objected that, since we know whether a function is a state function only once we have satisfied ourselves that it occurs in some law statement, the above definition is circular. Not so, because we have not *defined* state functions in terms of law statements. All we have asserted is that lawfulness is a test or criterion of state functionality.)

If a law statement concerns a certain thing x, we call it $L(x)$, and we may call $\mathbb{L}(x) = p(x) \cap \mathbb{L}$ the totality of laws, or rather law statements, for x. Likewise we call $L(T)$ a law possessed by every thing in the set T, and $\mathbb{L}(T) = p(T) \cap \mathbb{L}$ the totality of laws "obeyed" by everything in T. This is not a mere matter of notation for, as we saw in Ch. 2, Sec. 3.3, laws are properties. And, being properties, they are representable as functions. Indeed, a law statement may be construed as the value of a certain function – a *law function* – with domain the class T of things concerned, and codomain the set of law statements of the form $L(x)$. In short,

$$\text{If } T \subset \Theta, \quad \text{then} \quad L\colon T \to L(T).$$

For example, Ohm's law for a battery-resistor circuit x (an individual of a certain class C) can be written

$$L: C \to L(C), \quad \text{where} \quad L(x) = \ulcorner e(x) = R(x) \cdot i(x) \urcorner$$
$$\text{for every} \quad x \in C,$$

where in turn e, R and i are real valued functions on C representing the electromotive force, the resistance, and the current intensity respectively. This manner of writing shows clearly that the laws are properties of things and some of them interrelate properties of things.

The same ideas can be represented in an alternative way that lends itself more easily to generalization, namely as follows. Consider again the set C of battery *cum* resistor circuits. As a state vector for things of this kind we may choose either the voltage-current pair or the voltage-charge pair. We pick the former:

$$\mathbb{F} = \langle e, i \rangle : C \to \mathbb{R} \times \mathbb{R} \quad \text{where } \mathbb{R} \text{ is the set of real numbers.}$$

This function assigns to each thing $x \in C$ the pair of real values $\langle e(x), i(x) \rangle$, in such a way that $e(x) = R(x) \cdot i(x)$, where $R(x)$ is a real number. We define now the first and second projections, G and H, of $\mathbb{F}$, as follows:

$$G: \mathbb{R} \times \mathbb{R} \to \mathbb{R}, \qquad H: \mathbb{R} \times \mathbb{R} \to \mathbb{R}$$

such that

$$\langle e(x), i(x) \rangle \overset{G}{\mapsto} e(x)$$

$$\langle e(x), i(x) \rangle \overset{H}{\mapsto} R(x) \cdot i(x)$$

$$\begin{tikzcd}
 & C \arrow[dl, "G \circ \mathbb{F}"'] \arrow[d, "\mathbb{F}"] \arrow[dr, "H \circ \mathbb{F}"] & \\
\mathbb{R} & \mathbb{R} \times \mathbb{R} \arrow[l, "G"] \arrow[r, "H"'] & \mathbb{R}
\end{tikzcd}$$

Since

$$(G \circ \mathbb{F})(x) = e(x) \quad \text{and} \quad (H \circ \mathbb{F})(x) = R(x) \cdot i(x),$$

Ohm's law now reads

$$G \circ \mathbb{F} = H \circ \mathbb{F},$$

i.e. as a statement of the identity of two function compositions.

The previous treatment carries over to any other situation where a fixed thing is being considered and the domain of the state function $\mathbb{F}$ is taken to be an arbitrary set M, such as the collection of all instants, or a portion of a certain manifold. We could multiply the examples, analyzing more and more complex cases, but this would not lead us very far. It is far more profitable to look into general frameworks for scientific theories, such as lagrangian and hamiltonian dynamics (for which see Bunge, 1967b) – but we must get on with the matter of states.

2.4. *State Space*: *Preliminaries*

Every theoretical model of a thing is concerned with representing the really possible (i.e. lawful) states, and perhaps also the really possible (lawful) changes of state, of the thing. A few typical examples should give us a feel for this matter.

Example 1 Let N be a set of neurons, or of nerve fibres, and suppose that each such unit can be in either of two states: *on* (firing) or *off* (not firing). That is, we can introduce a state function $F: N \to \{0, 1\}$ representing the neuronal activity, such that

$$\text{For each } n \in N, F(n) = \begin{cases} 1 & \text{iff } n \text{ is on} \\ 0 & \text{iff } n \text{ is off.} \end{cases}$$

The functional schema of the neural system is then $\langle N, F\rangle$ with N and F as described above. And the corresponding state space for each neuron $n \in N$ is $S(n) = \{0, 1\}$. If the neurons are regarded as mutually independent, the state space of the aggregate $[N]$ of neurons (i.e. the system of interest) is $S([N]) = \{0, 1\}^{|N|}$. Thus for a system composed of 3 neurons, the state space has 2^3 elements: $S = \{\langle 0, 0, 0\rangle, \langle 1, 0, 0\rangle, \langle 0, 1, 0\rangle, \langle 0, 0, 1\rangle, \langle 1, 1, 0\rangle, \langle 1, 0, 1\rangle, \langle 0, 1, 1\rangle, \langle 1, 1, 1\rangle\}$. *Example 2* In the genetics of populations, three state functions are often employed: the size N of a population, the probability p of some particular gene, and the latter's adaptive value v. Hence for a system composed of two interacting populations, A and B, the state space is the region of $\mathbb{R}^6$ spanned by $\langle N_A(t), N_B(t), p_A(t), p_B(t), v_A(t), v_B(t)\rangle$ in the course of time. *Example 3* In the elementary theory of the ideal gas, the state function is the triple pressure-volume-temperature functions. The corresponding state space is a cube contained in $(\mathbb{R}^+)^3$. *Example 4* In chemical kinetics the instantaneous state of a chemical system is described by the values of the partial concentrations of both reactants and products. Therefore the state space of the system is inside $(\mathbb{R}^+)^n$, where n is the number of system components (reactants, catalyzers, and products). *Example 5* In elementary electrostatics the state function is $\mathbb{F} = \langle \rho, \varphi\rangle$, where ρ represents the electric density and φ is the electric potential. Hence the local state of the given field is the value of $\mathbb{F}$ at $x \in E^3$, where E^3 is Euclidean three space. And the entire state space is the set of ordered couples $\{\langle \rho(x), \varphi(x)\rangle \in \mathbb{R}^2 | x \in V \subseteq E^3\}$, where V is the spatial region occupied by the field. *Example 6* In quantum mechanics the state of a system is represented by a one dimensional subspace (or ray) of the Hilbert space assigned to the system. Since a thing of this kind is typically not attributed a pointlike location but assumed instead to be spread over some spatial region $V \subseteq E^3$ (with a definite probability distribution), the state of the thing is the set of all values its state vector takes in V.

Before attempting to jump to any generalizations let us emphasize a point of method made in Sec. 2.2. We may certainly assume that, whether we know it or not, each thing – in particular each isolated thing – is in a definite state relative to some reference frame and at each instant (or else point in spacetime). Yet our *representation* of such a state will depend upon the state function chosen to represent the thing – which choice depends in turn upon the state of our knowledge as well as upon our goals. What holds for each single state holds a fortiori for the entire state space for a thing. That is, far from being something out there, like physical space, a state space for a thing stands with one leg on the thing, another on a reference frame, and a third on the theoretician (or modeller). To persuade oneself that this is so it is enough to take a new look at Example 5 above, where a reference frame at rest relative to the field source was assumed. If the system is now considered relative to a moving frame – moving, that is, with respect to the field source – a four vector current density will have to replace the single charge density, and a four vector potential will take the place of the single scalar potential. (Alternatively – and this is where the scientist's freedom comes in – the four potential can be replaced by an antisymmetric tensor representing the electric and magnetic components of the field relative to the chosen frame.)

Having emphasized the conventional ingredient of every representation of states, let us now stress that it has an objective basis as well. This can be seen from the existence of two different concepts of state space, one of which is more realistic than the other. Suppose we have settled on a certain total state function $\mathbb{F}$. If we form the cartesian product of the codomains of the various components of $\mathbb{F}$ (in tune with Definition 3.8), we obtain the codomain V of $\mathbb{F}$ itself, a set that will be called the *conceivable state space* for the thing represented. This is precisely what we did in the examples that sparked off this section.

However, a state function may not take values in its entire codomain but may be restricted to a subset of the latter, and this by virtue of some law. (Recall Sec. 2.3.) Therefore for every component of $\mathbb{F}$ our concern should be the range of it rather than its codomain. For example, the total population of organisms of a given kind in a given territory is constrained not only by the carrying capacity of the latter but also by the birth and death rates, as well as by additional factors such as sunshine and rainfall. Again, although the range of the speed function for a body is the entire real interval $[0, c)$, where c is the speed of light in a void, an electron traveling in a transparent medium will not come close to the upper bound c, for it is subject to further laws. In general: Only those values of the components of the total state function that are compatible with the laws will be really (not just conceptually) possible. In other words, because the laws impose restrictions upon the state functions and their values, hence upon the state spaces, only certain subsets of the latter are accessible to the thing represented. We shall call the accessible part of the state space the *lawful state space* of the thing in the given representation and relative to a given frame. (It is sometimes called the space of physical states: cf. Hirsch and Smale, 1974.) To say that a thing *behaves lawfully* amounts then to saying that the point representing its (instantaneous) state does not wander beyond the bounds of the state space chosen for the thing (See Figure 3.1).

2.5. *Definition of a State Space*

The preceding remarks can be summarized in terms of the concepts introduced in Sec. 2.3:

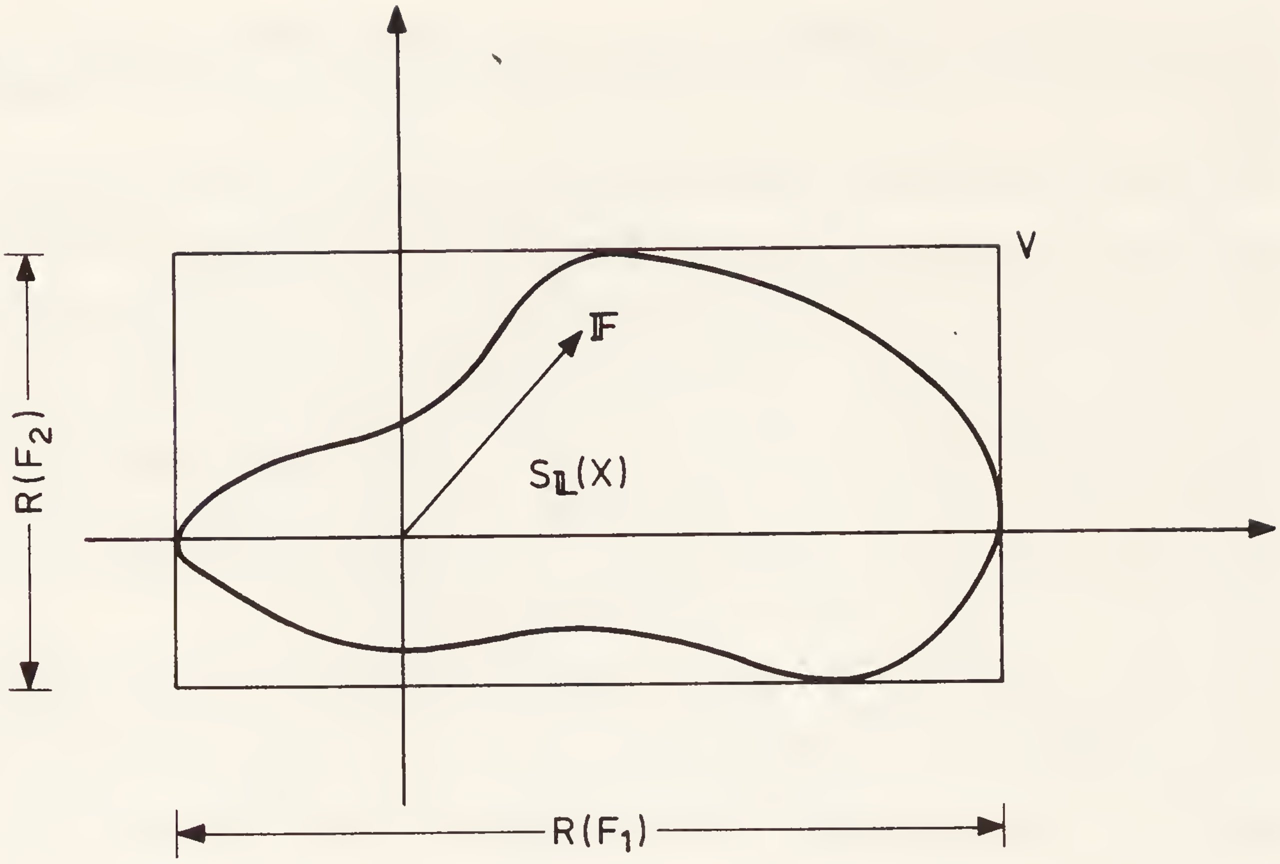


Fig. 3.1. The lawful state space $S_{\mathbb{L}}(X)$ for a thing X is a subset of the cartesian product of the codomains of the components of the state function (in this case only two).

DEFINITION 3.11 Let $X_m = \langle M, \mathbb{F}\rangle$ be a functional model for a thing X, where $\mathbb{F}: \langle F_1, F_2, \ldots, F_n\rangle: M \to V_1 \times V_2 \times \ldots \times V_n$ is the state function, and call $\mathbb{L}(X)$ the set of all law statements of X. Then the subset of the codomain $V = V_1 \times V_2 \times \ldots \times V_n$ of $\mathbb{F}$ restricted by the conditions (law statements) in $\mathbb{L}(X)$ is called the *lawful state space* of X in the representation X_m, or $S_{\mathbb{L}}(X)$ for short:

$$S_{\mathbb{L}}(X) = \{\langle x_1, x_2, \ldots, x_n\rangle \in V_1 \times V_2 \times \ldots \times V_n \mid \mathbb{F} \text{ satisfies jointly every member of } \mathbb{L}(X)\},$$

and every point of $S_{\mathbb{L}}(X)$ is called a *lawful* (or *really possible*) *state* of X in the representation X_m.

Clearly, the lawful state space is included in the corresponding conceivable state space: $S_{\mathbb{L}}(X) \subseteq S(X)$ for every $X \in \Theta$ and in any fixed representation X_m of X. For example, if $\mathbb{F} = \langle F_1, F_2\rangle$ takes values in $\mathbb{R}^2$, subject to the restriction (law statement) $\ulcorner F_2 = kF_1 \urcorner$, where k is a real number, then $S_{\mathbb{L}}$ is a one dimensional subspace of $S = \mathbb{R}^2$, i.e. a curve on the plane.

Example In Example 5 (electrostatics), of Sec. 2.4 the conceivable state space was

$$S=\{\langle\rho(x), \varphi(x)\rangle\in\mathbb{R}^2|x\in V\subseteq E^3\}.$$

Since the two components of the state function $\mathbb{F}=\langle\rho, \varphi\rangle$ are tied together by the law statement: $\ulcorner\nabla^2\varphi(x)=4\pi\rho(x)\urcorner$, the lawful state space of the thing is the subspace of S defined by

$$S_{\mathbb{L}}=\{\langle\rho(x), \varphi(x)\rangle\in\mathbb{R}^2|x\in V\subseteq\mathbb{R}^3\ \&\ \nabla^2\varphi(x)=4\pi\rho(x)\}.$$

Because most of the state functions occurring in scientific theories are real valued, and because $\mathbb{R}$ and any of its cartesian powers are vector spaces, the majority of the conceivable state spaces are vector spaces. However, because of the restrictions imposed by the law statements, the lawful state spaces, though usually included in vector spaces, need not be vector spaces themselves – let alone metric spaces.

We close this subsection with a handful of assorted remarks.

Remark 1 If we pretend that the collection of states of a thing is finite, then we are dealing with a *finite state model* of the thing, otherwise with an *infinite state model* of it. Actually there are no finite state things but only model things restricted to a finite number of states, such as automata. The finite state models are reasonable only when our interest is restricted to global properties. In such cases one can use the notion of *capacity* of a thing, defined as $I=\log_2 n$, where n is the number of states of the thing. *Remark 2* The aggregate (or noninteracting composition) of two finite state things can be represented by a state space with $n_1\cdot n_2$ points, where n_1 and n_2 are the number of states of components 1 and 2. Accordingly the capacity of such an aggregate equals the sum of the partial capacities:

$$I(1\dotplus 2)=\log_2(n_1\cdot n_2)=\log_2 n_1+\log_2 n_2=I_1+I_2.$$

But this case, central to linear system theory (cf. Zadeh and Desoer 1963), is too particular to constitute a general basis for ontology. Think that the simplest atom can be in any of infinitely many energy states or in a linear combination thereof. *Remark 3* The next case in order of complexity is that of a thing with an infinite but denumerable state space, such as the collection of stationary states of an atom. In the simplest case of this kind a thing is characterized by a quadruple $\langle n, l, m, s\rangle$ of quantum numbers (radial, orbital, azimuthal, and spin). Beyond a certain energy threshold, though, the integer n must be replaced by a continuous parameter, so that the state space acquires a continuous component. *Remark 4* If, during a part of the existence of a thing (e.g. when it is being observed), only some components of its state function change their values, one says that the remaining components are *ignorable* and the study of the thing can be restricted to the state subspace spanned by the active state variables. This subspace may be called the *reduced state space*. Experimental science presupposes that such a reduction can always be effected. *Remark 5* While in most of general systems theory the state space is assumed to be finite dimensional, the state (or Hilbert) spaces occurring in the quantum theories are infinite dimensional. Every point in such spaces can be analyzed into infinitely many components, namely those along the axes constituted by the orthonormal eigenfunctions of an arbitrary hermitian operator in the Hilbert space.

2.6. *Equivalent Representations of States*

Recall that every law statement for a given thing may be regarded as the value of a certain function L which we called the corresponding *law function* (Sec. 2.3). For a fixed thing the arguments of this function are components of the state function or functions thereof. Therefore a law function may also be construed as a function transforming the state space into itself. That is, for any given thing, $L: S \rightarrow S$ is a function that assigns each state $s \in S_{\mathbb{L}} \subseteq S$ another state $L(s) \in S_{\mathbb{L}}$, not of course an arbitrary one but a state lawfully related to the former. Consequently the totality of laws of a given thing is contained in the set of all the transformations of its state space. This point will be amply exploited in Ch. 5 on change.

Surely not every transformation of a state space represents a law. For one thing the identity map on $S_{\mathbb{L}}$ does not represent any law. Besides, certain transformations of $S_{\mathbb{L}}$, though lawful or law abiding, represent not laws but just different choices of state functions or representations. Consider a certain state function transformation concerning a fixed thing: $\mathbb{F}^* = f(\mathbb{F})$, where f is a function subject to certain restrictions. (A typical case is that f be one-to-one bicontinuous, i.e. that its Jacobian be non-null.) Every such transformation ensues in a different representation of the states of the thing, i.e. in a different state space $S_{\mathbb{L}}^*$. In other words, if $f: S_{\mathbb{L}} \rightarrow S_{\mathbb{L}}^*$ is such a bijection then $f(S_{\mathbb{L}})$ is an alternative state space for the same thing: see Figure 3.2. Again: $X_m = \langle M, \mathbb{F} \rangle$ and $X'_m =$

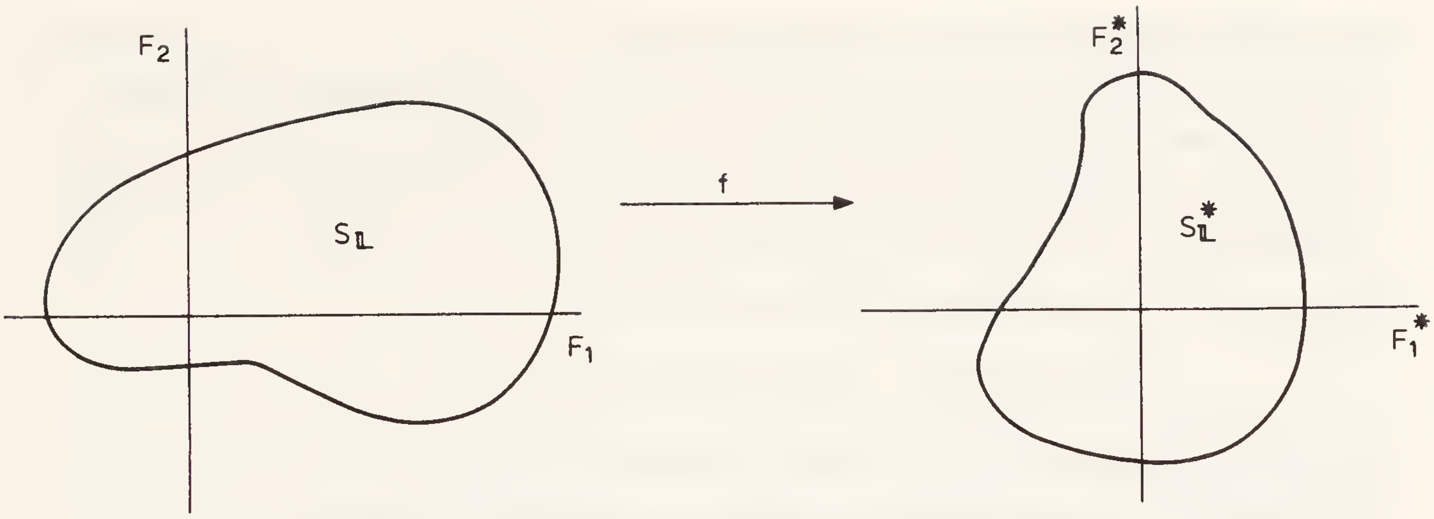

Fig. 3.2. Alternative state spaces for one and the same thing. Two such alternatives are equivalent just in case the law statements in $\mathbb{L}$ are invariant under the bijection f relating the two state spaces.

$=\langle M, f(\mathbb{F})\rangle$ are *alternative representations* of the same thing X iff f is a bijection on $S_{\mathbb{L}}$, where $S_{\mathbb{L}}$ is the space spanned by $\mathbb{F}$ with the restrictions $\mathbb{L}$.

Not every representation change is admissible: only those changes are admissible that keep the laws unchanged. We consecrate this important dichotomy by introducing

DEFINITION 3.12 Let $\mathbb{F}$: $M \to V$ be a state function for a given thing X in a given functional schema $X_m = \langle M, \mathbb{F}\rangle$. Then

(i) the *lawful transformations* of $\mathbb{F}$ are those transformations f: $V \to V^*$ such that $\mathbb{F}^* = f \circ \mathbb{F}$ and that leave the laws $\mathbb{L}$ of X form-invariant;

(ii) every transformed lawful state space $S_{\mathbb{L}}^* = f(S_{\mathbb{L}})$ is an *equivalent representation* of the states of X iff it is the image of $S_{\mathbb{L}}$ under a lawful transformation f;

(iii) the collection of all the equivalent representations of the states of X constitutes *the representation* of the states of X.

Example 1 In special relativistic theories the position and time coordinates transform according to the Lorentz formulas. These are not only laws but induce transformations of any state function such that the basic laws – e.g. the axioms of mechanics or of electrodynamics – retain their form, or are *Lorentz covariant.* And the components of the state function that do not change under a Lorentz transformation are called *invariant.* Examples of invariants: electric charge and entropy. *Example 2* In hamiltonian theories – whether they occur in physics or in biology or elsewhere – the state variables are the generalized coordinates q and momenta p (one set of each for every component of the system of interest). These variables span the state (or phase) space of the thing. New state functions $\mathbb{F}^* = \langle f(q, p), g(q, p)\rangle$ can always be introduced. But only those will be admissible that leave the canonical (or Hamilton's) equations invariant, i.e. those for which $q^* = f(q, p)$ and $p^* = g(q, p)$ are such that

$$\dot{q}^* = \partial H^*/\partial p^* \quad \text{and} \quad \dot{p}^* = -\partial H^*/\partial q^*.$$

Such transformations are called *canonical.* Every one of them induces an equivalent representation of the states of the thing concerned.

2.7. *State and State Preparation*

Whether a thing is in a given state (relative to some frame) as a result of its inner dynamics and its interactions with other things, or as a result of a sequence of human operations, is immaterial for the elucidation of the concept of an objective (though relative) state. After all, the manipulations leading to the preparation of a thing in a given state are strictly physical (or chemical or biological or social) processes even when they are controlled by a supposedly intelligent organism, and they are no less so when the thing concerned happens to be another organism – who is, say, being trained or brainwashed to behave in a certain way.

The previous platitude had to be stated because certain contemporary varieties of subjectivism claim that, unlike macrothings, microthings cannot be regarded as leading an autonomous existence because they are always prepared by some observer to be in (or jump into) preassigned states. More precisely, some quantum mechanics experts have argued as follows. (i) A microthing *is* in no definite state as long as it has not been forced into some state by some observer. (ii) Now, a state preparation is a human operation. (iii) Hence a microthing adopts a definite state only as a result of its being subject to certain human actions. The key formulas that illustrate this argument are the following. Before measuring the property represented by the operator Q, the system is in a superposition of states

$$\psi = \sum c_n\varphi_n, \quad \text{with} \quad Q\varphi_n = q_n\varphi_n,$$

where the φ_n are the eigenfunctions and the q_n the corresponding eigenvalues of the operator Q. Upon measuring whatever Q represents, ψ collapses into one of its components, say φ_m, with probability $|c_m|^2$.

The thing is only now in a definite Q-state φ_m, whereas before the measurement operation (which involves the design and reading of measuring instruments) it was in no definite (eigen)state.

The previous argument is a version of the old subjectivist thesis that properties, hence states, are dependent upon some observer rather than being objective. Moreover, it is not an argument proper, as the conclusion is just a reformulation of the premises (cf. Bunge, 1973b). Besides, the first premise happens to be false: from the fact that I happen not to know the state a thing is in, it does not follow that the thing is in no state at all – unless of course Berkeley's principle *esse est percipii* is adopted. The subjectivist thesis is moreover mathematically untenable. In fact properties are represented by functions (or by operators) and these concepts are not defined unless their entire ranges (of possible values) are given. Whether or not such a range is being sampled by empirical means is irrelevant to the objective (though relative) state of affairs, and so is the circumstance that a microthing may not be in a state that happens to be an eigenstate of the operator we may pick: a state is a state even when it is not an eigenstate of some operator. In other words, for the sake of mathematics one has to assume that the function has all of the values in its range even though only a few of them may be accessible to measurement. Consequently every thing is supposed to be in some state or other even if we have not prepared it to be in any one particular state. When an experimenter prepares a thing he picks a certain subset (occasionally even a point) of the state space of the thing. He thereby induces a real change in a real state of a real thing: he does not create either out of nothing. In sum, despite the subjectivist interpretation of quantum mechanics, states do not depend wholly on the way one looks at them but are objective (though relative) properties of real things.

2.8. *Concluding Remarks*

Every state is a state of some concrete object or other: there are no states in themselves. And conceptual objects are in no states whatsoever. Therefore a thing could be defined as *whatever is in some state or other.* Things differ by the states they are in, and their changes are changes of state. But all the things of a given (natural) kind share the same (lawful) state space – which is a way of saying that they share the same general properties. In sum, states serve to characterize not only individual things but also natural classes of things – hence the centrality of the state concept. But the matter of kinds deserves a special section.

3. FROM CLASS TO NATURAL KIND

3.1. *Classes of Things*

In this section we shall elucidate the concepts of class, kind, and species (or natural kind) of things. To this end we shall make use of some of the ideas introduced in the theory of properties expounded in Ch. 2, Sec. 3 and shall borrow freely from Bunge and Sangalli (1977). To begin with the scope function $\mathcal{S}$ introduced by Definition 2.5 of Ch. 2, Sec. 3.2 can easily be redefined for things:

DEFINITION 3.13 The *scope* of a property is the set of things possessing it. I.e. the function $\mathcal{S}: \mathbb{P} \rightarrow 2^{\Theta}$ such that '$x \in \mathcal{S}(P)$', for $x \in \Theta$ and $P \in \mathbb{P}$, is interpretable as "*x possesses P*", is the *scope.*

Correspondingly the Definition 2.6 of a class of substantial individuals now reads

DEFINITION 3.14 A subset X of the set Θ of things is called a *class* (of things) iff there is a property $P \in \mathbb{P}$ such that $X = \mathcal{S}(P) \in 2^{\Theta}$.

And Postulate 2.6 now reads

POSTULATE 3.5 The intersection of any two classes of things, if nonempty, is a class: For any two compatible properties $P, Q \in \mathbb{P}$ there is at least a third property $R \in \mathbb{P}$ such that $\mathcal{S}(R) = \mathcal{S}(P) \cap \mathcal{S}(Q)$.

We proceed to investigate the algebra of classes of things, which differs from the algebra of sets if only because unions and complements are not defined in our theory. A useful tool for this investigation is the modified scope function introduced by Definition 2.12(iii) of Ch. 2, Sec. 3.4. In terms of the thing concept, it is the function $[\mathcal{S}]: [\mathbb{P}] \rightarrow 2^{\Theta}$ that assigns each set of concomitant properties the collection of things possessing them.

3.2. *Ideals and Filters of Classes of Things*

The modified scope function $[\mathcal{S}]: [\mathbb{P}] \rightarrow 2^{\Theta}$, which is injective, induces whatever structure its codomain has on its domain. Now, the power set of any nonempty set, such as 2^{Θ}, has the lattice structure under the inclusion relation. Indeed, 2^{Θ} is closed under the union and intersection operations, and intersections precede (are included in) unions. So, $\langle 2^{\Theta}, \cup, \cap, \subseteq \rangle$ is a lattice. And, being a lattice, we can define ideals and filters on it. Since these structures will turn out to have interesting ontological interpretations, we shall briefly recall the notions of an ideal and a filter.

An *ideal* of a lattice $\mathscr{L} = \langle L, \vee, \wedge, \leqslant \rangle$ is a structure $\mathscr{I} = \langle I, \vee, \leqslant \rangle$ such that

(i) $I \subseteq L$;
(ii) every ancestor is in: if $x \in L$ and $y \in I$ and $x \leqslant y$, then $x \in I$;
(iii) all suprema are in: if $x, y \in I$, then $x \vee y \in I$.

We designate by $\mathscr{I}\mathscr{L}$ the collection of all the ideals of $\mathscr{L}$. This set has a lattice structure. If $I, I' \in \mathscr{I}\mathscr{L}$, their infimum is $I \cap I'$, while their supremum, designated $I \sqcup I'$, is the intersection of all the ideals which contain both I and I'.

Dually, a *filter* of a lattice $\mathscr{L} = \langle L, \vee, \wedge, \leqslant \rangle$ is a structure $\mathscr{F} = \langle F, \wedge, \leqslant \rangle$ such that

(i) $F \subseteq L$;
(ii) every successor is in: if $x \in F$ and $y \in L$ and $x \leqslant y$, then $y \in F$;
(iii) all infima are in: if $x, y \in F$, then $x \wedge y \in F$.

We call $\mathscr{F}\mathscr{L}$ the collection of all filters of $\mathscr{L}$. $\mathscr{F}\mathscr{L}$ is a lattice.

It will soon become apparent that neither entities nor their properties are stray: substantial individuals come in filters while substantial properties come in ideals.

We introduce next a sort of inverse of the scope function, namely a function that assigns each family of sets of entities a collection of properties. More precisely, look at

DEFINITION 3.15 The *starred scope* is the function from the power set of the power set of the collection of things into the power set of the collection of properties,

$$\mathscr{S}^*: 2^{2^{\Theta}} \to 2^{\mathbb{P}},$$

such that $\mathscr{S}^*(\mathscr{X}) = \{P \in \mathbb{P} \mid \mathscr{S}(P) \in \mathscr{X}\}$, where $\mathscr{X} \subseteq 2^{\Theta}$ is a family of subsets of Θ.

It will be recalled that, since $\mathscr{S}(P \wedge Q) = \mathscr{S}(P) \cap \mathscr{S}(Q)$, the scope function takes suprema into infima. Well, the starred scope function does just the opposite: if $\mathscr{X}$ is a filter of subsets of Θ then $\mathscr{S}^*(\mathscr{X})$ is an ideal of properties. Hence $\mathscr{S}^*$ can be construed as a function

$$\mathscr{S}^*: \mathscr{F}(2^\Theta) \to \mathscr{I}\mathbb{P}$$

that takes filters of sets of entities into ideals of substantial properties.

Our next step requires

DEFINITION 3.16 If $T \subseteq \Theta$ is a set of things, then the *filter of* 2^Θ *generated by* T is the intersection of all the filters of 2^Θ that count T as a member, i.e. $[T) = \bigcap\{X \in \mathscr{F}(2^\Theta) \mid T \in X\}$, or also $[T) = \{X \in 2^\Theta \mid T \subseteq X\}$.

If we now apply the definition of $\mathscr{S}^*$ to the computation of $\mathscr{S}^*([T))$, we find

$$\begin{aligned}\mathscr{S}^*([T)) &= \{P \in \mathbb{P} \mid \mathscr{S}(P) \in [T)\} = \{P \in \mathbb{P} \mid T \subseteq \mathscr{S}(P)\} \\ &= \{P \in \mathbb{P} \mid \text{For all } x \in \Theta\text{: } x \in T \Rightarrow x \text{ possesses } P\}.\end{aligned}$$

Thus $\mathscr{S}^*([T))$ turns out to be the set of all properties possessed by all members of T. But, by the remarks following Definition 3.15, $\mathscr{S}^*$ takes its values in the ideals of P. Hence $\mathscr{S}^*([T))$ is an ideal of P. Hence by the Definition 2.3 of p, we obtain

COROLLARY 3.3 Let $x \in T \subseteq \Theta$. Then

(i) $p(T) = \mathscr{S}^*([T)) =$ The ideal of all the properties of all T's;

(ii) $p(x) = \mathscr{S}^*([x)) =$ The ideal of all the properties of thing x.

To put it another way: Both the set of properties of a thing and the set of all the properties shared by all the members of an arbitrary set of things, far from being unstructured sets, are ideals. In particular if the set of things happens to be a class then the set of all the properties shared by all the members of the class consists of all the properties preceding the property defining the class. In fact we have

THEOREM 3.1 Let $T = \mathscr{S}(P)$ be the class defined by property $P \in \mathbb{P}$. Then the collection of properties of the members of T equals the set of all the properties preceding P:

$$p(T) = \{Q \in \mathbb{P} \mid Q \preccurlyeq P\}.$$

Proof For all $Q \in \mathbb{P}$, $T \subseteq \mathscr{S}(Q)$ iff $\mathscr{S}(P) \subseteq \mathscr{S}(Q)$ iff $Q \preccurlyeq P$.

Note that $p(T)$ is the *principal ideal* of P in $\mathbb{P}$, i.e. $(P)_{\mathbb{P}}$. (See Figure 3.3.) Note also that $p(T)$ is not an arbitrary notation but the value of the

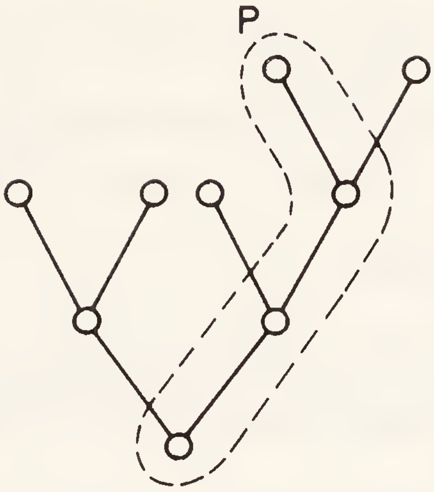

Fig. 3.3. The principal ideal of a property P is a fragment of the tree of properties. The dotted lines indicate $(P)_{\mathbb{P}}$, the bottom element represents a universal property.

function $p: 2^{\Theta} \rightarrow \mathscr{I}\mathbb{P}$ at $T \in 2^{\Theta}$. This function p reverses order, in the sense that the greater the set of things the fewer properties they share. In fact we have

COROLLARY 3.4 Let $T, T' \subseteq \Theta$. Then

$$\text{If } T \subseteq T' \text{ then } p(T') \subseteq p(T).$$

3.3. *Kinds and Species*

Whereas a single property determines a class (Definition 3.14), a set of properties will be said to determine a *kind*, and a set of lawfully related properties a *natural kind*. That is, the members of a kind are all those and only those things that share all the properties in the given set. (See Figure 3.4.)

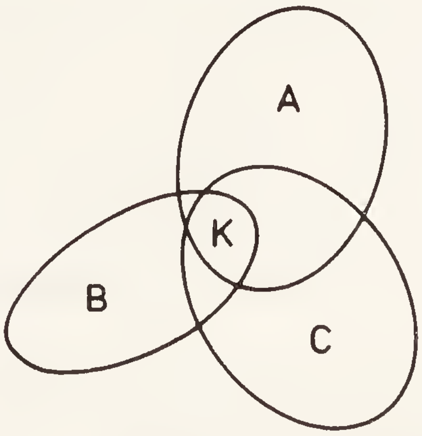

Fig. 3.4. Kind K is the intersection of classes A, B, and C.

More precisely, we make

DEFINITION 3.17 Let $k: 2^{\mathbb{P}} \to 2^{\Theta}$, be the function assigning to each nonempty set $\mathbb{R} \in 2^{\mathbb{P}}$ of substantial properties the set

$$k(\mathbb{R}) = \bigcap_{P \in \mathbb{R}} \mathscr{S}(P)$$

of things sharing the properties in $\mathbb{R}$. This value $k(\mathbb{R})$ is called the $\mathbb{R}$-*kind* of things. [Throughout this subsection and the next, $\mathbb{R}$ does not designate the real line.]

If $\mathbb{R}$ is finite, the corresponding $\mathbb{R}$-kind is a class. In fact calling $\mathbb{R} = \{P_1, P_2, \ldots, P_n\}$,

$$k(\mathbb{R}) = \bigcap_{i=1}^{n} \mathscr{S}(P_i) = \mathscr{S}(P_1 \wedge P_2 \wedge \ldots \wedge P_n),$$

so that $k(\mathbb{R})$ is the class of entities possessing the single (though compound) property $P_1 \wedge P_2 \wedge \ldots \wedge P_n$.

The notion of an $\mathbb{R}$-kind underlies all classing. In fact it allows one to introduce the notion of equivalence, or equality in certain respects, which is the very basis for the grouping of items:

DEFINITION 3.18 Let $\mathbb{R}$ be a set of substantial properties. Then two things $x, y \in \Theta$ are said to be $\mathbb{R}$-*equivalent*, or *equal in every respect* $P \in \mathbb{R}$, iff they possess precisely the same properties in $\mathbb{R}$:

$$x \sim_{\mathbb{R}} y =_{df} (P)(P \in \mathbb{R} \Rightarrow (x \text{ possesses } P \Leftrightarrow y \text{ possesses } P))$$

or, equivalently,

$$x \sim_{\mathbb{R}} y =_{df} p(x) \cap \mathbb{R} = p(y) \cap \mathbb{R}.$$

For example, since all the cells in an organism originate in a single cell, they are genetically identical. Even being different in other respects they are equal in the genetic respect, or G-equivalent. The totality of such cells, *qua* set not *qua* entity (organism), is called a *clone.*

Since $\sim_{\mathbb{R}}$ is an equivalence relation on S, it splits any set T of things into disjoint equivalence classes, variously called species, genera, orders, and so on. Such a splitting (or grouping) deserves a name:

DEFINITION 3.19 Let $\mathbb{R} \subset \mathbb{P}$ be a set of substantial properties and $T \subset \Theta$ a set of things. Then the $\mathbb{R}$-*classing* of T is the partition $T/\sim_{\mathbb{R}}$, and every member of it is called a *cell.*

Different equivalence relations induce different partitions. Of particular interest are those pairs of classings that, far from being on the same footing, are of different degrees of fineness (or coarseness). This notion is made precise by

DEFINITION 3.20 Let $\mathbb{R}$ and $\mathbb{R}'$ be sets of substantial properties, $\sim_{\mathbb{R}}$ and $\sim_{\mathbb{R}'}$ their respective equivalence relations, and $T/\sim_{\mathbb{R}}$ and $T/\sim_{\mathbb{R}'}$ their respective classings. Then $\sim_{\mathbb{R}}$ and $T/\sim_{\mathbb{R}}$ are *finer* than $\sim_{\mathbb{R}'}$ and $T/\sim_{\mathbb{R}'}$ respectively iff $\mathbb{R}' \subseteq \mathbb{R}$, in which case, for any $x, y \in S$,

(i) If $x \sim_{\mathbb{R}} y$ then $x \sim_{\mathbb{R}'} y$;

(ii) each cell of $T/\sim_{\mathbb{R}'}$ is the union of cells of $T/\sim_{\mathbb{R}}$.

This is precisely how the classings of items into species, genera, etc., are performed, namely with the help of equivalence relations of different power. (The higher powered of two equivalence relations is the finer. And the relation of fineness, whereby fine precedes coarse, is a partial order.)

The number of cells contained in each partition $T/\sim_{\mathbb{R}}$ depends upon $\mathbb{R}$, i.e. upon the number of respects that are being considered. Since there are at most as many $\sim_{\mathbb{R}}$-cells as there are subsets of $\mathbb{R}$, the following important result is obtained:

COROLLARY 3.5 If $\mathbb{R}$ is finite, so is the corresponding partition $T/\sim_{\mathbb{R}}$ of an arbitrary set T of entities.

Since in practice only a finite number of properties is handled, every classing of any collection of entities results in a finite number of classes. One of these classes is the scope of the conjunction of all the properties in $\mathbb{R}$.

Now, there are two ways of ascertaining whether two things are in the same $\sim_{\mathbb{R}}$-cell or are $\sim_{\mathbb{R}}$-equivalent. One is to note and match all their observable properties regardless of their weight: this is the pretheoretical method characteristic of classical taxonomy and also the one adopted by contemporary numerical taxonomy. It can be misleading, for a uniform appearance may hide important differences – and small differences may conceal basic kinship.

An alternative method, and the deepest, consists in grouping things by the laws they possess. When laws are made the *fundamentum divisionis* of a set of things, the resulting kinds are maximally natural – or, in Aristotelian jargon, accident is then unlikely to prevail over essence. The outcome is a set of natural kinds or species. Such sets – such as the chemical species and the biological species characterized in evolutionary terms – are typical of advanced modern science in contrast to purely empirical knowledge and to descriptive science. The definition of the concept of natural kind is obtained by just specializing that of an $\mathbb{R}$-kind (Definition 3.17). More precisely, we can get it by taking the restriction of the kind function k to the power set of the collection of all laws:

DEFINITION 3.21 Let $\mathbb{L}$ be the set of laws and let $k_{\mathbb{L}}: k|2^{\mathbb{L}}: 2^{\mathbb{L}} \to 2^{\Theta}$ be the function assigning to each $\mathbb{L}_i \subset \mathbb{L}$ of laws the set

$$k(\mathbb{L}_i) = \bigcap_{L \in \mathbb{L}_i} \mathcal{S}(L)$$

of entities sharing the laws in $\mathbb{L}_i$. This value $k(\mathbb{L}_i)$ is called the $\mathbb{L}_i$-*species* or *natural kind.*

Things have then properties of two kinds: the laws characteristic of their natural kind, and idiosyncratic properties: see Figure 3.5. That is, we can make

DEFINITION 3.22 Let $\mathbb{L}_i \subset \mathbb{L}$ be a set of laws and $k(\mathbb{L}_i)$ the corresponding natural kind. Further, call $p(x)$ the set of properties of a member x of $k(\mathbb{L}_i)$. Then

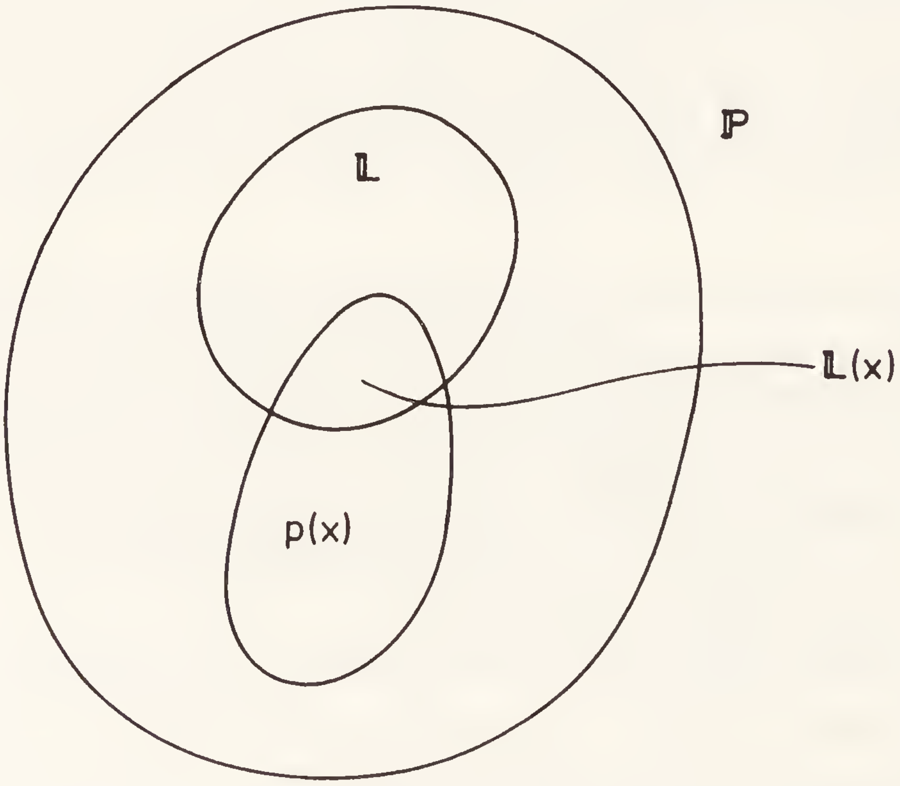

Fig. 3.5. Some of the properties of a thing x are its laws $\mathbb{L}(x)$; the rest, $p(x) - \mathbb{L}(x)$, are its idiosyncratic properties.

(i) the *species-specific properties* of x are all those in $\mathbb{L}_i$;

(ii) the *idiosyncratic properties* of x constitute the complement of its species-specific properties, i.e. $p(x)-\mathbb{L}_i$.

Two things sharing the properties characteristic of their common kind, though possibly different in every other respect, are equivalent with respect to the laws defining their kind. For example two chunks of material are golden iff, whatever their shape, weight, location, etc., they satisfy the laws defining the natural kind (chemical species) Au. In general:

DEFINITION 3.23 Let x and y be two things and $\mathbb{L}_i \subset \mathbb{L}$ a set of laws. Then x and y are *nomologically equivalent relative to* $\mathbb{L}_i$ iff x and y share all their species-specific properties, i.e. all the laws in $\mathbb{L}_i$:

$$x \sim_{\mathbb{L}_i} y =_{df} p(x) \cap \mathbb{L}_i = p(y) \cap \mathbb{L}_i.$$

And of course two things are *nomologically inequivalent* if they do not possess exactly the same laws – or, what amounts to the same, if they do not belong to the same natural kind. Hence just as individuation consists in the emergence (or the recognition) of a thing with idiosyncratic properties, so speciation consists in the emergence (or the recognition) of a collection of things with peculiar laws – i.e. a natural kind or species.

Finally we combine the notion of natural kind with that of composition (Definition 1.6). An entity may or may not be composed of parts of the same natural kind. If it is not so composed we say it is an atom of its kind. More precisely we propose

DEFINITION 3.24 Any thing belonging to a natural kind $k(\mathbb{L}_i)$ is an *atom* of that kind, or $k(\mathbb{L}_i)$*-elementary*, iff it has no proper parts of the same kind. Otherwise it is called *molecular*.

3.4. *The Algebra of Kinds*

Since properties do not satisfy the algebra of predicates – i.e. they do not form Boolean algebras – it may be surmised that kinds do not obey the algebra of sets. The following investigation will show that this is indeed the case.

Recall how the kind function k was introduced by Definition 3.17. Like p, the kind function k reverses order:

$$\text{If } \mathbb{R} \subseteq \mathbb{R}' \text{ then } k(\mathbb{R}') \subseteq k(\mathbb{R}).$$

I.e., as more conditions are added fewer individuals satisfy them. We have then two order reversing functions relating the family of sets of properties and the family of sets of things:

$$2^{\mathbb{P}} \underset{p}{\overset{k}{\rightleftarrows}} 2^{\Theta}.$$

While k assigns to every $\mathbb{R} \subseteq \mathbb{P}$ the set of all things possessing every one of the properties in $\mathbb{R}$, p assigns to a subset T of Θ the set of all the properties shared by all members of T. More precisely we find the following bridge between sets of properties and sets of things:

THEOREM 3.2 For all $\mathbb{R} \subseteq \mathbb{P}$ and all $T \subseteq \Theta$,

$$\mathbb{R} \subseteq p(T) \text{ iff } k(\mathbb{R}) \supseteq T.$$

Proof If $\mathbb{R} \subseteq p(T)$ then, for all $Q \in \mathbb{R}$, $T \subseteq \mathscr{S}(Q)$. So, $T \subseteq \bigcap\{\mathscr{S}(Q) \mid Q \in \mathbb{R}\} = k(\mathbb{R})$. Conversely, if $T \subseteq k(\mathbb{R}) = \bigcap\{\mathscr{S}(Q) \mid Q \in \mathbb{R}\}$, then $T \subseteq \mathscr{S}(Q)$ for all $Q \in \mathbb{R}$, so $\mathbb{R} \subseteq p(T)$.

This theorem has a number of interesting consequences – first of all

THEOREM 3.3 The composition pk (i.e. function k followed by function p) is a closure operator on $2^{\mathbb{P}}$. I.e., for all $\mathbb{R}, \mathbb{R}' \subseteq \mathbb{P}$

(i) $\mathbb{R} \subseteq pk(\mathbb{R})$;
(ii) $\mathbb{R} \subseteq \mathbb{R}' \Rightarrow pk(\mathbb{R}) \subseteq pk(\mathbb{R}')$;
(iii) $pk\,pk(\mathbb{R}) = pk(\mathbb{R})$.

Proof (i) follows from Theorem 3.2 by taking $T = k(\mathbb{R})$. (ii) follows from the fact that both k and p reverse order. Proof of (iii): $pk(\mathbb{R}) \subseteq pk\,pk(\mathbb{R})$ follows from (i). To check the inclusion the other way use first Theorem 3.2 with $\mathbb{R} = p(T)$ to get: For all $T \subseteq \Theta$, $kp(T) \supseteq T$. Now apply twice this last result, with $T = k(\mathbb{R})$ and $T = kp(k(\mathbb{R}))$, obtaining $k(\mathbb{R}) \subseteq kp(k(\mathbb{R})) \subseteq kp\,kp(k(\mathbb{R}))$. Hence by Theorem 3.2 $pk\,pk(\mathbb{R}) \subseteq pk(\mathbb{R})$.

Because of the symmetry described by Theorem 3.2 there is the further consequence that kp too is a closure operator on 2^{Θ}.

The subsets $\mathbb{R}$ of $\mathbb{P}$ such that $pk(\mathbb{R}) = \mathbb{R}$ will be said to be *closed* with respect to pk. By Theorem 3.1 only subsets of $\mathbb{P}$ which are ideals can be closed. We shall see in the sequel that these closed ideals play a special role. They are precisely those sets $\mathbb{I}$ of properties such that the things that share all the properties in $\mathbb{I}$ do not share any other properties. I.e. in general we have clause (i) of Theorem 3.3, which just states that, for a given $\mathbb{I}$, the things sharing all the properties in $\mathbb{I}$ (viz., $k(\mathbb{I})$) may also share other properties: $\mathbb{I} \subseteq pk(I)$. But if $\mathbb{I} = pk(\mathbb{I})$, then $\mathbb{I}$ is a set of properties characterized by the set of individuals which possess them.

We arrive thus at the next consequence of Theorem 3.2, which supplies alternative characterizations of the concept of a kind:

THEOREM 3.4 For any subset $T \subseteq \Theta$ of things the following statements are equivalent:

(a) T is a kind (i.e. there exists a subset $\mathbb{R}$ of $\mathbb{P}$ such that $T = k(\mathbb{R})$).

(b) T is determined by the properties shared by all of its members (i.e. $T = k(p(T))$).

(c) T is an $\mathbb{I}$-kind for a (unique) closed ideal $\mathbb{I}$ (i.e. there exists a necessarily unique closed ideal $\mathbb{I}$ of $\mathbb{P}$ such that $T = k(\mathbb{I})$).

Proof (a)$\Rightarrow$(b): apply kp to both members of $T = k(\mathbb{R})$ to get $kp(T) = kpk(\mathbb{R})$. Using Theorem 3.2 check that $kpk(\mathbb{R}) = k(\mathbb{R})$.

(b)$\Rightarrow$(c): it suffices to show that $p(T)$ is a closed ideal (the uniqueness assertion is easy to check). From the fact that kp is a closure operator we get $T \subseteq k(pkp(T))$. By Theorem 3.2 it now follows that $pkp(T) \subseteq p(T)$.

(c)$\Rightarrow$(a): trivial.

From the last clause of Theorem 3.4 it follows that, in order to generate all kinds, it is enough to consider the closed ideals of properties. Indeed, the correspondence between kinds and closed ideals is one to one. Furthermore we have

THEOREM 3.5 The collection of all kinds forms a complete lattice under inclusion, and this lattice is isomorphic to the dual of the lattice of all closed ideals.

Proof If χ is a family of kinds, the intersection $\bigcap\limits_{X \in \chi} X$ is again a kind and it is the infimum of χ. The supremum is the kind $k\left(p\left(\bigcup\limits_{X \in \chi} X\right)\right)$. The order reversing isomorphism is the function k that sends the closed ideal $\mathbb{I}$ into the $\mathbb{I}$-kind $k(\mathbb{I})$. Indeed, for any two closed ideals $\mathbb{I}$, $\mathbb{I}'$, applying Theorem 3.2 with $\mathbb{R} = \mathbb{I}$ and $T = k(\mathbb{I}')$ we get $\mathbb{I} \subseteq \mathbb{I}'$ iff $k(\mathbb{I}) \supseteq k(\mathbb{I}')$. (The inverse isomorphism is the function p.)

Note the difference between the structures of the family of kinds and the family of subsets of Θ (i.e. the classes). Whereas the latter forms a Boolean algebra, the family of kinds does not: for one thing the union of two kinds is not necessarily a third kind. This is of course a feature of the world and one that a purely extensional or nominalistic approach cannot possibly reveal.

Finally, Theorem 3.5 may be given the following twist. Designate with $\mathbb{P}^*$ the collection of all closed ideals of properties. This set contains not only the substantial (or really possessed) properties but others as well. In this larger set $\mathbb{P}^*$ the sup of arbitrary (possibly infinite) families of elements exist; they can be interpreted as the conjunction of (possibly infinite) families of properties. Theorem 3.5 tells us then that there is a 1 : 1 correspondence between the kinds of things and the sum total of (real and imaginary) properties. This correspondence is the function k, which may be regarded as a generalization of the scope function $\mathscr{S}$, for it agrees with $\mathscr{S}$ on the set $\mathbb{P}$ of substantial properties. (I.e. $k((P]) = \mathscr{S}(P)$, where $(P]$ is the closed ideal $\{Q \in \mathbb{P} | Q \preccurlyeq P\}$.) Besides, k also assigns scopes $k(\mathbb{I})$ to the property ideals. Moreover the correspondence k is such that to the (possibly infinite) conjunction (i.e. the supremum) of a set of properties corresponds the intersection of their scopes.

So much for the algebra of kinds – which applies of course to natural or nomological kinds as a particular case.

We now have a theory of properties, distinct from the theory of predicates, and a theory of kinds, different from the algebra of sets. We can therefore use without qualms the concepts of a property and a kind. The differences between predicates and properties, and between sets and kinds, suffice to ruin the ontological interpretations of logic and of set theory. There is no reason to expect that pure mathematics is capable of disclosing, without further ado, the structure of reality.

3.5. *Variety*

We close this section by casting a glance at the concepts of variety. There are at least two of them. One consists in the diversity of kinds of thing "represented" (to speak platonically) in a restricted set of things, such as a random sample of the collection of organisms present in one cubic centimeter of top soil. There are several measures of this kind of variety, or *local variety*: the sheer number of different species, various indices of ecological variety, or variety conducive to ecological equilibrium (see Pielou, 1969), the information theoretic measure (see Ashby, 1956), and so on. These are all specific measures of the variety found, or to be expected, in some restricted set of things. Hence their study belongs in science.

Here we are interested in the concept of *universal variety*, or the diversity in the sum total of things. We have assumed that there are infinitely many things (Postulate 3.1). But of course we have empirical access to smallish samples of that totality. However we can transcend this limitation by dint of imagination – mainly by classing and by conjecturing patterns. Classing enables us to play down idiosyncrasies and it prepares the ground for finding regularities. And hypothesizing general patterns, or laws, allows us to play down particular circumstances as well as to refine and deepen the previous classings.

Now, we grasp laws only through our conceptual reconstruction of them, i.e. law statements. Among such scientific formulas there are some which discard both particular circumstances and idiosyncrasies: they are the *generic* or *basic* laws, in contrast to the specific or derivative ones. This difference is logically, methodologically and ontologically crucial and it boils down to this. Whereas every scientific theory contains at best a finite number of generic or basic laws, it also contains all the logical consequences obtained by conjoining such axioms with other premises of the theory – and these consequences are just as entitled to be called 'laws'. The basic/derived, or generic/specific dichotomy is so fundamental that only the basic (or generic) laws are required to possess covariance properties (Bunge, 1967b).

The consequence for the matter of universal variety is rather obvious, namely this. Whereas classing things according to any laws guarantees infinite variety (because there are infinitely many law statements), classing according to basic laws alone warrants the partition of the set of things into a finite number of natural kinds. These two modes of classing are so important that they warrant one more convention:

DEFINITION 3.25 The set of all things that share a basic law is called a *natural genus*, and that which shares a particular law, a *natural species*.

This law-natural kind correspondence, together with our metatheoretical knowledge of the structure of scientific theories, entails

THEOREM 3.6 There is a finite number of natural genera and there are infinitely many natural species.

We realize now that the question 'How varied is reality?' is ambiguous. The answer is: Whereas the specific variety of reality is infinite, its generic variety is finite. And, whereas the latter trait of reality renders scientific research possible, the former makes it open ended.

4. THE WORLD

4.1. *What Does the World Consist in and of?*

Most metaphysicians have asked, and some have answered, the following questions: (i) What does the world consist in – i.e. what basic kinds of thing are its constituents?, and (ii) What does the world consist of – i.e. what is there? We have an answer to the first question not to the second.

Our answer to the question about the kinds of thing the world is "made" of follows from Postulate 3.2 and Definition 3.5: *The world is the aggregation of its constituents, which are things.* Or, if preferred, the world is that thing which is the physical sum of all concrete or material existents. This is of course a materialist answer. However, most materialists seem to prefer the formula "The world is material". We do not adopt the latter formula because it suggests the physicalist thesis that the only realities are physical systems, while in point of fact living systems and supersystems (e.g. ecosystems and societies) are just as real – and concrete.

Our answer, being neither new nor striking, is not popular among the more sophisticated contemporary philosophers. Indeed consider but a few typical contemporary answers to question (i): The world consists in sensations (Mach, 1906) or in *Erlebnisse* or elementary experiences (Carnap, 1928); the world is the totality of facts (Wittgenstein, 1922); the world is the sum total of processes (Whitehead, 1929); the world is the sum of individuals of all kinds (Goodman, 1956); the world is made of bodies and persons (Strawson, 1959). Having to sketch our own view on the matter we shall not attempt to discuss any of these alternatives. Nevertheless we cannot help but submit that none of those views is continuous with science, hence none of them worthy of belonging in scientific metaphysics. In particular the subjectivist doctrines are inconsistent with natural science; the view that the world consists in facts, or events, or processes, is incompatible with physical cosmology and fails to clarify the very notions of fact, event, and process; the body/person dualism conflicts with physiological psychology and the evolutionary study of behavior; and the thesis that the world consists of individuals is unsatisfactory unless one adds the clause that such individuals are concrete. On the other hand, the thesis that the world is the aggregate of all things, is continuous with science, for things are what every factual science investigates.

As for the second question – namely What is there? – we shall abstain from answering it. That is, we shall not list the kinds of constituent of the world but shall leave the task to the special sciences. For, no sooner does the metaphysician pronounce the world to be "made of" such and such kinds, than the scientist discovers either that some of the alleged species are empty or that others are missing in the metaphysician's list.

4.2. *Individuals, Populations, Communities, and Species*

Scientists do not stop at individuals but group and interrelate them. And they gather things not into arbitrary sets but into kinds and, more particularly, into natural kinds. They recognize as many natural kinds as laws, yet they manage to keep down the count of natural species. This they do, not only by focusing on basic or generic laws (cf. Sec. 3.5) but also, when the latter are not available, by disregarding slight individual differences such as local (ecological) variations which, though real, are rated as secondary – rightly or wrongly so. In other words, scientists distinguish species from varieties and, though keeping an eye on the latter (for some of them may eventually evolve into separate species), they focus on the former. (For the methodological injunction *Species non sunt multiplicanda praeter necessitatem* see Hooker, 1853, Introductory Essay pp. xii–xvii, and Allen, 1870–71.)

Scientists, in particular biologists, recognize three levels of concrete entity: the individual thing, the aggregate of individuals of a given kind, or population, and the aggregate of individuals of different kinds, or mixture of populations (e.g. the ecosystem or biological community). Unlike both an individual thing and a kind, a population is a concrete aggregate of entities of one or more species. In particular a biological population is a group of organisms of a given species inhabiting a limited territory, interacting and interbreeding, and relatively isolated from other populations. According to modern evolution theory, the evolutionary unit – that involved in inheritance and selection – is neither the individual organism nor the species but the population (or perhaps even the ecosystem). This is so because the organisms in a population share a gene pool and an environment. (Different populations of the same species are detached: they share neither a gene pool nor exactly the same environment, and are thus likely to evolve exclusive characters whose accumulation and selection may result in speciation, i.e. the formation of a population belonging to a new species.) A species, on the other hand, has neither a uniform environment nor a common set of genes, hence no selection and survival mechanism: unlike a population, which is a thing, a species is a concept – albeit an indispensable one.

The logical relation between the concepts of individual, population, and species are elucidated by

DEFINITION 3.26 A thing X is

(i) a *monospecific population* iff X is the aggregation of some set A of individual things belonging to a single natural kind $K_{\mathbb{L}}$:

$$X=[A] \quad \text{with} \quad A \subseteq K_{\mathbb{L}};$$

(ii) a *polyspecific population* (or *community* or *mixture* as the case may be) iff X is the aggregation of two or more sets A_i of individuals belonging to different natural kinds $K_{\mathbb{L}_i}$:

$$X=\left[\bigcup_i A_i\right] \quad \text{with} \quad A_i \subseteq K_{\mathbb{L}_i}$$

$$\text{and} \quad K_{\mathbb{L}_i} \neq K_{\mathbb{L}_j} \quad \text{for} \quad i \neq j, 1 \leqslant i, j \leqslant n.$$

(Conversely, any given species or natural kind may be regarded as the union of the membership of all the possible populations of things of the kind. But this construal cannot be formalized in our system since we have defined a population with the help of the species concept.)

The preceding considerations are relevant to overcoming the nominalism/realism deadlock in biological taxonomy. The question is whether biology concerns individual organisms or species of such. Our answer is of course: Both plus populations, for taxonomic systems are relations among natural kinds, and a kind is a collection of individuals which, in the case of organisms, live in populations. Thus we escape being impaled in either horn of the dilemma: we do not have to choose between individuals belonging to no species (nominalism) and species transcending their membership (Platonism). Both individual organisms and populations of such are real, but both share certain clusters of properties (in particular laws) and thus belong to definite natural kinds. The Platonist is right in holding that every individual belongs to ("participates in") some species (or in the union of several species), wrong in assigning priority to the latter: a set consists of its membership. And the nominalist is right in claiming that kinds are things of the mind but wrong in holding that all kinds are arbitrary inventions: natural kinds are inventions adequate to reality insofar as they are sets of nomologically equivalent things.

In sum each of the philosophical poles, nominalism and realism, contains a grain of truth, none the whole truth, and both ignore the *tertium quid* that population genetics and ecology have interpolated between the individual organism and its species, namely the population. This conclusion reinforces our previous critique of Platonism in Ch. 2, Sec. 5.2: there are no universals in and by themselves. There are only things with definite properties. A general property (in particular a law) may be said to be universal in a given kind if every member of the latter possesses that property. (Recall Definition 2.18.)

4.3. *Existence Concepts*

The ordinary language expression 'there are' is ambiguous, as it designates two different concepts: the logical concept *something* and the ontological concept of *existence*. Logic takes care of the former, analyzing it as the existential quantifier, which it might be better to rechristen *particularizer*, or *indefinite quantifier*, to distinguish it from both the *universalizer* (or universal quantifier) and the *individualizer* (or descriptor).

Surely most contemporary philosophers hold that $\exists$ formalizes both the logical concept "some" and the ontological concept of existence. I shall argue that this is a mistake. Consider the statement "Some sirens are beautiful", which can be symbolized "$(\exists x)(Sx \; \& \; Bx)$". So far so good. The trouble starts when the formula is read "There are beautiful sirens". The existential interpretation is misleading because it suggests belief in the real existence of sirens, while all we intended to say was "Some of the sirens existing in Greek mythology are beautiful". The particularizer formalizes the prefix 'some' but not the phrase 'existing in Greek mythology'. (The juxtaposition of two particularizers bearing on the same variable makes no sense.) We need then an exact concept of existence different from $\exists$. Much to the dismay of most logicians we shall introduce one in the sequel. In fact we shall introduce an *existence predicate*, thus vindicating the age-old intuition that existence is the most important property anything can possess.

We shall introduce the concept of relative or contextual existence, exemplified by "Disjunction exists in logic but not in nature", and "Birds exist in nature but not in logic". We do that by making

DEFINITION 3.27 Let A be a well formed set included in some set X, and χ_A the characteristic function of A, i.e. the function $\chi_A : X \rightarrow \{0, 1\}$ such that $\chi_A(x) = 1$ iff x is in A, and $\chi_A(x) = 0$ otherwise. Then

(i) *x exists in A* $=_{df} (\chi_A(x) = 1)$;

(ii) *x does not exist in A* $=_{df} (\chi_A(x) = 0)$.

Remark 1 Note the condition that A be a well formed set, i.e. a set proper and not a meaningless array of symbols such as 'The set of all objects differing from themselves'. *Remark 2* It might be rejoined that Definition 3.27 could be replaced by a simpler one, namely

$$x \text{ exists in } A =_{df} x \in A.$$

True, but the membership relation is not a function, hence it does not allow one to take the next step, which is the introduction of an existence predicate:

DEFINITION 3.28 The *relative* (or *contextual*) *existence predicate* is the statement-valued function

$$E_A : A \rightarrow \text{Set of statements containing } E_A$$

such that $\ulcorner E_A(x) \urcorner$ is true if and only if $\chi_A(x) = 1$.

Therefore the old boring question whether existence is a predicate is seen to be ambiguous: the answer depends on whether $\exists$ or E_A is concerned. Whereas the particularizer or quantifier is not a predicate (statement valued function), the concept of relative existence we have just introduced, i.e. E_A, *is* a predicate.

The following examples show how to handle the concepts χ_A and E_A. In them 'M' stands for the set of characters in Greek mythology, 'c' for Chiron, 'C' for "is a Centaur", and 'W' for "is wise".

The centaur Chiron exists in Greek mythology.

$$Cc \;\&\; \chi_M(c) = 1, \quad \text{or} \quad Cc \;\&\; E_M c.$$

Some of the centaurs (existing) in Greek mythology are wise.

$$(\exists x)(Cx \;\&\; Wx \;\&\; \chi_M(x) = 1), \quad \text{or}$$
$$(\exists x)(Cx \;\&\; Wx \;\&\; E_M x).$$

All of the centaurs exist in Greek mythology and none of them is real.

$$(x)(Cx \Rightarrow (\chi_M(x) = 1 \;\&\; \chi_\Theta(x) = 0)), \quad \text{or}$$
$$(x)(Cx \Rightarrow (E_M(x) \;\&\; \neg E_\Theta(x))).$$

χ_A and E_A are concepts of unqualified relative existence as long as the reference set A remains unspecified. In tune with Postulate 3.4 in Sec. 1.3 we must distinguish two specific concepts of existence, namely those of conceptual existence (or existence in a conceptual context) and real existence (or existence in the world). The corresponding definitions are obvious:

DEFINITION 3.29

(i) *x exists conceptually* $=_{df}$ For some set C of constructs, $E_C x$;

(ii) *x exists really* $=_{df}$ For some set Θ of things, $E_\Theta x$.

For example the Pythagorean theorem exists in the sense that it belongs in Euclidean geometry. Surely it did not come into existence before someone in the Pythagorean school invented it. But it has been in conceptual existence, i.e. in geometry, ever since. Not that geometry has an autonomous existence, i.e. that it subsists independently of being thought about. It is just that we make the indispensable pretence that constructs exist provided they belong in some body of ideas – which is a roundabout fashion of saying that constructs exist as long as there are rational beings capable of thinking them up. Surely this mode of existence is neither ideal existence (or existence in the Realm of Ideas) nor real or physical existence. To invert Plato's cave metaphor we may say that ideas are but the shadows of things – and shadows, as is well known, have no autonomous existence. Nevertheless conceptual existence must be reckoned with not only to account for logic, mathematics and semantics, but also to better understand real existence.

Definition 3.29(ii) asserts that *all* things, and *only* things, possess the property of existing really – a property represented by E_Θ. This vindicates Aristotle's principle that *real existence is singular*. There are no general things: every real existent is an individual. (Therefore 'general systems theory' is a misnomer for 'general theory of systems'.) Whatever is general is either a property (e.g. a law) or an attribute (in which case it may be called a universal) or a proposition or a set of propositions (e.g. a theory).

A first consequence of Definition 3.29 is the non-Aristotelian principle that only fully qualitied objects are real. In particular neither the bare substance without properties nor the property without a substratum are real: they are so many fictions. Also: *pace* Quine, being the value of a bound variable does not guarantee existence – not even shadowy conceptual existence.

A second consequence of our identifying being with being a thing (or being a member of the set of things) is

THEOREM 3.7 (i) The world exists really. (ii) Every part of the world exists really.

Proof Part (i) follows from Postulate 3.3, Definition 3.4, and Definition 3.29. Part (ii) is entailed by Corollary 3.2 jointly with Definition 3.29.

Remark 1 Our postulated identity of existents and things amounts to stating that the world is *the world of things* and that no other world exists really. The extra worlds invented by the idealist philosophers as well as by Chwistek (1949) and Popper (1968) are so many fictions. *Remark 2* The identity of existents and things does not debase thoughts: it just denies the latter an independent existence. In Vol. 4, Ch. 10, we shall construe "person x thinks idea y" as "x brains y" much in the way as "x does y". *Remark 3* We are not identifying reality with actuality: for all we know reality might be the union of actuality and real possibility. More on this in Ch. 4, Sec. 2.4. *Remark 4* The existence function χ_Θ and the existence predicate E_Θ allow us to characterize very succinctly the main contenders over concrete or material existents:

Materialism $(\exists x)(\chi_\Theta(x)=1$, or $(\exists x)E_\Theta x$,

Immaterialism $(x)(\chi_\Theta(x)=0)$, or $(x)\neg E_\Theta x$.

4.4. *Nothingness and Virtual Existence*

To be, to exist really, is to be a thing. Consequently nonbeing, or nothingness, is failing to be a thing. There are several ways of handling the ontological concept of nothingness, depending on the context. These are some:

(i) b does not exist really: $\neg(b \in \Theta)$, or $\chi_\Theta(b)=0$, or $\neg E_\Theta b$;

(ii) there is nothing of kind K: $K=\varnothing$, or $(x)(\chi_K(x)=0)$, or $(x)\neg E_K x$;

(iii) there exists nothing with property P: $\mathscr{S}(P)=\varnothing$, or

$$(x)(\chi_{\mathscr{S}(P)}(x)=0), \text{ or } (x)\neg E_{\mathscr{S}(P)}x.$$

In each case nothingness or nonbeing is identified with nonexistence, not with some positive entity or even with some positive property. All three statements are negative, as they amount to either "There are no elements in the given set", or "The given individual does not belong to the given set". Therefore it is nonsense to regard nothingness as an entity, the way Heidegger and Sartre do, and even more to claim that existence is the synthesis of being and nothingness, as Hegel did.

The concepts of being (a thing) and nonbeing (or nothingness) are dichotomic. In other words, χ_A is a two valued function, and E_A is a unary predicate. That is, there are no intermediate degrees of existence, whether real or conceptual: the expression 'degree of existence' (or 'degree of reality') is a *flatus vocis*. Aquinas and some of his followers (e.g. Maritain) notwithstanding, there is nothing between being and nothingness: there are no degrees of being. For the same reason it is nonsense to hold that, while perceptible things may well exist, their atomic constituents have no autonomous existence but are either mere mathematical formulas or else an outcome of repeated human observations – as the Copenhagen interpretation of the quantum theory used to maintain.

However, there are two puzzling concepts in contemporary theoretical physics that, *prima facie*, denote neither existence nor nothingness. One is the concept of a vacuum occurring in quantum field theories, the other is the concept of a virtual quantum (e.g. particle, or photon). We shall presently show that their status is not the same: that the physical vacuum is a thing all right while a virtual particle is a fiction.

The vacuum that quantum field theories refer to is the field in its lowest stationary energy state. When the field is in this state it does not cease being a field: only, it has no quanta (photons in the electrodynamic case). Thus it is a hypothesis of quantum electrodynamics that, although there may be no electrically charged matter in a given region of space, there is always an electromagnetic field – the zero field or ever present fluctuating background. So much so that the vacuum is assigned definite physical properties, which become manifest when an intruder (matter or radiation) disturbs it. In sum, *vacuum field* $\neq$ *nothingness*. All that happens is that the word 'vacuum' has become inadequate, for it has acquired a new signification – it designates a new concept. The new picture of the physical world synthesizes atomism and plenism, by assuming that every cranny of the world is filled with things, although matter and radiation exist only in discrete units or quanta and not everywhere.

As for virtual particles and virtual photons, they are alleged to be extremely short lived and in principle unobservable, and to take part in (virtual) processes that do not conserve energy. For example, the interaction between a proton p and a neutron n is usually pictured as being embodied in, or transmitted by, a virtual pion π^+ emitted by p (i.e. $p \rightarrow n + \pi^+$) and then reabsorbed by n (i.e. $n + \pi^+ \rightarrow p$). The energy gained in the first virtual process is lost in the second, so that there is no net energy change. Besides, the period is so short (of the order of 10^{-24} sec) that the process is unobservable, whence the hypothesis is declared to be out of reach of experimental criticism. Strangely enough, the same people who accept these assumptions (*a*) recognize that the basic formulas of the theory entail the theorem of the conservation of energy, and (*b*) usually pay lip service to the operationalist philosophy.

Fortunately there is no need to take virtual particles seriously, i.e. to assign them a degree of reality midway between full reality and nothingness. The whole idea of a virtual particle stems from two mistaken philosophical assumptions. One is the naive realist belief that every term in an infinite series (or every branch in a Feynman diagram) must have a real counterpart. The other is the corpuscularian hypothesis that particles are the only realities, whence any interaction among them must be mediated by some of them – even if they have to be virtual. If both opinions are shed then the virtual particles and the shady transactions in which they are allegedly involved are seen to be idle fictions (Bunge, 1970a).

4.5. *Existence Criteria*

Our theory of things supplies no criterion for either establishing or refuting any hypothesis to the effect that such and such an object really exists. It is not the business of metaphysics to offer existence criteria, just as it is not within the province of the philosophy of mathematics to propose criteria for the existence of definite mathematical objects such as, e.g., the solutions to a given equation. However, a general indication can be given in either case.

In mathematics an object is said to exist in a given context if it satisfies certain conditions – e.g. an equation – i.e., if it has certain properties and holds certain relations to the other mathematical objects. Likewise in factual science something can be inferred to exist if it holds certain connections (not just relations) to something else whose existence has already been established or at least assumed. (Cf. Peirce, 1909, 6.318.) We sum up this idea in the following methodological

CRITERION 3.1 An object other than the entire world exists really if it is shown to be connected to some real object other than it.

This is a criterion of relative existence. Absolute existence cannot be established even though it need not be excluded. In order to show that x exists we must exhibit its connections with some thing y whose existence is not questioned in the given investigation. In particular, but not necessarily, this second object can be a human observer. In this case, if x is real then x will be a link in a chain ending up in an observer y, and the existence of x will make itself felt in some change in y – such as e.g. y's sudden perception of x.

Our reality criterion must not be taken for a *condition*, let alone a *definition*, of reality. Our definition of "reality" cannot be other than this:

DEFINITION 3.30 Let Θ be the set of all things and $[\Theta]$ its aggregation. Then

$$\textit{Reality} =_{df} [\Theta] = \Box = \textit{the world}.$$

The reality of an object consists in its being a part of the world. And the conjecture of the reality of an object must be *tested* through its immediate or remote perceptible effects but it does not *consist* in the latter. To say that it does condemns the greater part of reality to nonexistence and amounts to mistaking being for a being criterion – as operationism has been doing since the days of Peirce (cf. 5.406). If the world were to consist of a single indivisible physical thing, it would still exist or be real but there would be nobody to experience it and use or even reject Criterion 3.1.

Real existence statements should be taken in metaphysics just as seriously and as critically as they are taken in science. They must be regarded as pointing (rightly or wrongly) to actual or possible external referents, and also as being susceptible to correction in the light of fresh knowledge (i.e. new data or new conjectures or alternative theories). While methodical scepticism is indicated in this regard as in everything else, systematic scepticism won't do. That is, we may well doubt the existence of some particular thing but, if we want to check – i.e. to test the existence hypothesis – then we must, according to Criterion 3.1, assume without blinking, at least for the time being, the existence of something else. In practice we assume the existence of the entire world and we do not identify the latter with its explored part.

Assuming my own existence is necessary but insufficient for testing any existence hypothesis concerning some other thing. For one thing solipsism does not even account for my own birth, let alone for that of my enemy. Nor does solipsism explain the many disturbances – some agreeable, others disagreeable – impinging upon the subject. Not even phenomenalism suffices if we want to attain objectivity and efficiency. Consider the sentences 'There are cars' and 'Cars have at least three wheels'. To a realist, whether naive or critical, these sentences signify exactly and literally what they say. Not so to a phenomenalist: he will regard them as abbreviations of 'A subject has a car-like perception', and 'Whenever somebody has a car-like perception he can count at least three wheel-like perceptions' – or something of this sort. This subjectivism of his alienates him from science and can get him into trouble in everyday life. For, if the phenomenalist's car breaks down in the midst of a desert, when asking for a tow truck he might not say that *there is* a car stuck in the desert, let alone that there is nothing wrong with its wheels – that *they are* still on the car though unperceived. Unless he asks the Deity to do the perceiving for him in the meantime, the phenomenalist will have to contrive some complicated counterfactual sentences that no car mechanic would be interested in unravelling (e.g., 'If I were there now, I would perceive...'). For all practical purposes the phenomenalist will have to adopt a realist philosophy – unless he is willing to let his car go up in philosophical smoke. In short, the phenomenalist is bound to do double talk.

Finally, as for the concept of existence in a possible world and, even worse, that of existence in several different possible worlds, we shall leave them to the possible worlds metaphysician. The real world ontologist, busy as he is trying to figure out what the real world is like, has not time to waste with those figments of the idle imagination.

5. Concluding remarks

We have built a concept of thing out of the notions of a bare individual (Ch. 1) and of a property (Ch. 2). We have defined a thing as a substantial individual possessing substantial properties. And we have identified being, or real existence, with being a thing. Moreover we have assumed that the world contains only things. In fact we have defined reality as the aggregation of all things and indeed nondenumerably many of them.

There are conceptual objects to be sure but not as constituents of the world, much less constituting a realm of their own. Constructs, whether busy or idle, are fictions. Hence although in our ontology every class of objects is split into a class of things and one of constructs, the latter are not assigned an independent existence. It is not just that only individuals are real: only individual things – whether simple or aggregate – exist really.

Things can be represented schematically by what we have called functional schemata. A functional schema is a certain set equipped with a state function having a certain number of components. This state function is subject to restrictions – the law statements supposed to represent objective patterns. These laws limit the conceivable states a thing can be in: they restrict the domain of the state function for the thing. The set of all nomologically possible states of a thing constitutes its state space – or rather the state space for the thing in the given representation or functional schema.

Things come in natural kinds or species, i.e. classes of things possessing ("obeying") the same laws. The family of natural kinds or species does not have a Boolean structure but one of its own: it is a semilattice. This is due to the lack of isomorphism between the set of substantial properties and the set of predicates. A natural kind constitutes a natural grouping because it rests on a bunch of laws, but it is not a real thing: it is a construct – only, not an idle one.

The world consists in and of things but not every member of the class of things is actual. There are possible things, such as my great-great-grand children. Hence there are possible properties and possible facts. Besides, every actual thing has some actual properties and others which it may – or may not – acquire. In other words we are tacitly acknowledging real possibility. And we need this concept before we tackle the problem of change, as nothing will happen unless it is possible to begin with – i.e. unless there are things with possible states. Let us then turn to the problem of possibility.

CHAPTER 4

POSSIBILITY

We have assumed that the world is constituted by things only (Ch. 3). But things change and, as Aristotle saw, if a change occurs then it was possible to begin with (*Metaphysics* IX, 3). The seed germinates because it has the potentiality to do so. A becomes B only if it is in the nature of A that A *can* turn into B: this possibility of A's is one of its properties. (The converse is false: A may have the capacity to become B but this possibility may not be actualized due to adverse circumstances.)

Possibility, then, is inherent in reality because reality is changing. In other words, there are real possibles not just conceptual ones. An immutable world would be deprived of real possibility – and so would a changing world subject to inscrutable and unworldly Fate. But reality is neither unchanging nor chained to Fate, so there are real possibles. That is, we may partition reality into actuality and real possibility. (If on the other hand reality were identical with actuality, there could be no real possibility.) Therefore our metaphysics is possibilist not actualist.

Still, recognizing possibility, even objective possibility, does not entail regarding it as irreducible. Indeed an actualist may acknowledge possibility but will attempt to construe it in terms of actuality. He is bound to mistake real possibility for its test or for its measure. Thus he will tend to define the possible as that which either is or will be (Diodorus Chronos). Or he will assert that 'possible' means "sometimes" while 'necessary' means "always" (Russell, 1919). Or at least he will slight the importance of possibility by rendering it dependent upon actuality or somehow grounded in it – as is the case with Sellars (1963, Ch. 3) and Smart (1963, p. 23).

We shall see in this chapter that there is indeed a sense of 'possible' which is partially reducible to actuality, as when a child given the opportunity to eat a candy won't fail to actualize his natural bent or disposition to do so. This kind of possible property, that becomes actualized whenever the necessary conditions occur, will be called *causal disposition.* However there is another, deeper concept of possibility that is not so reducible and seems to have escaped the attention of most philosophers. An atom in an excited state can decay – with or without an external disturbance – into any of a number of lower energy levels none of them being predetermined. And the shuffling of genes that occurs in the fertilization of an egg cell is likewise random: any of a huge number of possible genomes can be realized. This kind of real possibility, to be called *chance propensity*, is not accounted for by actualism.

Real possibility will then be admitted as an ontological category not to be confused with either conceptual possibility or uncertainty. And we shall begin by distinguishing various kinds of possibility. First of all we shall study the concepts of conceptual possibility – alas, only to show that they are philosophically secondary because thoroughly reducible. Thereupon we shall analyze the two concepts of real or physical possibility. In the course of our study we shall have no occasion to employ modal logic, which will turn out to be too coarse a tool.

1. CONCEPTUAL POSSIBILITY

1.1. *Possibility Concepts*

There are several possibility species. They fall into either of two genera: *conceptual possibility* and *real possibility*. The former concerns formulas (in particular propositions) while the latter concerns factual items. Having such utterly different referents one may well wonder whether there is such a thing as a neutral concept of possibility subsuming those two, as modal logic presupposes. In any case, before analyzing the various concepts of possibility let us exhibit them globally: see Table 4.1.

1.2. *Four Concepts of Conceptual Possibility*

In the following 'K' will designate a body of knowledge – a set of data, conjectures, theories, etc. We propose first of all

DEFINITION 4.1 Let p be an arbitrary formula and A a subset of a body of knowledge K. Then

(i) p is *logically possible relative to* $A =_{df} A$ does not entail $\neg p$;

(ii) p is *mathematically possible relative to* $K =_{df}$ There is a model M in K such that p is satisfiable (formally true) in M;

(iii) p is *epistemically possible relative to* $K =_{df} p$ and K are mutually compatible (i.e. p contradicts no member of K);

TABLE 4.1
Concepts of possibility

Genus	Species	Referents	Meaning sketch
Conceptual or *de dicto*	Logical	Statements	Non contradiction
	Model theoretic	Partially interpreted formulas	Satisfiability in some model
	Epistemic	Factual statements	Consistency with what is known
	Methodological	Formulas	Provability or confirmability
Real or *de re*	φ-ontic	Physical facts	Lawfulness
	ψ-ontic	Psychical facts	Conceivability (compatibility with psychological laws and with background of subject)
	Deontic	Human actions	Not prohibited (by moral or positive law)
	Pragmatic	Human actions	Feasibility

(iv) p is *methodologically possible relative to* $K =_{df}$ There is no method m in K such that tests run with m disconfirm p relative to K.

(v) p is *conceptually possible relative to* $K =_{df}$ p is either logically or mathematically or epistemically or methodologically possible relative to K.

Example 1 Any noncontradictory proposition is logically possible, for all systems of logic admit the principle of noncontradiction. *Example 2* The formula "$x^2 = -1$" is mathematically possible since it is satisfied e.g. in the field of complex numbers (namely by $x := i$). *Example 3* For all we know Oparin's theory of the origin of life might be true. *Example 4* The predictions calculated with the help of specific scientific theories are methodologically possible since their negates are refutable in principle.

Remark 1 Our definition reduces conceptual possibility to conceptual actuality. Consequently it renders the concept of conceptual possibility redundant – in principle though not in practice. *Remark 2* The various concepts refined by Definition 4.1 are concepts of *conditional or relative possibility*. Absolute possibility can be construed as hidden conditional possibility, by just adding suitable existential quantifiers. For example, on the basis of Definition 4.1(i) we could make the following definition:

p is logically possible $=_{df}$ There is no set of premises entailing $\neg p$. But one wonders what the use of this concept could be, as every responsible judgement is made by taking some definite premises for granted. *Remark 3* Our concepts of conceptual possibility satisfy no system of modal logic. In particular logical possibility, as defined above, satisfies only one of the two axioms common to all modal logics, namely "If p then it is possible that p". (See Hughes and Cresswell, 1968.) Besides, the standard systems of modal logic deal with absolute not conditional (relative) possibility.

The only ingredient of modal logic we do need is Aristotle's definition of necessity ($\Box$) in terms of possibility ($\Diamond$), namely:

p is necessary $=_{df}$ It is not possible that $\neg p$, or $\Box p =_{df} \neg\Diamond\neg p$. This definition, together with Definition 4.1, entails

DEFINITION 4.2 Let p be an arbitrary formula and A a subset of K. Then

(i) p is *logically necessary relative to* $A =_{df} A$ entails p;

(ii) p is *mathematically necessary relative* to $K =_{df} p$ is satisfied in every model contained in K;

(iii) p is *epistemically necessary relative to* $K =_{df} K$ implies p.

(iv) p is *methodologically necessary relative to* $K =_{df}$ For all methods m in K, tests on p run with m confirm p relative to K.

(v) p is *conceptually necessary* relative to $K =_{df} p$ is either logically or mathematically or epistemologically or methodologically necessary relative to K.

Again, none of these concepts of conceptual necessity coincides with those handled by modal logic. To begin with, they are concepts of relative (contextual) not absolute (context free) necessity. Besides, our notion of logical necessity, which reduces to the entailment relation, violates the modal axiom: $\Box(p \Rightarrow q) \Rightarrow (\Box p \Rightarrow \Box q)$. Instead it satisfies $\Box q \Rightarrow \Box(p \Rightarrow q)$, as can be seen with the help of the principle of conditional proof. (Anyway, what would be gained by constructing a deviant modal calculus?) In sum we have no use for modal logic because it is incapable of elucidating any useful notion of conceptual possibility and – to anticipate a result to be obtained in the next section – because it is equally impotent in tackling the notion of real or physical possibility.

Though for different reasons, we concur with the verdict that "Modal logic is of no philosophical significance whatsoever" (Bergmann, 1960).

1.3. *Conceptual Possibility*: *Relative*

We close by emphasizing the relativity of conceptual possibility as well as its difference from factual or real possibility. Formulas, just like actual facts, are neither possible nor impossible in themselves: they just are. What is possible or impossible with regard to a formula is some relational property of it such as exemplifying it, or proving it, or confirming it, or showing that it is compatible with a certain body of knowledge. In other words possibility is not inherent in formulas but is a relation between them and certain other conceptual items. That is, a statement of the form "It is possible that p" is not on the same level as p itself but is a metastatement. Moreover it belongs in pragmatics not in semantics, let alone in ontology.

Not so states of affairs: these are either actual or possible absolutely, in the sense that their possibility does not depend upon any body of knowledge. Propositions such as "That atom may disintegrate within the next minute", and "This organism is viable", are object statements not metastatements; they involve the notion of real possibility not that of conceptual possibility. Moreover these two concepts are unrelated except linguistically. To begin with they have nonoverlapping reference classes: while the referents of the concept of conceptual possibility are propositions, those of the concept of real possibility are facts. Hence their meanings are radically different. Therefore the attempt to have a single theory (namely modal logic) cover both concepts is bound to fail just as miserably as the attempt to describe wedding rings and algebraic rings with the same theory.

So much for conceptual possibility.

2. REAL POSSIBILITY

2.1. *Fact*

Unlike the concept of conceptual possibility, that of real (or physical or ontic) possibility refers to factual items. That is, the statement that p is really possible assigns the factual referent(s) of the proposition p, not p itself, the property of being really possible. So much so that a proposition of the form "p is really possible", where p describes some fact, may in turn be conceptually impossible relative to some body of knowledge.

Our referents are then factual items: things, properties of things, kinds of thing, states of things, and changes of state of things. Factual items are represented by definite descriptions and propositions such as the following:

Thing b	Thing b exists.
Property P	Thing b possesses property P.
Kind K	Thing b is of kind K.
State s	Thing b is in state s.
Event e	Thing b undergoes change e.

The concepts occurring in the above, with the exception of that of event, have been elucidated in the previous chapter; the notion of change will be clarified in the next chapter. We proceed to single out two kinds of factual items, namely being in a given state and going from one state to another:

DEFINITION 4.3 Let X be a thing. Then f is a *fact* involving X iff either

(i) f is a *state* of X, i.e. there is a state space $S_{\mathbb{L}}(X)$ for X such that $f = s \in S_{\mathbb{L}}(X)$, or

(ii) f is a *change of state* of (or *event* in) X, i.e. there is an $S_{\mathbb{L}}(X)$ such that $f = e = \langle s, s' \rangle \in S_{\mathbb{L}}(X) \times S_{\mathbb{L}}(X)$.

Note that, as here conceived, a state is always a state of some thing, and likewise an event is a change in the state of some thing. Note also that the states in question are only those which are lawful, as indicated by the subscript $\mathbb{L}$. (However, there is an ambiguity with regard to 'event', since although a pair $\langle s, s' \rangle$ may be lawful it may well happen that there is more than one way to go from s to s'. In other words, $\langle s, s' \rangle$ does not represent a single event but rather a whole collection of events. This ambiguity, to be removed in Ch. 5, won't do any harm at present.)

Let us now turn to a structural characterization of the notion of a fact. Call F the set of facts as defined by Definition 4.3. This set is of course the domain on which the predicates "is really possible" and "is actual" (or "is the case") are defined. (For example, we have "State s of thing b is really possible" and "Thing b is actually in state s".) These two concepts can be characterized in simple terms, namely thus. Assume, as is usual in the applications of probability theory, that every single factual item is construed as (represented by) a set – even if the latter is just a singleton or even void. That is, the set F of facts will be regarded as a family of subsets of some set – never mind which one. Stipulate that, if x is in F and is nonvoid, then x is an unspecified possible fact, whereas if $x = \varnothing$ then x is impossible. Assume further that possibles can conjoin, disjoin and invert. That is, if x and y are really possible factual items (i.e. nonempty members of F) so are $x \cap y$, $x \cup y$, and $x^{-1} = F - x$. The intersection of x and y represents the compossibility of x and y, the union represents the alternative possibility, and the inverse or complement x^{-1} of x represents whatever is possible when x is not. (Note that x^{-1} is not a fact but a set of facts.)

On the other hand actuals either occur or they don't, and some of them occur jointly but never disjointly. Indeed there is no such thing as the actual fact that fact *a or* fact *b* happens, even though the corresponding proposition may be true. Nor does x^{-1} happen. There is no such thing as the unique complement or inverse of an actual fact. Complementation and disjunction are marks of possibility (as well as of constructs) not of actuality. Further, if x and y are really possible, we call $A(x)$ the actualization or occurrence of x, $A(x^{-1})$ the nonoccurrence of x, $A(x \cap y)$ the occurrence of both x and y, and $A(x \cup y)$ that of at least one of the facts. (See Table 4.2.) And we lay down

POSTULATE 4.1 Let F be a collection of sets, $\cap$, $\cup$, and $^{-1}$ the boolean operations on F, and A a function from F into a set of propositions. Then the structure $\mathscr{F} = \langle F, \cap, \cup, ^{-1}, A\rangle$ is a *space of facts* iff

(i) $\langle F, \cap, \cup, ^{-1}\rangle$ is an algebra of sets;

(ii) F represents the set of facts (actual or possible) involving some thing or things X;

(iii) A is a function from F into the set of propositions concerning the thing or things X, such that

TABLE 4.2

Real possibility and actuality. Proviso: $x, y \neq \varnothing$

Formula	Interpretation	Formula	Interpretation
$x \in F$	x is a possible fact	$A(x)$	x occurs
$x \cap y \in F$	x and y are compossible	$A(x \cap y)$	x and y occur
$x \cup y \in F$	x or y is a possible fact	$A(x \cup y)$	x occurs or y does
$x^{-1} \subset F$	that which is possible when x is not, is a possible fact	$A(x^{-1})$	x does not occur

(a) for any $x \in F$, $A(x^{-1}) = \neg A(x)$;

(b) for any $x, y \in F$, $A(x \cap y) = A(x) \,\&\, A(y)$ – i.e. A is a morphism of opposition and multiplication;

(iv) for any $x, y \in F$ other than the empty set, $A(x)$ represents the occurrence (actualization, realization) of (the possibility) x, $\neg A(x)$ the nonoccurrence of x, and $A(x) \,\&\, A(y)$ the occurrence of both x and y.

It is easily shown that the actualization function A has the following further properties:

THEOREM 4.1 Let A be the propositional function on F defined by Postulate 4.1. Then for all $x, y \in F$

(i) $A(x \cup y) = A(x) \vee A(y)$;

(ii) $A(x^{-1} \cup y) = A(x) \Rightarrow A(y)$;

(iii) $A(x \cap x^{-1}) = A(x) \,\&\, \neg A(x)$.

The last result is of course the reason for interpreting $\varnothing$ as impossibility.

Our Postulate 4.1 is at variance with an alternative set of axioms of occurrence (Suppes, 1970, p. 38), supposed to characterize the notion of occurrence or actualization. These axioms do not discharge this function if only because the first of them states that, if x and y are events, and x occurs, then their union $x \cup y$ occurs as well. In our ontology there are no disjunctive facts: there are only disjunctive possibilities and disjunctive propositions about facts whether possible or actual.

Postulate 4.1 constitutes only a partial characterization of the possibility/actuality contrast. It tells us just that (*a*) the set of occurrences is a proper subset of the set of possibilities, and (*b*) the algebraic structure of the latter is richer than that of the former. The actualization process is somehow representable as a collapse of the richer structure into the poorer one: in this process union (or disjunction) and complementation (or negation) are forgotten. However, this characterization in terms of a forgetful functor is insufficient because it fails to specify (*a*) which subset of the conceptually possible facts (for this is what F is) constitutes the *really* possible facts and (*b*) which subset of the collection of really possible facts gets actualized. These defects cannot be repaired by proposing a more complex theory in the same vein: no a priori theory, independent of considerations concerning laws and circumstances, can single out the set of really possible facts, let alone that of actuals. Let us then get in touch with reality.

2.2. *Chrysippian Possibility*

The profound Stoic philosopher Chrysippus defined the possible as "that which is not prevented by anything from happening even if it does not happen". Contrast this view to that of Diodorus Chronos, according to whom "the possible is that which either is or will be true". (Cf. Kneale and Kneale, 1962; Rescher and Urquhart, 1971.) According to this other view the concepts of actuality and possibility are coextensive: that which never happens is impossible. (See also Hartmann, 1938.) Consequently the notions of unrealized potentiality and of missed opportunity find no room in this conception. Yet, as Aristotle and Chrysippus saw, not all possibles are realized: "thus it is possible that this gem will break even if it never does" (Cicero, *De fato* IX).

Chrysippus' definition of real possibility hinges on the notion of lack of constraint or absence of inhibition. The latter notion can be construed as follows:

DEFINITION 4.4 If x and y are possible facts (i.e. $x, y \in F$) then x ***inhibits*** (or ***prevents***) the occurrence of $y =_{df} A(x) \Rightarrow \neg A(y)$.

Chrysippus' idea is then perhaps rendered by

DEFINITION 4.5 A fact is *really possible* iff there is no actual fact the occurrence of which prevents it: If x is a fact then

$$\Diamond_r x =_{df} \neg(\exists y)(y \text{ is a fact } \& \ y \text{ occurs } \& \ y \text{ prevents } x)$$

$$\Leftrightarrow \neg(\exists y)(y \in F \ \& \ A(y) \ \& \ (A(y) \Rightarrow \neg A(x))).$$

In other words, anything is (really) possible that is unhampered or free to happen. Freedom, whether physical or moral, is thus equated with real possibility. (Physics and ethics acquire therefore a common metaphysical basis.) The concept of real impossibility is obtained by negating the two sides of the previous definition: a fact is *really impossible* iff it is inhibited by some other fact. We infer then that if anything is impossible then it is not the case. This corollary is just the contraposition of "Whatever is the case is possible".

We shall not elaborate on the Chrysippian notion of possibility because we shall adopt an alternative conception of possibility, namely the nomological one to be expounded presently.

2.3. *Real Possibility as Lawfulness*

Our point of departure will be Bolzano's conception of possibility as lawfulness: "physically possible is that which does not contradict any of the so called laws of nature" (Bolzano, 1821, art. 'Möglich', p. 65). However, we cannot adopt this definition literally because we regard laws as objective patterns not as propositions and consequently cannot make use of the concept of consistency occurring in Bolzano's statement.

To begin with recall the Definition 4.3 of a fact as either a lawful state or a lawful change of state of a thing. We shall assume that these are the only really possible facts. That is, we identify real possibility with nomic possibility. More explicitly, we assume

POSTULATE 4.2 A fact f is *really possible* iff f is a lawful fact, i.e. iff either $f \in S_{\mathbb{L}}(X)$ or $f \in S_{\mathbb{L}}(X) \times S_{\mathbb{L}}(X)$ for some thing X and some state space $S_{\mathbb{L}}(X)$. In symbols,

$$\Diamond_r f \text{ if and only if } f \text{ is a lawful fact.}$$

Note that this is not a definition but a hypothesis and moreover one used surreptitiously when framing Definition 4.3. In fact Postulate 4.2 can be ignored or even negated. An empiricist ontology – one recognizing no objective laws, as was the case with Hume's and James' – finds no use for that assumption. And a religious metaphysics, unless it be of the Cartesian or Leibnizian kind where the Deity is always strictly law-abiding, will negate our axiom.

The following consequences follow immediately from our postulate:

(i) *Lawless individual facts are impossible.*

(ii) If, with Hume, we define the miraculous as the lawless, then we infer that *miracles are impossible.* If this conclusion is rejected then the concept of real possibility must be redefined – or just dropped, perhaps together with that of an objective law or pattern. Either alternative would be consistent with an empiricist ontology.

(iii) Randomness too has been defined as lawlessness, but this is not satisfying. First, whereas the predicate "lawful" applies to individual facts, "random" applies only to sets of facts – such as e.g. a sequence of hits and misses of shots aimed at an object with unknown location. Second, randomness is a kind of lawfulness not its opposite. What is the opposite of lawfulness is chaos or the absence of all laws, even stochastic (probabilistic) laws. But chaos too is a property of sets of facts not of individual facts. For example, by collecting haphazardly a number of facts (possible or actual) concerning unrelated things we can form a lawless collection of individually lawful facts. (Think of a set made up of an arbitrary collection of astrophysical, genetic, and political events.) In sum randomness – a basic feature of reality if we are to believe contemporary science – is, unlike chaos, compatible with lawfulness or nomic necessity. More on these matters in Sec. 6.4.

(iv) We conclude the falsity of the identification of lawfulness and necessity, popular since the 17th century, made obsolete by the birth of statistical theories from the 1870's on, assailed by Peirce, and recently revived by Montague (1960, repr. in 1974). That identity is in fact a cornerstone of Montague's possible-world semantics and metaphysics – of which more in Sec. 6. In short lawfulness is not identical with necessity but with (real) possibility. More on necessity anon.

2.4. *Factual Necessity*

Conceptual necessity, it will be recalled, can be introduced in terms of conceptual possibility by way of Aristotle's definition, namely: $\Box p = \neg\Diamond\neg p$. We cannot use this definition to obtain the notion of nomic necessity out of that of nomic possibility as coextensive (though not cointensive) with that of lawfulness. For one thing negation applies to propositions, not to facts: the expression '$\neg x$' makes no sense when x denotes a fact. We might of course reinterpret '$\neg x$' as "It is not the case that x", i.e. as $\neg A(x)$. But even so Aristotle's definition would not help us, because real or factual necessity has a component absent from lawfulness, namely *circumstance.*

Indeed for anything to actually happen and thus be (really) necessary it must not just "obey" certain laws but also "count on favorable circumstances". Not even a deterministic (nonstochastic) law statement describes only what is actually the case: *every law statement describes possibles* – without of course the help of modal operators. (Think of the bundle of trajectories in the state space representing the set of solutions of an equation of evolution.) A fortiori, stochastic laws describe even weaker possibles, namely chance facts, i.e. facts occurring only with a fixed frequency. In sum we may keep Aristotle's definition of possibility for the conceptual realm – as we did in Sec. 1.2 – but it is inapplicable in science and in scientific ontology. Here we need rather

DEFINITION 4.6 Let $x \in F$ be a really possible (i.e. lawful) fact. Then

(i) x is *necessary* iff there is another fact $y \in F$, called the *circumstance attending* x, such that $A(y) \Rightarrow A(x)$;

(ii) x is *contingent* iff x is not necessary.

For this reason actual states of affairs, or situations, are best accounted for (described, explained or predicted) with the help of both law statements and propositions representing the circumstances (idiosyncrasies, initial conditions, boundary conditions, etc.) jointly necessary for the situations of interest to actually occur either always or with a fixed frequency. In other words, the preceding considerations constitute the ontological ground for the familiar schema of nomological explanation:

$$\text{Laws, Circumstances} \vdash \text{Facts.}$$

At first sight the necessity or contingency of a fact or situation depends exclusively on the kind of law involved: deterministic laws would cover necessary facts, nondeterministic laws contingent facts. For better or worse this simple schema is false. In fact deterministic laws can cover contingent facts and stochastic laws can cover necessary facts. A familiar example of the former kind is the impact of a classical particle on a wedge: see Figure 4.1. In this case there are two equally probable trajectories, i.e. the problem has two different solutions on an equal footing. And a familiar example of the second type is the repeated

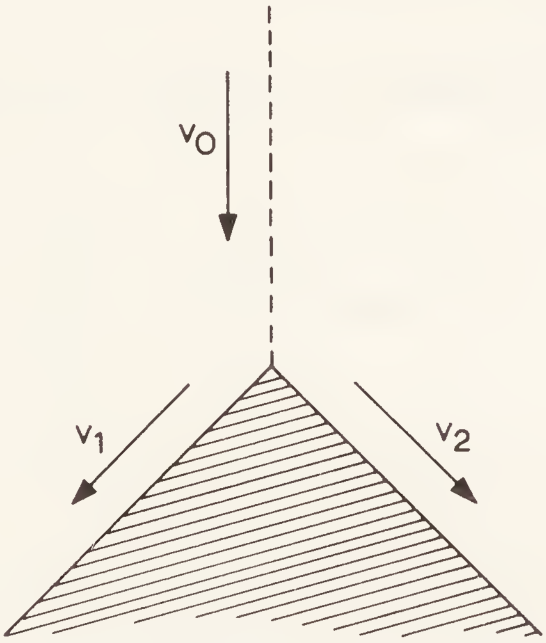

Fig. 4.1. A particle (or a fluid jet) collides against a rigid wedge and is deflected either left or right with the same speed. For a classical discussion see Truesdell (1974).

tossing of a penny: in the long run certain regular sequences, such as five heads in a row, are bound to occur and in fact they occur with a fixed probability.

In sum, the explanatory schema $\ulcorner L, C \vdash \mathit{Fact} \urcorner$ lumps together four accounts:

Deterministic law, C_1
$\vdash$ Necessary fact (occurs whenever C_1 or C_2)

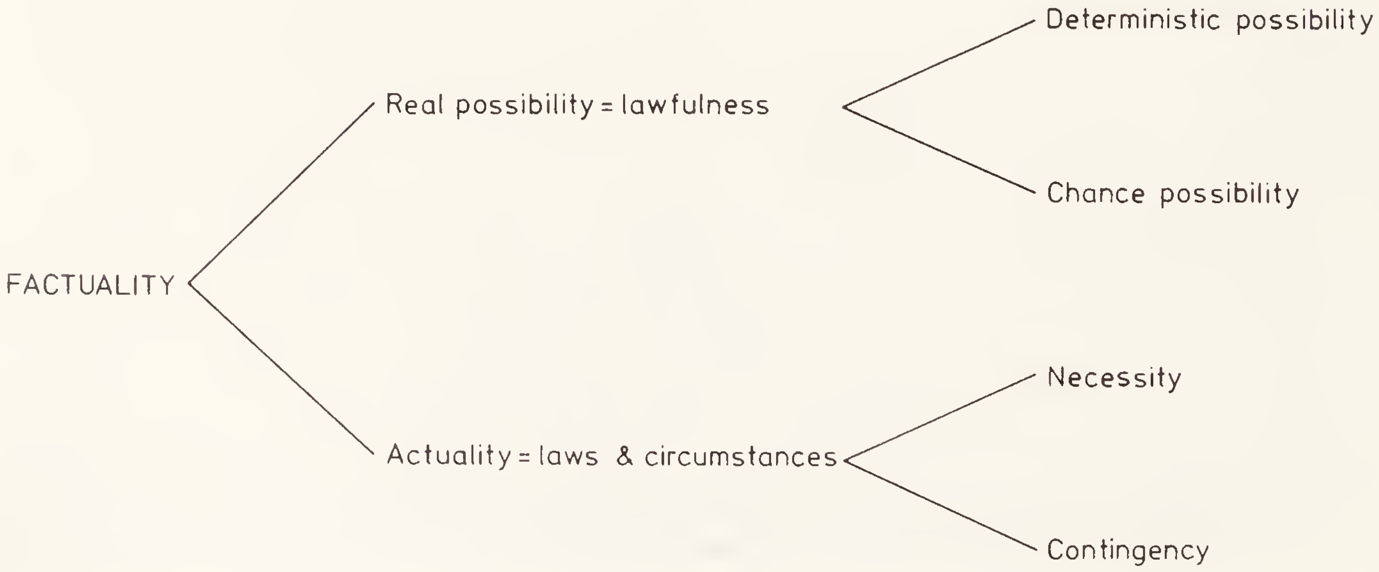
Stochastic law, C_2

Stochastic law, C_3
Contingent fact (occurs with fixed probability whenever C_3 or C_4)

Deterministic law, C_4

To conclude this subsection. Real possibility is identical with lawfulness. But real necessity is not definable in terms of possibility and negation. Never mind, for the concept of necessity plays hardly any role in factual science except as a synonym for actuality: whatever happens to be the case must be, and conversely. Little is gained by replacing "It is snowing" with "Necessarily it is snowing", or "The snowfall probability is $\frac{3}{4}$" with "Necessarily the snowfall probability is $\frac{3}{4}$", let alone with "The probability that it snows is necessarily $\frac{3}{4}$". *The prefix 'necessarily' is unnecessary*. An actual particular fact is a fact is a fact. Calling it 'necessary' is just a way of saying that, far from being merely possible, it is the case.

In sum, we have the following partition of the factual realm:



FACTUALITY
Real possibility = lawfulness
Deterministic possibility
Chance possibility
Actuality = laws & circumstances
Necessity
Contingency

2.5. *Possibility Criteria*

If scientific research is conceived of as being ultimately the search for objective laws (Bunge, 1967a, Vol. I, Ch. 6), and if lawfulness is equated with nomic possibility (Postulate 4.2), then science must be regarded as the study of the really possible. In fact every scientific activity of the theoretical kind deals not only with actual facts but also with real possibilities. Thus theoretical mechanics – unlike experimental mechanics and applied mechanics – studies all possible motions of all possible bodies. Theoretical chemistry – unlike experimental chemistry and chemical engineering – studies in principle all possible chemical compounds. And theoretical genetics studies all possible gene recombinations and mutations.

In other words all theoretical science utilizes the concept of a possible thing and even that of a possible state of a possible thing, much to the dismay of actualist philosophers. But of course the notion of a possible individual of this kind is not characterized with the help of either modal logic or model theory – let alone with that of any system of possible worlds metaphysics. In theoretical factual science a possible thing, such as a possible compound or a possible organism or a possible community, is an arbitrary member of the class of hypothetical referents of the theory of interest – i.e. an individual possessing ("obeying", "satisfying") the law statements of the theory. On the other hand the notion of a possible world (nowadays often identified with that of a model of an abstract theory) is alien to factual science: we have access to no substantial world other than the real world. True, possibility is inherent in the world, but there is no special carrier of possibility – no possible substantial world in addition to the actual world. Every concrete thing possesses certain possibilities to the exclusion of others.

What holds for theoretical possibility holds also, *mutatis mutandis*, for theoretical impossibility. Every theory rules out a number of possibilities just as it countenances others. Of course any theory can go wrong. But as the number and variety of theories agreeing on the impossibility of something increases, the likelihood of a "prohibition" increases. Even so one should keep an open mind. For example relativistic mechanics rules out the possibility that there be superluminal particles (tachyons). But the theory has nothing to say about noncorpuscular entities travelling faster than light. Moreover a good theory about such entities would help in searching for them.

Any theory hypothesizing the existence of a thing or a fact not envisaged by antecedent theories should respect the latter in their own "domains of validity" (extensions) and should enjoy the support of independent evidence or else stimulate the search for it. And any theory hypothesizing the existence of things "forbidden" by well corroborated theories should say whatever those theories tell us about the things those theories allow. Needless to say, even logic must be taken into account when listing impossibles. Metaphysics, on the other hand, is hardly in a position to admit or rule out any fact. What metaphysics can do is to clarify some of the concepts involved in scientific judgments of possibility or impossibility.

When shifting our attention from reality to science, talk of facts becomes talk of the knowledge of facts and, in particular, a definition of possibility may become a possibility criterion. If we were to adopt Chrysippus' concept of real possibility (Sec. 2.2) we would have to adopt the following criterion: *If x is a fact, then x is known to be really possible iff nothing is known to prevent x.* But since we have proposed a modification of Bolzano's notion of possibility (Sec. 2.3) we cannot accept the Chrysippian possibility criterion. We shall instead suggest a criterion inspired in the following example.

A theoretical chemist will declare an unknown compound to be really (chemically) possible iff (*a*) its components exist, (*b*) they can assume a stable configuration, and (*c*) a reaction mechanism resulting in the hypothesized molecule is theoretically possible, i.e. consistent with what we know. In short, the chemist's possibility statement is the conclusion of a (rather complex) argument involving items both theoretical and empirical. We generalize this procedure by proposing

CRITERION 4.1 Let T be a theory, and E a body of empirical evidence couched in the language of T and relevant to T, and suppose that both T and E refer to a fact x described by a proposition $p[x]$. Then x is *really possible according to* T *and* E iff $T \cup E$ fails to entail $\neg p[x]$.

This is a theoretical possibility criterion and it refers us back to what is already known (or presumed to be known), not to new observations or future theories. If a theoretically possible fact occurs it may count as a confirmer of the theory. If it fails to occur the theory remains unaffected and we have no case against the possibility of the fact. And if a theoretically impossible fact does occur then we shall have to revise either the theory or the evidence employed in inferring the impossibility.

Consider now the possibility criterion suggested by the Diodorean concept of possibility, namely: *Fact x is known to be possible iff x is observed to happen at some time.* This criterion is quite useless, as it works only *ex post facto*: it does not allow me to regard my own demise as possible until it is too late for doing any thinking of this kind. And once the fact is observed to happen it may as well be pronounced necessary. But if it is not observed to happen then the reasonable attitude is to wait and see rather than to declare it impossible. These are not defects that can be remedied while retaining the spirit of Diodorus' conception of possibility: they are inherent in any attempt to frame an *empirical* possibility criterion. Indeed such a criterion must refer to actuals and is therefore impotent in distinguishing possibility from actuality. In other words, the observation that something is the case only shows that it was indeed possible to begin with but does not suggest whether it was just possible or necessary. In conclusion, empirical criteria of possibility are impossible. We must remain content with a theoretical criterion like the above. Which is fitting, since the concept of possibility is theoretical not empirical.

3. Disposition

3.1. *Intuitive Idea*

Thus far we have been concerned with the general concept of real possibility. We shall study henceforth two special concepts of real possibility. One is *disposition*, or *causal propensity*, as exemplified by fragility and inherited susceptibility to TB. The other concept is that of *chance propensity*, as exemplified by a photon that may go through either slit of a two slit screen. Let us start with the former, which is the more familiar of the two – therefore probably not the more basic.

A force may cause a change in relative position, a lump of sugar may dissolve, a muscle cell may divide, a literate person may read, a viable society can survive. These potentialities will be realized provided the proper environment or means is supplied: otherwise they will not. (To repeat: Such potentialities are realized *whenever* suitable conditions are present.)

Moreover, as the Philosopher saw, potency precedes act. (And conversely, as is equally obvious. Thus, being born with a normal brain and being adequately fed are necessary conditions for a person to be capable of learning and doing certain things, even if he never actually learns or does them.) The disposition to do x is then prior to doing x. Thus a piece of matter will actually refract light provided it was refractive to begin with; and if it was refractive then it was so whether or not it was exposed to light. (Do not mistake a property for the tests for it.) Recall Newton's *Opticks* (1782 ed., Vol. IV, p. 6): "Refrangibility of the Rays of Light, is their disposition to be refracted or turned out of their way, in passing out of one transparent Body or Medium, into another". A light ray has all the time the refrangibility property, even while it propagates in a vacuum. Likewise a crystal retains its refrangibility while locked up in a chest.

A peculiarity of dispositions (or causal propensities) is that they come in pairs. Thus (all) light rays are refrangible iff (some) bodies are refrangible. And every lock can be opened by some key(s). Let us keep this complementarity in mind, for it will occur in the very definition of a dispositional property.

The peculiarity of a *causal* propensity, in contrast to a chance propensity, is that the former never fails to be actualized when conjoined with suitable circumstances. Solubility becomes actual dissolution, divisibility division, viability continued existence, and so on. In clumsy but few words: *Disposition & Circumstance = Actuality*. Equivalently: Disposition equals actuality minus certain circumstances. More precisely: A disposition is a condition that, though necessary, is not sufficient. Accordingly, if x is a fact, then:

$$\text{If } (\exists y)(y \in F \;\&\; y \neq x \;\&\; (A(y) \Rightarrow A(x)) \quad \text{then} \quad \Diamond_r x.$$

(The converse is false, as real possibility is not exhausted by causal propensity.) Real possibility of this kind, i.e. disposition, is then an insufficient condition: actuality ensues as soon as this shortcoming is remedied, i.e. when the missing conditions appear. (For a similar independent construal see Raggio, 1969.)

The circumstances favorable or unfavorable to the actualization of a potentiality of a thing x involve some thing y other than x and forming part of the environment of x. This other thing, to be called the *complement* of the first, must have a disposition matching that of the thing of interest, for the first disposition to actualize. Thus a certain key may open provided it is joined to a proper lock with the unlocking disposition. What exhibits an actual or manifest property is the whole formed

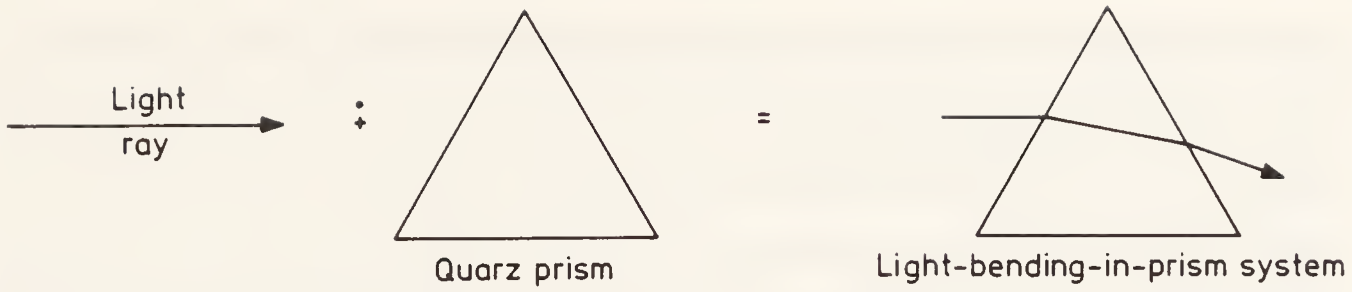


Fig. 4.2. Two entities, each with a certain disposition, aggregate into a third entity with a certain manifest property.

by the thing of interest and its complement. (See Figure 4.2.) The general schema is as follows:

> *Thing x with disposition P joins thing y with disposition Q to form thing* $z = x \dotplus y$ *with manifest property R.*

A few more examples should do no harm. *Example 1* If a piece of magnetizable material is placed in a magnetic field, it becomes magnetic. *Example 2* A fertilized bird's egg lying long enough in a nest at a suitable temperature becomes a chick. *Example 3* The inherited susceptibilities to TB, schizophrenia and other illnesses are parallel: the environment brings about, or else inhibits, such an inborn disposition.

We close this subsection by noting that the degree of a predicate is no indication of whether the property it represents is manifest or dispositional and, if the latter, whether it is causal or stochastic. Thus human abilities are often intrinsic properties (though of course displayed only under certain circumstances). On the other hand the velocity of a macrosystem is a mutual property (of thing and reference system) and a manifest one. Likewise with chance propensities. Thus the localizability of a quantum mechanical system is intrinsic in the case of a single "particle" and mutual for a pair of correlated "particles".

3.2. *Elucidation*

The preceding informal considerations are summed up and exactified in the following convention, which employs only concepts that have been clarified in the previous chapters:

DEFINITION 4.7 Let $z = x \dotplus y$ be a thing composed of different things x and y. Further, let P be a property of x and Q a property of y, with Q possibly equal to P. Then P is said to be a *disposition* (or *causal* *propensity*) of x, and Q the *complement* of P with respect to y, iff there is a third property R such that

(i) $z = x \dotplus y$ possesses R;
(ii) $z = x \dotplus y$ possesses neither P nor Q;
(iii) neither x nor y possesses R.

Note that what is called a *disposition* and what its complement is a matter of viewpoint or convention. Thus one says that sugar is soluble (in water), but this is because water has the disposition to dissolve sugar.

Example An aggregate of reactants won't start reacting unless the required pressure and temperature conditions become available – which conditions are properties of the immediate environment of the aggregate. When they do, the disposition to react in a certain way is actualized, and eventually new things (the reaction products) emerge that do not have all the properties of the reactants but are characterized instead by new properties determined by the former.

We are now in a position to elucidate a notion that has become incorporated into common knowledge:

DEFINITION 4.8 The totality of dispositions (causal propensities) of a thing is called the *causal potentiality* of the thing. I.e., if x is a thing then

$$\Pi_c(x) = \{P \in p(x) \mid P \text{ is a disposition of } x\}.$$

DEFINITION 4.9 One thing has a *greater causal potentiality than* another iff the potentiality of the former includes that of the latter. I.e., if x and y are things, then

$$\Pi_c(x) > \Pi_c(y) =_{df} \Pi_c(x) \supseteq \Pi_c(y).$$

Example 1 The potentiality of an individual organism consists of its genetic make-up or program. A poor genetic endowment yields few possibilities of a rich experience, just as a poor environment cuts out many possibilities of using the genetic make-up. *Example 2* Shortly before the birth of molecular biology it was considered preposterous to regard the human zygote as a potential man, or the acorn as a potential oak tree. Both assertions would have been laughed away as remnants of preformationism. But contemporary biology is preformationist insofar as it holds the whole mature organism to be programmed in the zygote. *Example 3* The psychological faculties or abilities, rejected by behaviorism, are back. Thus N. Chomsky, G. A. Miller and other psycholinguists stress the difference between ability and performance – an instance of the potentiality-actuality difference. Thus verbal behavior does not coincide with linguistic ability although it is the only overt hence observable manifestation of it. The ability is in this case the capacity to utter and understand sentences new to the speaker. But this potentiality can be either actualized or frustrated by the environment.

3.3. *Potency and Act*

To Aristotle potency was prior to act: actuality was the unfolding of potentiality. The latter was in turn left unexplained. The distinction between potency or disposition, on the one hand, and act or manifest property, on the other, has been kept by modern science – a fact suppressed by the positivist philosophy of science. Thus Newton: "Colours in the Object are nothing but a Disposition to reflect this or that sort of Rays more copiously than the rest" (Newton, 1782, Vol. IV). Other physical properties can be described with paraphrases of the latter statement: just think of conductivity, magnetic permeability, refrangibility, or viscosity. They are all powers or dispositions of the causal kind. Such examples have suggested the conjecture that "all physical (and psychological) properties are dispositional" (Popper, 1957, p. 70). But this would be impossible if only because the very concept of potency makes sense only relative to that of act – as shown e.g. by Definition 4.7.

Actualists have tried to ignore the long list of dispositions exhibited by modern science. They often argue against objective dispositions on the strength of an empiricist epistemology. They claim, and rightly so, that only actual things and manifest properties are publicly observable. (But they do not seem to realize that we cannot possibly do without dispositionals such as "observable".) They will try hard to define, and thus eliminate, dispositions in terms of observable properties. A favorite gambit of theirs is Carnap's method of introducing dispositionals by way of bilateral reduction sentences (Carnap, 1936–37), namely thus:

> Thing x subjected to test condition C is assigned disposition D just in case x exhibits behavior B: $Cx \Rightarrow (Dx \Leftrightarrow Bx)$.

But of course this is a *criterion* not a *definition*. Moreover in scientific theories, while some dispositionals (like solubility) are defined others (like electric conductivity) are not: they are taken as undefined. Likewise with psychological properties: even though actual aggression is an (ambiguous) indicator of rage, we should be ill advised to define anger as a disposition to attack, as has been suggested (Ryle, 1949) – if only because this fails to account for attacks in cold blood. Nor can we define thought as a disposition to talk, itching as a disposition to scratch, and so forth: this is just mistaking evidence for reference (Feigl, 1967). Thinking, feeling an itch and the like are just as actual as talking and scratching: that they are not public or intersubjective is another matter – one for methodology not ontology.

Dispositions are just as important as manifest properties even though the latter can explain the former, as shown by Definition 4.7. The possibility of dissolving is not the same as actual dissolution: while the latter is a property of a complex system (solute *cum* solvent), the former is a property of one of its components. For example, the solubility of salt in water consists in a certain feature of the crystal structure of dry salt which, when joined with water, gives rise to actual dissolution. We may then assert that dispositions of the causal kind are rooted in manifest properties. But this is not the same as eliminating the former. Besides, as will be seen in Sec. 5, noncausal dispositions are not so explainable: on the contrary, they help explain manifest properties. In conclusion, actualism cannot hold the fort.

3.4. *Unrealized Possibilities and Counterfactuals*

It will be noted that we have not employed counterfactuals in our elucidation of disposition. However, it is widely believed that dispositional expressions must be defined in terms of subjunctive conditionals. Thus it is commonly held that

> x is fragile $=_{df}$ If x *were* thrown against a rigid body, then x *would* break.

and

> x can do $y =_{df}$ If x *were* placed in suitable circumstances, x *would* do y.

This view seems to have originated in the operationist confusion between meaning and test: since actual breaking is evidence for fragility, and performance for ability, it is inferred that that is what they are. Science has paid no attention to this doctrine: if definable at all, i.e. if not primitive, dispositionals are defined with the help of declarative sentences only. Witness any scientific treatise or research paper.

There are good reasons for avoiding the subjunctive mood. Firstly to avoid ambiguity. Indeed one and the same subjunctive sentence may be construed in at least two different ways (Bunge, 1968d). In fact 'If A were the case then B would obtain' can be interpreted as representing either the statement

If A then B. But not A. (No inference at all.)

or the inference

If A then B. But not B. (Tacit inference: not-A.)

Such an ambiguity renders subjunctive conditionals unsuitable for scientific communication, except of course at the level of heuristic language. A second reason for avoiding subjunctive conditionals is that they are not propositions, hence they do not fall under the rules of logic. Therefore the "definitions" of fragility and ability at the beginning of this subsection are phoney.

It should not be concluded that subjunctives are junk: indeed they have considerable suggestive or heuristic power. But (*a*) they should be used with caution and (*b*) they should be avoided altogether in reconstructing scientific theories as well as in reporting experimental results. In any case, far from being capable of shedding any light, subjunctive conditionals are in need of clarification.

So much for dispositions of the causal kind. Let us now turn to a kind of disposition that is not reducible the way causal disposition is, namely chance propensity. But before doing so it will be convenient to play the probability interlude.

4. PROBABILITY

4.1. *Abstract Concept*

Let us recall the gist of the theory underlying any technical (as opposed to ordinary language) statements of the form "The probability of a equals b", or "$Pr(a)=b$" for short. Pr is a real valued function on a certain set F characterized only by its structure. To begin with F is a family of subsets of a certain abstract set S, i.e. $F \subseteq 2^S$. Further, F is closed under finite unions and intersections, and also under complementation. Therefore F is closed under finite unions and symmetric differences. So, F has a ring structure. Moreover, F is a *σ algebra* because it is a ring and $S \in F$. In other words, F is a σ algebra in the sense that its members obey the algebra of sets extended to countably finite unions. We shall call F the *probability space* or *support* of the *Pr* measure. (F is often called the *space of events* or the *sample space*, names as suggestive as they are out of place in pure mathematics.) We are now ready for

DEFINITION 4.10 Let F be a σ algebra on a nonempty set S, and *Pr* a real valued function on F. Then *Pr* is a *probability measure* on F iff

(i) *Pr* is a non-negative real valued function on F. [I.e., for every member A of the collection F of subsets of the basic set S, $Pr(A) \geqslant 0$.];

(ii) *Pr* is completely additive in F. [I.e., for any countably infinite collection of pairwise disjoint sets in F, the probability of their union equals the sum of their individual probabilities. In particular, if $A, B \in F$, and $A \cap B = \varnothing$, then $Pr(A \cup B) = Pr(A) + Pr(B)$.];

(iii) *Pr* is normed. [I.e., $Pr(S) = 1$.]

Note the following points. Firstly, the theory based on these sole assumptions is *semiabstract* insofar as it does not specify the nature of the elements of the probability space F. On the other hand the range of *Pr* is fully interpreted, hence the *semi*. This is why probability theory finds applications everywhere, from physics to metaphysics. Secondly, an obvious way in which one can satisfy the condition that F be a σ algebra, is by taking $F = 2^S$. Indeed, any power set is a σ algebra. Thirdly, the first two axioms define a *measure*, and the third makes it a probability measure. This shows that the foundations of the theory of probability constitute but a chapter of measure theory – not one of philosophy. However, such foundations, like any others, are insufficient for any applications. Indeed, as long as the probability space F is not specified, i.e. as long as no model is constructed, probability has nothing to do with possibility, propensity, or randomness. Let us dwell for a while on this important methodological point.

An *application* of any abstract or semiabstract theory to some domain of facts consists in joining to the theory two different items: (a) a model or sketch of the object or domain of facts to which the theory is to be applied, and (b) an interpretation of the basic concepts of the theory in terms of the object to which it is applied. In particular, an application of probability theory consists in joining Definition 4.10 (or some of its consequences) with (a) a stochastic model – e.g. a coin flipping model or an urn model-, and (*b*) a set of interpretation (or semantic) assumptions sketching the specific meanings to be attached to a point x in the probability space *F*, as well as to its measure $Pr(x)$. As long as these additional assumptions are not made, the theory is indistinguishable from measure theory: only those specifics turn the semiabstract theory into an application of probability theory or part of it. (For an elucidation of the notion of degree of interpretation or its dual, degree of abstraction, see Vol. 2, Ch. 7, Sec. 3.4.)

Now, before we proceed to build a model of a class of facts we must identify the latter, i.e. choose a definite ("concrete") probability space *F*. The latter may but need not represent a collection of states or of changes of state of a thing. (Whether or not a point x in *F* represents a state or an event, it is usually called either of the latter by most probability theorists.) Next we must make sure that *F* is a σ algebra, or else we must manufacture one out of the given basic set *S*. If *S* is the state space of some thing, and if we wish to speak of the probability of a state, we must make a détour: since the elements of *S* are points, not sets, we construct the power set 2^S. In other words, we construe the idiom 'the probability of state s' as "the probability of the singleton $\{s\}$". Once this algebraic matter has been attended to we can proceed to interpret the primitives *F* and *Pr*, for instance in terms of states and their propensities. Let us turn to this latter problem.

4.2. *Probability State Space*

In some cases the states of a thing can be assigned definite probabilities and some pairs of states of the same can be allotted definite conditional probabilities. As we saw in the last subsection, in order to assign probabilities to states it is expedient to construe the latter as sets. The cheapest way of doing so is to take the set of all the subsets of the set $S(X)$ of states of thing X, i.e. the power set $2^{S(X)}$, as the probability space. In this fashion we can manufacture

DEFINITION 4.11 Let X be a thing and $S(X)$ a state space for X. Then the structure $\langle 2^{S(X)}, Pr\rangle$ is a *probability state space* for thing X iff

(i) $S(X)$ is denumerable and

(ii) $Pr: 2^{S(X)} \to [0, 1]$ is a probability measure defined for every set of states and satisfying in particular the condition: $Pr(S(X)) = 1$.

Caution: the states in a probability state space are not ordered naturally according to their increasing probability, for it may well happen that different (e.g. succeeding) states have the same probability. Thus according to statistical mechanics the evolution of a closed system follows on the whole (i.e. with but a countable number of exceptions) the line of increasing vulgarity: see Figure 4.3. But the fact that there can be occasional decreases in probability values prevents us from identifying prior states with improbable states. In other words, the direction of a process is not given unambiguously by the direction of increasing probabilities.

If all the states of a thing are equally probable, the thing may be said to be *state homogeneous*. And, since no states are preferred, once the thing has attained a given state it remains there, i.e. it does not change any further. But this is of course a fiction: there are no unchanging things, hence no state homogeneous things. Real things are *state heterogeneous*, in the sense that some of their states are definitely more probable than others. In other words, a state heterogeneous thing is a thing with states that deviate from the homogeneity or equilibrium value p_0. (For a thing with a finite number N of equiprobable states, $p_0 = 1/N$.) This suggests adopting the number $h(s) = Pr(s) - p_0$ or its square as a measure of the deviance or distinction of state s. For the entire collection $S(X)$ of states of a thing X we adopt

DEFINITION 4.12 The *state heterogeneity* of a thing with state space S equals

$$H(S) = \sum_{s \in S} h^2(s), \quad \text{with} \quad h(s) = Pr(s) - p_0,$$

where p_0 corresponds to maximal (and ideal) state homogeneity.

Figure 4.4 shows three typical heterogeneity values. It will be noted that any given state heterogeneity value can be realized in diverse manners.

The following consequences follow easily because of the normalization of the total probability to unity:

(i) The state heterogeneity of a thing with N states is

$$H(S) = \sum_i p_i^2 - 1/N, \quad \text{with} \quad p_i = Pr(s_i) \quad \text{and} \quad s_i \in S.$$

(ii) As the total number of states of a thing approaches infinity, the state heterogeneity approaches the average probability:

$$\lim_{N \to \infty} H(S) = \sum_i p_i^2 = \bar{p}.$$

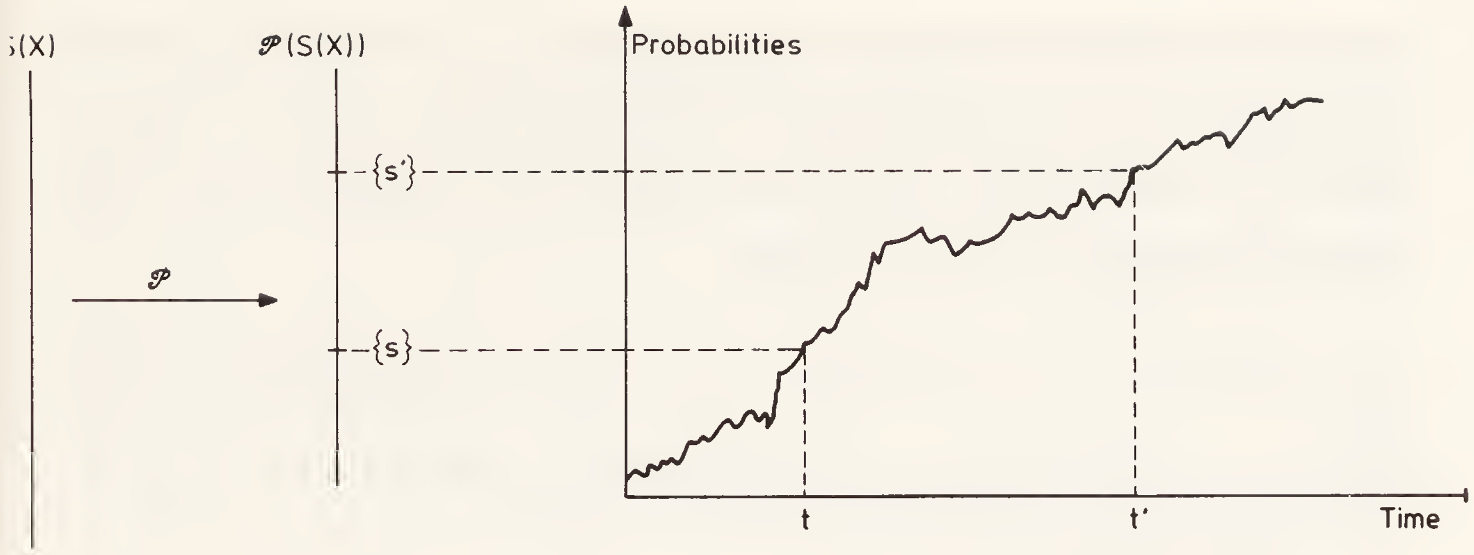

Fig. 4.3. The thermodynamic probabilities of the states of a statistical mechanical system: on the whole later stages have higher probabilities – but only on the whole, i.e. as a tendency.

The last quantity is sometimes regarded as a suitable measure of the degree of organization of a thing. This interpretation does not seem to be adequate in view of Definition 4.12. If anything, $H(S)$ measures the degree of mutability or mobility of a thing – provided S is a probability state space for the thing.

The last notion to be elucidated in this subsection is that of thing integration. Let X and X' be two different things that join to form a third thing $X \dotplus X'$. If the combination is of the conglomeration kind, the individual state spaces do not alter and the total state space is the union of the partial state spaces. And the probability that the components of the thing be in states s and s' respectively is the product of the probabilities of s and s', i.e. $Pr(s, s') = Pr(s) \cdot Pr(s')$. These probabilities change if the two components interact in the process of joining. And the stronger the interaction or correlation the greater will be the departure of $Pr(s, s')$ from the independence or noninteraction value $Pr(s) \cdot Pr(s')$.

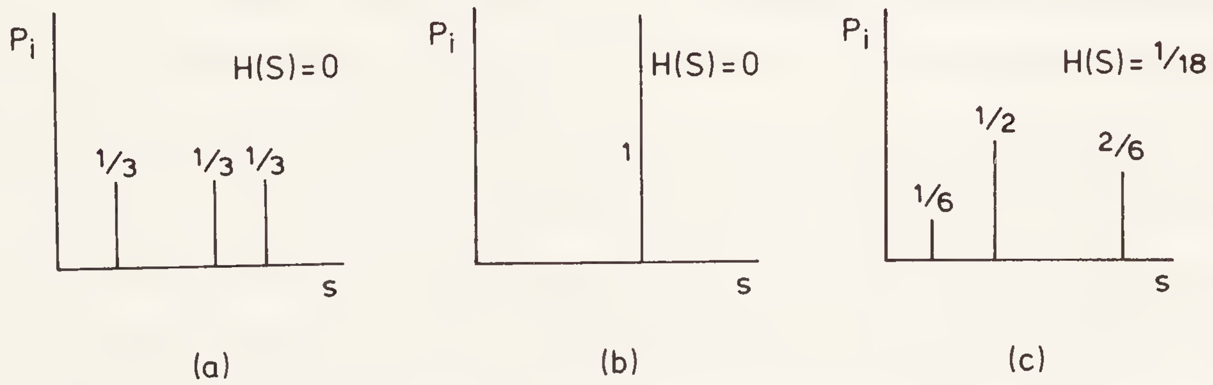

Fig. 4.4. State homogeneity (cases a and b) and heterogeneity (c).

We can then choose such a deviation, or $Pr(s, s') - Pr(s) \cdot Pr(s')$, as a measure of the interaction among the things in states s and s' respectively. The sum of the absolute values, or of the squares of these differences, for all states, seems to constitute a suitable measure of the degree of integration of the system:

DEFINITION 4.13 Let X and X' be two things with probability state spaces $\langle 2^{S(X)}, Pr\rangle$ and $\langle 2^{S(X')}, Pr\rangle$ respectively, and let $X \dotplus X'$ be the thing composed of X and X'. Then the *degree of integration* of $X \dotplus X'$ (or *strength of the interaction* between X and X') is

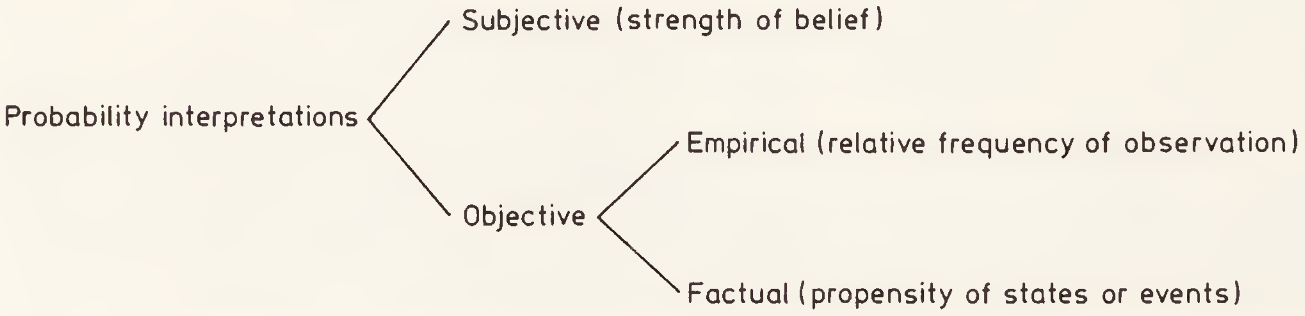
$$K(X, X') = \sum_{s \in S(X)} \sum_{s' \in S(X')} \left[\frac{Pr(s, s') - Pr(s) \cdot Pr(s')}{Pr(s) \cdot Pr(s')}\right]^2$$

provided this double sum converges.

Clearly, the above definition cannot be generalized to a system the components of which fail to have probability state spaces.

4.3. *Propensity Interpretation*

There are several interpretations of probability. The main contenders are the subjectivist (or personalist or Bayesian) interpretation and the objectivist interpretation, of which there are at least two variants: the empirical and the factual. The following tree summarizes these views.



Probability interpretations
Subjective (strength of belief)
Objective
Empirical (relative frequency of observation)
Factual (propensity of states or events)

According to the subjectivist school probability values are not objective individual properties of states of things or events in things but rather degrees of certainty about our information. Clearly, this interpretation is not the one occurring in scientific theories such as quantum mechanics or genetics, which do not concern our beliefs, let alone our beliefs about the strength of our beliefs. Science, and therefore also scientific ontology, employ an objective interpretation of probability. There are two main variants of this interpretation: the frequency and the propensity interpretations. According to the former, probability values are limits of observed frequencies: they are properties of sets of data rather than properties of the referents of such data. It has been shown repeatedly that this view is mathematically untenable, if only because frequencies fluctuate erratically around stable probability values. Strictly speaking then there is no such thing as a consistent frequency interpretation of probability: there are only frequency estimates of probability values (Bunge, 1973b, 1976a). We are then left with the strictly objective, or factual interpretation.

Recall from Sec. 4.1 that the probability calculus has two specific undefined notions: those of probability space F and probability measure Pr. And remember from Vol. 2, Ch. 6 that a full interpretation of a mathematical formalism involves interpreting all of its primitives. Now, a *factual interpretation of probability theory* consists in assigning F and every value $Pr(x)$, for $x \in F$, factual meanings. One such possible interpretation consists in regarding the basic set S, out of which F is manufactured, as the state space of a thing, hence every element of the probability space F as a bunch of states, and $Pr(x)$ as the strength of the thing's propensity to be in the state (or states) x. Similarly, if x and y are states (or sets of states) of a thing, the conditional probability of y given x, i.e. $Pr(y|x)$, is interpreted as the strength of the propensity or tendency for the thing to go from the state(s) x to the state(s) y.

Given the structure of the probability function and the interpretation of its domain F as a set of facts, the propensity interpretation is the only possible one. Indeed, if $x \in F$, then $Pr(x)$ cannot be but a property of the individual fact x. That is, contrary to the frequency view, probability is not a collective or ensemble property, i.e. a property of the entire F, but a property of every individual fact – its propensity to happen. (Hence the expression 'single case propensity interpretation', used by Giere, 1974, is redundant.) What *are* ensemble properties are derived functions such as the moments of a probability distribution (in particular its average), its standard deviation if it has one, and so on. This consideration suffices to ruin the frequency school, according to which probability is a collective or ensemble property.

As for the subjectivist (or personalist or Bayesian) interpretation, it is untenable even assuming that the domain F of Pr is a collection of mental facts. For, in the expression '$Pr(x) = y$', there is no room for a variable denoting the person who feels that the number y measures the strength of his belief in x. The personalist must interpret not only F in subjective terms: he should also have a variable representing his attitude towards his own mental facts *F*. If this variable is the generic probability value *y*, then it is the same for all persons, so there is no occasion for a subjectivist interpretation. And if it is a different variable then it does not occur in probability theory but in some psychological theory concerning uncertainty as a mental state. That different persons may come up with different estimates or guesstimates of the probability of one and the same fact is obvious but does not countenance the subjectivist interpretation any more than the uncertainties concerning electric charge values would justify a subjectivist electrostatics.

To return to the propensity interpretation. This must be distinguished from the probability elucidation or exactification of the presystematic notion of propensity, tendency, or ability. In the former case one attaches factual items to a concept, whereas in the latter one endows a factual concept with a precise mathematical structure. (Cf. Vol. 2, Ch. 6, Sec. 3.8.) In science and in ontology we need both factual interpretation and mathematical elucidation. Note also that an interpretation of probability is incomplete unless it bears on the two primitives of the theory, i.e. *F* and *Pr*. Thus the factual interpretations of Poincaré, Smoluchowski, Fréchet and others are incomplete for being restricted to assuming that a probability value is a "physical constant attached to an event *E* and to a category *C* of trials" (Fréchet, 1939). This is like saying that *e* is a physical constant without adding that *e* happens to be the electric charge of the electron. The propensity interpretation is not open to such a charge of incompleteness, for its asserts explicitly that $Pr(x)$, for $x \in F$, is the propensity or tendency for *x* to happen.

It is instructive to contrast the propensity to the actualist (or frequency) interpretations of probability values, assuming that both agree on the nature of the support set *F*. (This assumption is a pretence: not only a frequentist like von Mises but also Popper, the champion of the propensity interpretation, have emphasized that facts have no probabilities unless they occur in experimentally controlled situations.) This contrast is displayed in Table 4.3.

Note the following points. Firstly, although a probability value is meaningful – i.e. it makes sense to speak of the single fact propensity – it is so only in relation to a definite probability space *F*. Likewise a frequency value makes sense only in relation to a definite sample-population pair. For example, the formula "*x* is rare" presupposes a certain set of occurrences, to which *x* belongs, and among which *x* happens to be unfrequent.

TABLE 4.3

Potentialist vs. actualist interpretation of probability

$p = Pr(x)$	Propensity	Frequency
0	x has (almost) nil propensity	x is (almost) never the case
$0 < p \ll 1$	x has a weak propensity	x is rare
$0 \ll p < 1$	x has a fair propensity	x is fairly common
$p \doteq 1$	x has a strong propensity	x is very common
$p = 1$	x has an overpowering propensity	x is (almost) always the case

Secondly, in the case of continuous distributions, zero probability is consistent with very rare happenings: i.e. even if $Pr(x) = 0$, x may happen, though but rarely as compared with other events represented in the probability space. (All breakthroughs and all emergents – hence the most important events – have low probabilities, perhaps vanishing ones.) Consequently a fact with probability 1 can fail to happen. (Recall that the rationals have zero Lebesgue measure. Entire sets of states and events are assigned zero probability in statistical mechanics for this very reason even though the system of interest is bound to pass through them. This is what 'almost never' is taken to mean in that context, namely that the states or the events in question are attained only denumerably many times.)

Thirdly, the frequency column should be kept alongside the propensity interpretation though in a capacity other than interpretation or definition. Indeed although it fails to tell us what "$Pr(x) = y$" *means* it does tell us under what conditions such a formula is *true*. Long run frequency is in short a *truth condition* for probability statements. (For the problem whether truth conditions determine meanings, see Vol. 2, Ch. 8.)

Fourthly note again that our propensity interpretation differs from Popper's in that the latter requires the system of interest to be coupled to an experimental arrangement. No such hang-up from the frequency or empiricist interpretation remains in our own version of the propensity interpretation. Nor do we require that only events (i.e. changes of state) be assigned probabilities, as an empiricist must (since states may be unobservable): states too may be assigned probabilities, and in fact they are assigned in many a stochastic theory, e.g. statistical mechanics and quantum mechanics. (The statistical mechanical measure of entropy is a function of the probability of a state or, as Planck put it, it measures the preference [*Vorliebe*] for certain states over others.) In other words not only transition probabilities but also absolute probabilities can be factually meaningful. The requirement that only transition probabilities be considered in physics (Strauss, 1970) is untenable for the following reasons. First, since a transition probability is a conditional probability, and the latter is defined in terms of absolute probabilities – not the other way around – the former cannot have a factual meaning unless the latter has one. Second, an electron cloud (or position distribution for an electron) has a definite physical status, so much so that it can often be objectified by means of X rays.

So much for the propensity interpretation of probability. We shall see in the next section that the propensities of this kind, unlike the causal propensities, must be regarded as primary (irreducible) properties of things of certain kinds.

5. CHANCE PROPENSITY

5.1. *Irreducible Potentialities*

Classical physics assigns every point particle a definite position at each instant. On the other hand a quantum mechanical "particle" possesses at each instant a definite position distribution, i.e. a whole range of possible positions, each with a given weight or probability: see Figure 4.5. Likewise with other quantum mechanical properties, such as linear and angular momentum, spin, and energy: save in exceptional cases

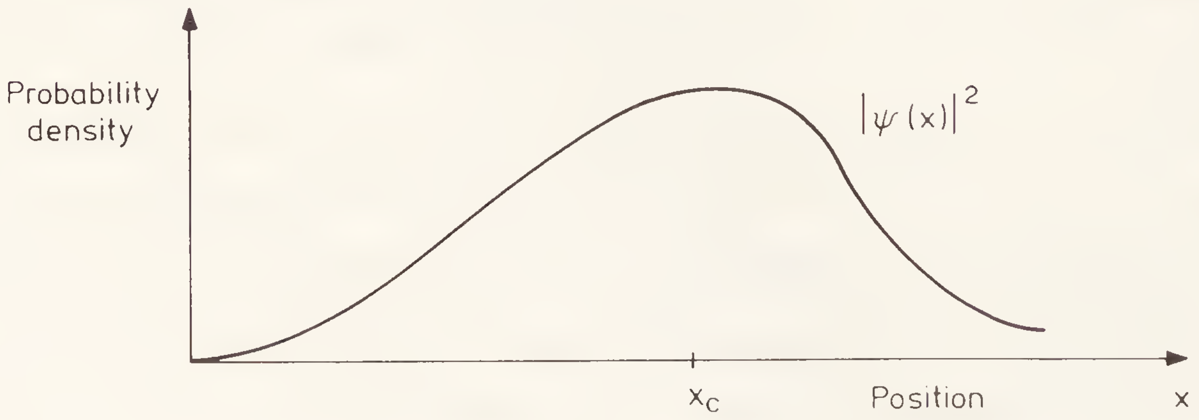


Fig. 4.5. The classical position value x_c and the quantal position distribution $\rho = |\psi(x)|^2$ of a "particle" at a given instant. The weighted average of x, i.e. $\langle x \rangle_{AV}$, coincides with x_c in the nonrelativistic limit.

each "particle" has a whole bunch (interval) of values of each of these properties. (The exceptions are constituted by the states of the "particle" that happen to be eigenstates of the corresponding property. For example, a thing in an energy eigenstate has a sharp energy value not a whole distribution of energy values. But such states, i.e. stationary states, are privileged.)

An alternative way of describing this contrast between classical and quantal properties is as follows. Where classical physics offers a nonstochastic dynamical variable Q_c, quantum physics introduces a distribution $\psi^* Q \psi$ (a "local observable"), where Q is an operator acting on the state function ψ, a place and time dependent function that determines the position probability density. (It may be assumed that these densities or bilinear forms represent the basic dynamical variables of a thing, whereas the operators Q are syncategorematic symbols serving to construct the distributions $\psi^* Q \psi$.) Every one of these random variables ("local observables") is a property of an individual thing, not a collective property of a whole bunch of similar things.

From a classical point of view this situation is intolerable. Hence the classicist will often interpret ψ as representing the state of a statistical ensemble rather than as a property of an individual thing. (This is in fact the interpretation favored by Einstein and Blokhinzev.) Yet the theory does not tolerate this interpretation of an expression such as '$\psi^* x \psi$': since it contains a single position variable x, it cannot be forced into representing a whole aggregate of particles. As long as we accept quantum mechanics we must become reconciled with its nonclassical features, such as that position is a random variable with a number of possible values, each with its own probability, for each microthing. Only the average of such a distribution is a sharp point and it coincides with the classical value. In other words, classical physics gives only a global or superficial account of microentities by ignoring the fact that the dynamical properties of the latter are random variables smeared over the entire space accessible to those entities. (See Bunge, 1977c.)

It must be stressed that the $\psi^* Q \psi$ do not just point to possible states and events: they represent properties possessed all the time by a microthing. That is, the $\psi^* Q \psi$ represent *manifest* (though not directly observable) properties rather than latent ones. On the other hand a sharp value of Q, such as any of the eigenvalues of Q, is a dispositional property of the thing concerned. In other words a thing with a Q-distribution $\psi^* Q \psi$ has the *propensity* to acquire this or that sharp Q

(eigen)value. For example, a photon travelling in free space is not concentrated at a point but, when bumping into an atomic electron, it may suddenly contract – only to be absorbed the next moment. And an electron may, under the influence of an external field, acquire a definite momentum value, though at the expense of its localization. Here the distribution is primary while the sharp values are exceptional. On the other hand in classical physics sharp values are basic and distributions derivative: they result from the interplay of numerous entities. (See Figure 4.6.) Only a classical foundation of quantum mechanics could reinstate the primacy of the sharp actual value, but then at the price of keeping the primacy of probability. (See de la Peña (1969) and de la Peña and Cetto (1975).)

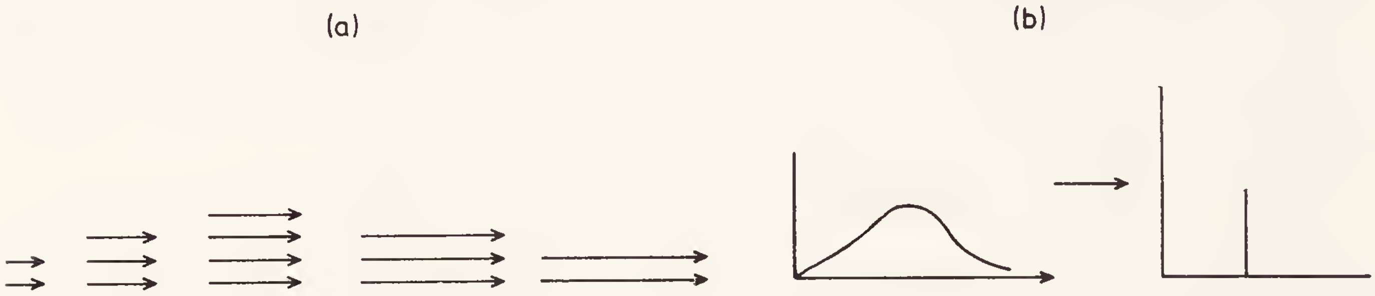

Fig. 4.6. (*a*) Classical physics: from sharp individual velocity values to distributions. (*b*) Quantum physics: from distributions to sharp individual values.

It should be stressed that the stochastic properties represented by the quantum mechanical operators Q (or their corresponding densities $\psi^*Q\psi$) are usually intrinsic properties, not properties of the thing interacting with an experimental set up. Indeed the Q's are defined as dynamical variables of the microthing of interest regardless of its circumstances: the apparatus, if present at all, has its own dynamical variables distinguished from the former by some index and acting only on the part of the state function that refers to the apparatus. The alleged ubiquity of the latter is not warranted by the mathematical formalism (Bunge, 1967b and 1973b). Besides, as emphasized by Mellor (1971), there is no point in talking of dispositions if one ascribes them to the whole "chance setup" or "experimental situation" rather than to the thing of interest, for the occurrence of a given situation is an opportunity for the disposition to display itself, not to be confused with the disposition itself. (For an excellent and detailed discussion of this matter see Settle (1974).)

5.2. *Analysis*

It will be remembered from Sec. 3 that a causal disposition or propensity is a potency that becomes actualized under suitable circumstances. The environment offers opportunities for actualization or curtails them and it is necessary and sufficient for actualization. In the case of chance propensities the possibilities lie wholly in the thing itself and the environment takes its pick. Moreover the environment may be nonexisting, in that the occurrence of an actual property may be spontaneous or uncaused, as is the case with natural radioactivity. In other words, whereas in the case of causal dispositions actualization requires that the thing of interest join another real entity, in the case of chance propensities actualization may occur if the thing joins the null thing – which is of course an artifice introduced to gain uniformity. More precisely, we make

DEFINITION 4.14 Let $z = x \dotplus y$ be a thing composed of different things x and y, where y is possibly the null thing. Further, let Q be a property of x. Then Q is said to be a *chance propensity* of x iff

(i) Q is representable nontrivially by a random variable or a probability distribution, so that each value (or interval) q of Q has a definite probability p;

(ii) y has a property R such that, when x joins y to form $z = x \dotplus y$, the probability that x acquires the individual property q (a value of Q) equals p. [I.e., $Pr(Q = q|R) = p$.]

Example 1 $x =$ electron, $y =$ diffraction system, $Q =$ position distribution of x, $R =$ letting the electron pass through a slit. *Example 2* $x =$ person, $y =$ learning environment, $Q =$ learning ability, $R =$ = allowing the person to learn.

Finally we make

DEFINITION 4.15 The *chance potentiality* of a thing x is the collection of its chance propensities:

$$\Pi_X(x) = \{P \in p(x) | P \text{ is a chance propensity}\}.$$

A thing has a greater chance potentiality than another just in case the chance potentiality of the former includes that of the latter. For example, an atom has a greater chance potentiality than any of its components; likewise a community has a greater chance potentiality than any of its members. Finally, the *potentiality* of a thing equals the union of its causal potentiality and its chance potentiality:

$$\Pi(x) = \Pi_c(x) \cup \Pi_\chi(x).$$

5.3. *Upshot*

In the present chapter we have introduced a trichotomy in the set $p(x)$ of properties of any thing x. Indeed we have assumed that $p(x)$ splits into three disjoint subsets: those of

(i) *manifest properties*, i.e. those possessed by the thing under all circumstances as long as the thing exists and remains in the same natural kind – e.g. the electric charge of an electron and the protein synthesizing activity of an organism;

(ii) *causal dispositions*, or propensities to acquire certain manifest properties under certain circumstances – e.g. the chemical reactivity of an atom and the impregnability of a mature female mammal;

(iii) *chance propensities*, or dispositions to acquire with probability certain manifest properties, depending (or not) on the circumstances.

Moreover we have drawn a radical distinction between causal and chance propensities, two categories that are usually conflated. To begin with, chance propensities are not ordinary or causal dispositions such as fragility, as there is nothing necessary about the former. In fact a distribution may collapse into any of a number of values, each possible transition having a definite probability. (Conversely, a sharp property may end up by being blurred.) Secondly, chance propensities are often basic, as shown by quantum physics and genetics. But not always: see Table 4.4. It is not true that every manifest property is rooted in a chance propensity, as extreme possibilism would have it. Nor is it true that every disposition and every chance propensity is rooted in a manifest property, as actualism claims. Both kinds of reductionism are at variance with science.

Real possibility is objective or absolute in an epistemological sense, i.e. for being independent of the knowing subject. But it is not absolute otherwise. Potencies, whether causal (like the viability of a seed) or stochastic (like the ability to learn an item on first presentation), are actualized under certain circumstances, frustrated under altered circumstances. Moreover the possibilities themselves depend upon the circumstances just as much as upon the thing concerned. Thus a peasant who migrates to a town acquires certain job and educational possibilities

TABLE 4.4

Examples of actual or manifest property, causal disposition, and chance propensity. Arrows indicate property precedence

Manifest property	Causal disposition	Chance propensity
Electric charge ———	———	→ Ionizing capacity
Sharp position value ←	———	——— Position distribution
Body mass ———	→ Body weight in a gravitational field	
Display or performance of ← an inheritable ability	——— Possession of an ← inborn ability	——— Acquisition of an inheritable ability by random gene shuffling.

that were formerly denied him, and on the other hand loses a number of traits, such as integration in a community. Hence, rather than as a monadic operator possibility should be construed as a dyadic one: fact x is possible (or impossible) under circumstance (state of the environment) y. If only for this reason modal logic is impotent in handling real possibility, whereas the relativity of possibility is incorporated into the notion of conditional probability. But modal logic deserves a separate subsection.

6. MARGINALIA

6.1. *Modal Logic and Real Possibility*

Modal logic was built in order to elucidate both the logical and the ontological concepts of possibility (see e.g. Lewis and Langford, 1932). For this reason it has often been regarded as a prerequisite for both logic and metaphysics (see e.g. Marcus, 1968). Having disposed of the former claim in Sec. 1 let us now examine the latter.

One of the most vigorous and well known defenses of the thesis that modal logic elucidates the concept of real possibility is Montague's (1960, 1974). He claimed that the principles of a certain modal calculus hold under the interpretation of '$\Box$' as "it is physically necessary that", which in turn is defined as follows: "ϕ is physically necessary iff ϕ is deducible from a certain class of physical laws specified in advance". In other words, Montague identified necessity with (theoretical) lawfulness, and disregarded circumstances. (Besides, he attributed formulas, not their referents, physical necessity, thus conflating the latter with logical necessity.) But, as we saw in Sec. 2.4, law statements, whether stochastic or not, specify only possibilities: they are so universal that they concern all possibles of a kind rather than just necessary facts. In other words, a really possible fact is one referred to by a law statement. Necessity cannot be specified without the help of the notion of circumstance, which is not incorporated into that of law. Just think of the simplest case of an equation of motion: the actual (necessary) trajectories cannot be determined unless the initial conditions are adjoined to the solutions.

Furthermore no system of modal logic is a calculus of real possibles for the simple reason that it concerns propositions not facts. For this very reason the modal logician is forced to twist "It may rain" into "It is possible that the proposition ⌜It will rain⌝ be true", or "⌜It will rain⌝ is true under some conceivable circumstances". That is, he shifts possibility from reality to statements about reality – so much more docile – thereby concealing real possibility under the rug of conceptual possibility and truth. He does the same, of course, with regard to necessity. (Worse: he has no notion of truth independent of that of satisfiability in a possible world, which he identifies with a model. And he does not know of the existence of factual and partial truth as distinct from formal and total truth.)

In science and in ontology we have little use for the notion of absolute (unconditional) possibility as well as for the modal principle ⌜$p \Rightarrow \Diamond p$⌝. What would be important is an altogether different thesis, namely: "Whatever is now the case was possible at some earlier time". But this statement includes a concept of time, which is not yet available to us and in any case is alien to modal logic. Finally ⌜$\Diamond p$⌝ is ontologically indistinguishable from ⌜$\Diamond \neg p$⌝. Thus, "That tile may fall down" has intuitively the same meaning as "That tile may not fall down" – not so in modal logic. The probabilistic versions of these statements too have the same meaning: "The probability of that tile's falling down is $\frac{1}{2}$" means the same as "The probability of that tile's not falling down is $\frac{1}{2}$" because these statements are interdeducible. Modal logic ignores all this. So we can ignore modal logic.

Most mathematical logicians ignore modal logic because they do not need it. And some, notably Quine, dislike modal logic for the wrong reason, namely because they distrust the very notion of possibility. My own evaluation of modal logic has a different rationale: I believe it is a futile game because it fails to deliver the goods it promised, namely a clarification of the notions of conceptual and of real possibility – which, to make things worse, it confuses. It is not that these notions are unimportant; on the contrary, they are much too important to be left in the care of so poor a theory as modal logic. In particular the notion of real possibility is rampant in science, which manages to handle it without the help (or rather hindrance) of modal logic. In fact every scientific theory concerns possible facts: its very referents are possible things in possible states, and every such state is representable as a point (or a region) in the state space of the thing. (To meet actuals, which theory treats as merely special cases of possibles, one has to visit observation, measurement or experiment.) But science, as we have seen, handles possibles in a way which is at variance with modal logic. For one thing in science a possible fact is a fact compatible with the laws, constraints, and circumstances (e.g. initial and boundary conditions). If the circumstances are given then the fact is either actualized or probabilified. In either case the possibility notion is construed in a fashion alien to modal logic. In other words the possibles of science are just members of some set or other – e.g. the set of nomologically possible states. Hence they are treated in a fully truth-functional way, without the assistance of modal logic. (See Figure 4.7.)

What holds for traditional modal logic holds also for the model

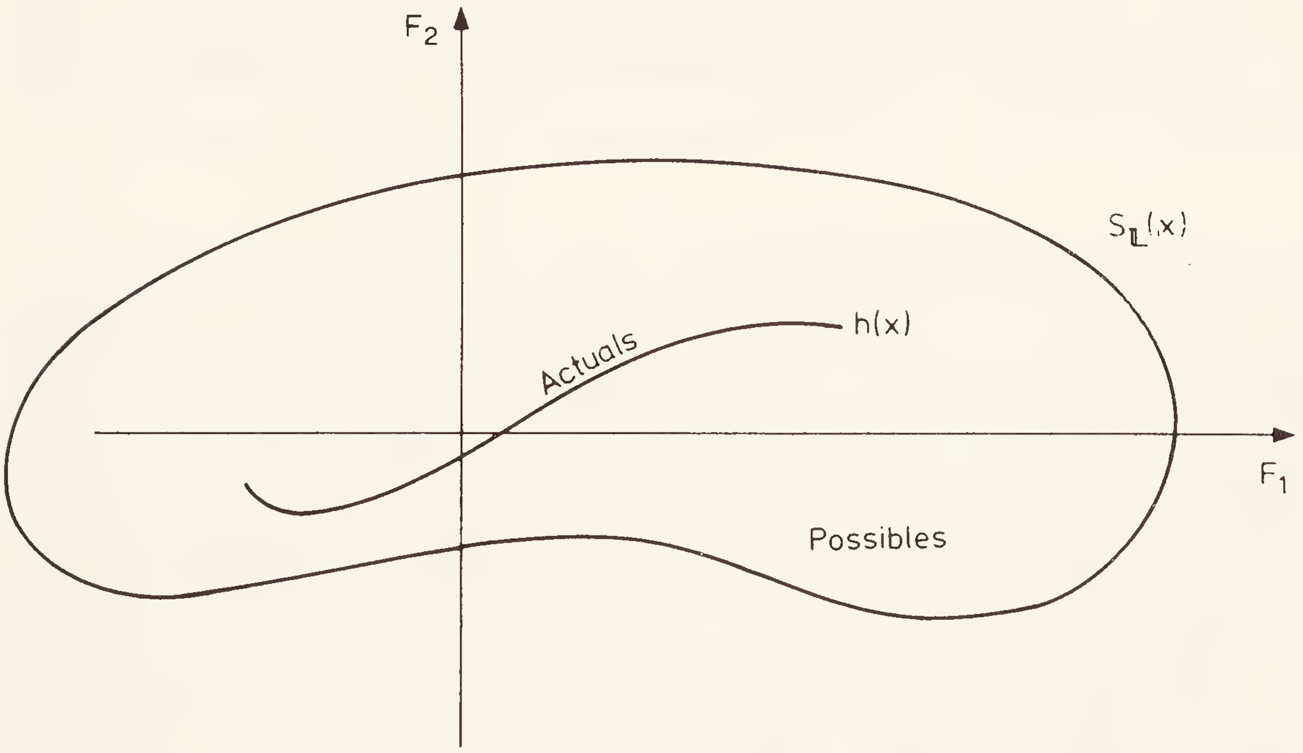

Fig. 4.7. Possibility and actuality in science and in ontology. An arbitrary point in the nomological state space $S_{\mathbb{L}}(x)$ of a thing x represents a possible state of x. The history $h(x)$ of x represents the sequence of actual states of x. No modal logic is involved.

theoretic construal of modalities (Kripke, 1959; Cresswell, 1973). According to this view possibility is satisfiability (in some model) whereas necessity is satisfiability in every model. We have admitted this idea as providing an elucidation of *one* of the four notions of *conceptual* possibility (Sec. 1.2). But the predicate "is satisfiable" refers to abstract or semiabstract (i.e. not fully interpreted) formulas – not to facts. Hence the contemporary view of modality is just as irrelevant to ontology as was Leibniz' construal of possibility as truth in some possible world.

The related notion of a model set does not fare any better with reference to ontology. In fact recall its definition (Hintikka, 1969, p. 72): "a model set [i.e. a set of formulas that are wholly true under some interpretation of the extralogical constants occurring in them] may be thought of as a partial description of a possible state of affairs or as a possible course of events ('possible world')". Here again we are concerned with abstract or semiabstract formulas not with factual law statements, let alone with factual circumstances.

In sum, neither modalities nor models for modalities elucidate the notion of real possibility. If they did, subjective idealism would be true and science redundant: we would ask the philosopher not the biologist whether sparrows could mutate into daffodils. In conclusion, modal logic fails to elucidate the concepts of real possibility – in particular those of causal disposition and chance propensity –, so it is just as useless in ontology as in semantics. Nevertheless, modal logic has promoted a new metaphysics, or rather metaphysics fiction – to which we turn presently.

6.2. *Possible Worlds Metaphysics*

If real possibility is construed as lawfulness (Sec. 2.3), then the question 'Which are the possible worlds?' becomes 'Which are the real laws?' Now, the answer to the latter is of course: 'The real laws are those inherent in the real world'. Hence the solution to the original problem is: "The set of really possible worlds is the singleton formed by the real world". Hence ours is neither the best of all possible worlds (as Leibniz and Wolff professed to believe) nor the worst of them (as the Hebrew and Christian traditions have it). Ours is the only (nomologically, really) possible world. Any alternative worlds are imaginary and belong in nonscience fiction, such as mythology. All of the (logically) possible worlds but one are (really) impossible.

Philosophers with little taste for the real world like to indulge in daydreaming about conceptually possible worlds. These provide a cozy shelter and do not have the rude manners of the real world – in particular the habit of refuting conjectures about real possibilities. A quick look at three typical problems handled by such speculations will suffice.

A first problem faced by any system of possible worlds metaphysics is of course that of defining the very concept of a possible world. This task has been performed in an elegant way by Cocchiarella (1974), who has refined, with the help of contemporary formal tools, some of the intuitions of C. I. Lewis (1923). A possible world is defined as a certain set of propositions – not of things or of facts. But this is of course a possible world of the conceptual kind (Sec. 1) – one abiding by the laws of logic not by those of factual science. Hence it is of no interest to ontology, which is concerned with the general concept of real possibility and with the question: What makes certain factual items really possible and others impossible?

As soon as one assumes the existence of a multiplicity of possible worlds one faces the question of what if anything they share. In particular, assuming that a certain individual belongs to two possible worlds, how are we to identify it? (This is the problem of transworld identification.) A special technical tool has been devised to attack this problem, or rather pseudoproblem, namely the concept of a rigid designator (Kripke, 1971). This technicality is of course unnecessary in our ontology for the simple reason that it deals only with the one real world.

Finally, some systems of possible worlds metaphysics have been applied to certain (mini)problems such as that of the counterfactuals (David Lewis, 1973). Lewis contends that "there are possible worlds other than the one we happen to inhabit" and elucidates with their help the ambiguous notion of a counterfactual. This is a typical case of what the schoolmen called an explanation of the obscure by the more obscure. Besides, who needs counterfactuals in science except as heuristic props – and even so restricted to the case when the antecedent, though contrary to actual fact, is really possible? (See Sec. 3.4.)

The following objections can be raised against possible worlds metaphysics in general:

(i) It employs modal logic, which is perfectly dispensable in all contexts except perhaps in ethics. (Whether modal logic would be needed to cope with a world different from ours we do not know. Perhaps it would be relevant in a chaotic, i.e. lawless, world – but such a world would be unlivable anyhow.)

(ii) Because it is concerned with a general concept of possibility, instead of with real possibility, possible worlds metaphysics is indifferent to worldly matters, which it is not prepared to handle. (Just think of the questions 'Is it possible to stop inflation?' and 'Is it possible for a butterfly to turn into a frog?') Hence it constitutes no ontology proper but is just an exercise in modal logic or in model theory.

(iii) Possible worlds metaphysics does not take real possibility seriously enough for, far from regarding it as inherent in the real world, it confines it to imaginary worlds. The scientific ontologist, on the other hand, has learned from quantum physics, genetics, learning theory, the theory of social mobility, and others, that possibility is inherent in reality. He has also learned that the philosopher should face the world and learn from it instead of retreating from the world by building escapist systems.

If possible worlds metaphysics is philosophically just as powerful as chess, so is the epistemology based on it. I mean the system of inductive logic where hypotheses are assigned probabilities on the basis of a count of possible worlds. Granted that counting such ghostly objects may appeal to the like of those who used to count the number of angels that could stand on the tip of a needle, one cannot help but ask two nasty questions. First: Even assuming there is a reasonable criterion for such a count, how does one go about verifying the outcome? Second: How does one allot probabilities to the various possible worlds?

6.3. *Modality and Probability*

Probability exactifies possibility, but not everything possible can be assigned a probability. There are possibilities with reference to which probability makes no sense, for the simple reason that they are not the object of a stochastic theory. For example forces may be characterized as "tendencies towards change of relative position" (Maxwell, 1892, II, pp. 211, 215). Likewise, solubility and magnetic permeability are (causal) dispositions that classical physics assigns no probabilities. Even in atomic physics, which is basically stochastic, we have similar cases. For example, a hydrogen atom at a given energy level occupies a $(2\ell+1)$-fold degenerate state, in the sense that the given energy value is consistent with $2\ell+1$ different possibilities of spatial orientation. An external field acting on the atom may remove the degeneracy by throwing the atom into any one of $2\ell+1$ nondegenerate states. This number measures the potential variety of the original (degenerate) state, or its potentiality. But as long as such possible nondegenerate states (or the possible transitions to them) are not assigned any probabilities, they remain individually nonquantified. In short, possibility does not warrant probability, be it in classical or in contemporary science.

The converse does hold of course: *wherever there is probability there is possibility*. In such cases, and in these only, "Probability is the *quantitative measure* of possibility" (Terletskii, 1971, p. 15). In other words probability provides a numerical exactification of possibility if and only if (*a*) one is dealing with chance propensity and (*b*) a stochastic theory of the facts of interest is available (Bunge, 1976a). Needless to say, a probabilistic or stochastic theory is one containing at least one random variable – i.e. a function every value of which is assigned a definite probability. In such a theory a particular probability value will occur only by postulation or by recourse to experience. For example, given a law of evolution of a probability p in the course of time, such as e.g. $\ulcorner dp/dt = kp \urcorner$, we may compute the probability value $p(t)$ at an arbitrary time t provided we give (by assumption or by observation) the initial value $p(0)$. If this additional piece of information is added, then we are allowed to make the inference to any (past or future) value of p, namely thus: $p(t) = p(0) \,.\, exp\,(kt)$. (This result is mathematically necessary but it represents only real possibility.)

In other words, we adopt the principle that anything probable according to a scientific stochastic theory T is deemed to be possible on T and moreover that the strength or weight of a possibility is equal to the corresponding probability. (Note that facts, not propositions, are assigned probabilities by scientific theories.) This idea is perfectly consistent with our nomological concept of possibility (Sec. 2.3) because, by definition, a scientific theory contains law statements (Bunge, 1967a, Chs. 6 and 7). When dealing with a stochastic theory we may use a possibility criterion more specific than the general Criterion 4.1 of Sec. 2.5 namely

CRITERION 4.2 Let T be a stochastic theory referring to a domain F of facts, and E a body of empirical data couched in the language of T and moreover relevant to T. Then if x is in F, *x is really possible according to T* and E iff $T \cup E$ contains the formula $\ulcorner Pr(x) \geqslant 0 \urcorner$.

Note that we are not equating zero probability with impossibility. Impossibility (relative to a given T-E pair) may be construed instead as the absence of a probability value. That is, anything that fails to be assigned a probability with the help of T and E will be regarded as *impossible on T and E* – though not necessarily impossible according to different premises. And anything assigned the probability value 1 with the help of T and E may be called *necessary according to T and E*. Further, two facts will be held *compossible* on T and E if the probability of their joint occurrence is defined in $T \cup E$.

We can also introduce the notion of a possibility field, namely as follows.

DEFINITION 4.16 Let F be a set of facts and let T be a stochastic theory referring to F. Then $F_0 \subseteq F$ is a *possibility field according to T* iff T defines a probability measure Pr on F_0, i.e. if, for every $x \in F_0$, $Pr(x) \geqslant 0$.

Consider now some subset F_0 of F. If the possible facts in F_0 are mutually exclusive – i.e. if the actualization of one of them precludes that of all others – they are said to constitute a *possibility fan*. In general the rays in such a fan are not equally probable. The spread of the fan, i.e. the *indeterminacy* of the bundle of possibilities, can be measured in various ways. (The best known measures are the mean standard deviation and the information-theoretic "entropy" or average information content of the bundle. However, we shall make no use of these notions here.)

In sum, whenever a set of facts constitutes a possibility field that is the concern of a stochastic theory, such a theory exactifies the coarse modal notions – not however any of the modal calculi. Table 4.5 exhibits the correspondence between the handful of modal expressions not involving iterated modalizers, and the infinitely many probabilistic statements. Out of generosity we have included the notions of near impossibility and near necessity, which are not actually handled by modal logic. On the other hand the latter makes certain distinctions, e.g. between $\Diamond p$ and $\Diamond \neg p$, and between $\Box p$ and $\Box\Box p$, which are unintelligible elsewhere.

Whereas in modal language there are only possibility and contingency between the poles of impossibility and necessity, in any probabilistic context there is a rich spectrum between them – often a nondenumerable one. Moreover what is merely possible in the short run (for a small

TABLE 4.5

Exactification of modal notions by a stochastic theory involving discrete probabilities only (i.e. excluding possibles of zero probability)

Ordinary modal language	Exact probabilistic language
x is possible	$0 < Pr(x) < 1$
x is contingent	
x is just possible	$0 < Pr(x) \ll 1$
x is almost impossible	
x is impossible	$Pr(x) = 0$
x is necessary	$Pr(x) = 1$
x is almost necessary	$0 \ll Pr(x) < 1$

sample or a short run of trials) may become necessary or nearly so in the long run. Thus the probability that a single hydrogen atom will emit a certain 21 cm line is one in 10^7 per second, yet we detect as many such waves as we wish because of the huge numbers of hydrogen atoms. The most basic physical events are extremely improbable, but they have an impact because of their sheer numbers. Give chance a chance and it will become necessity. For this reason particle physicists, atomic physicists, molecular physicists and geneticists cannot accept Borel's injunction – in the name of mathematical empiricism – to discard improbable events for being "meaningless" (Borel, 1949). Quite on the contrary, microphysicists accept the so-called "principle of compulsory strong interaction", originally formulated with tongue in cheek as follows: "Anything that is not forbidden is compulsory" (Gell-Man, 1956; see also Melvin, 1960, p. 481). A somewhat more careful wording of the above principle reads thus: All possible repetitive chance events (in particular those consistent with the conservation laws) are likely to occur in the long run. Biologists have come to accept a similar principle, namely this: Any given ecological niche where life is possible, ends up by being inhabited.

To sum up, the classical modal principles are much too poor to account for the continuum lying between impossibility and necessity. Not even the ordinary concept of probability suffices, if only because of the ambiguity of the ordinary language phrase 'x is not probable', which may stand either for "$Pr(x)$ is small" or for "Pr is not defined at x". Chance propensity can be caught only with the fine mesh of stochastic theories, which presuppose the mathematical theory of probability.

There is no better trap for catching what Hermann Weyl (1940) called "the evasive ghost of modality".

6.4. *Randomness*

Calls arrive at a telephone exchange roughly at random rather than regularly because they are made (roughly) independently from one another. However, there is nothing haphazard or chaotic about such an irregular sequence of events. In fact there is a definite probability for an arrival to occur within any given time interval. That is, the set of arrivals is what we have called (Definition 4.16) a *possibility field*. (See Figure 4.8.) Consequently a number of (probabilistic) predictions can be computed – e.g. concerning the most probable number of calls over a certain long time interval.

Fig. 4.8. Random arrival times – of e.g. customers at a counter, or of cosmic rays at a Geiger counter. The probability of an arrival within any given time interval is unaffected by arrivals in other intervals. See e.g. D. R. Cox, *Queues* (Methuen, London, 1961), p. 6.

In other words, because the set of arrivals has a definite probabilistic structure, a theory about it can be built; this theory is called *queuing theory*. Likewise with all other random events. For example the zig-zag walk of a drunkard is random and so is the trajectory of a pollen corpuscle immersed in a fluid, and of a particle of smoke moving in mid air. Randomness consists in this case in that there is a definite probability for each segment and each angle. Surely the precise trajectory is unpredictable. However, a number of predictions can be made for the entire set of steps because of the stochastic lawfulness of the set. For example one can predict what will be the average total distance travelled by the particle (or the drunkard) over a given time interval.

The preceding considerations suggest the following elucidation of the concept of full randomness:

DEFINITION 4.17 A set F of facts is *fully random* iff $\langle F, Pr \rangle$ is a possibility field such that the probability of any member of F is independent of the occurrence or nonoccurrence of any other possibilities in F.

If on the other hand the probability of each fact is conditional on the occurrence of some other fact, then the set of facts is not fully random.

Thus a Markov chain, though stochastic, is not fully random but is somewhere between a fully random chain and a fully determinate one. This suggests that randomness comes in degrees. In fact we can construct a measure of the degree of randomness, namely as follows. (We shall do it for a finite possibility field but the generalization to the infinite case is straightforward.) Here it is:

DEFINITION 4.18 Let F be a set of n facts and suppose that the absolute probabilities $Pr(x)$ and the conditional probabilities $Pr(y|x)$ are defined for all $x, y \in F$. Then the *degree of randomness* of F is

$$r = 1 - (1/n) \sum_{x,y \in F} |Pr(y|x) - Pr(y)|.$$

The extreme values of r are

(a) $r = 1$, i.e. *full randomness*, if the occurrence of any one fact makes no difference to that of any other fact, i.e. if $Pr(y|x) = Pr(y)$ for all $x, y \in F$;

(b) $r \cong 0$, i.e. *near determination*, if, for every x and y in F, the differences between the conditional probabilities and the absolute ones are near unity.

One might think of identifying causation with $r = 0$, since in this case whatever happens is conditioned by some other fact. ("Every event has a cause.") But this would be mistaken for the following reasons: (*a*) whereas the degree of randomness (r) is defined for facts in general, the causal relation holds only between events; (*b*) in the case of causation we do not need, and usually do not have, any probabilities; (*c*) as defined above r never becomes exactly zero.

Randomness, being a special case of stochasticity, is a type of order and should therefore not be mistaken for chaos or the total absence of law. Chaos may be defined as follows:

DEFINITION 4.19 A set of facts is *chaotic* iff no probability measure can be defined on it.

For example, the set of facts

G = {The last shot in World War II, The reader's latest dream, My first car crash, The independence of Angola} is chaotic because it is impossible to allot a probability to each member of the set in such a way that $Pr(G) = 1$ – and this because it is not possible to build a theoretical model of G.

Of course the particular set G we have just introduced to illustrate the concept of chaos or haphazardness is an artifact: the members of G do not form a natural sequence. In other words such facts cannot compound to form a real fact. We surmise therefore that chaos, though conceivable – in a nonchaotic way – is unreal. That is, none of the chaotic sequences we can imagine will be found in reality. Reality is to a large extent stochastic and even random but not chaotic, i.e. lawless.

Chaos is difficult to diagnose. Take for instance a time series or any other sequence. If the sequence is finite then, no matter how long it is, there exists at least one random variable that maps the sequence. (Think of a sequence of the form $\langle x_i \mid f(x_i) = p_i \ \& \ i \in \mathbb{N} \rangle$.) So, the sequence cannot be said to be chaotic. If on the other hand the sequence is infinite, then it cannot be drawn from observation since all experience is finite. Such a sequence must be the outcome of a calculation with some formula or algorithm. Hence it is not chaotic either. In sum even if there were chaotic sets of facts, other than those we make up for the sake of an argument, we would not be able to recognize them by their lawlessness. (See however the Kolmogoroff–Chaitin definition of a "random" – in our view chaotic – sequence in information theoretic terms: Chaitin (1974). A number sequence would be said to be completely chaotic iff the smallest algorithm capable of specifying it to a computer has about the same quantity of information as the sequence itself – i.e. if there is no general rule compressing the given information.)

6.5. *Probability and Causality*

Some philosophers, among them Suppes (1970) and Popper (1974), have offered a probabilistic elucidation of causality. It boils down to the following definition: For any events a and b,

> a is a *cause* of $b =_{df}$ The probability of b given a is greater than the absolute probability of b, i.e. $Pr(b \mid a) > Pr(b)$.

In this way those philosophers hope to reduce causal determinacy to a particular case of what may be called stochastic determinacy.

However, the reduction of causation to probabilistic correlation won't do, as shown by the innumerable counterexamples of the following kind (cf. Bunge, 1973c). The conditional probability of the reader's reading these lines, given that he was born, is greater than the absolute probability of that event, yet his birth cannot be regarded as a cause of his reading these lines. A necessary condition of course but not a cause – unless one believes in predestination. Hence causation cannot be defined in terms of probability. Both concepts are used by the scientist who computes the *probability* that a given event will *cause* a certain effect.

Whatever causes probabilifies but not conversely. Anything that probabilifies (increases chance propensities) may be called an *influence*. More precisely, if the occurrence of a state (or of a change of state) is more probable given the occurrence of another, then the latter may be said to influence the former. The concept of influence can then be elucidated in probabilistic terms provided all the state spaces of the patient are probabilistic. But this is not so in general, except of course at the level of quantum physics. Therefore we shall not adopt this definition of influence.

6.6. *The Many Worlds Interpretation of Quantum Mechanics*

We have claimed throughout this chapter that contemporary science, in particular quantum mechanics, espouses possibilism and eschews actualism. However, there is a certain interpretation of the relative state formulation of quantum mechanics (Everett, 1957) that is definitely actualist, namely the many worlds interpretation. This view, taken by DeWitt (1970), Stapp (1971), Hart (1971) and a few others, is best discussed with reference to the expansion of the state function ψ in orthogonal functions φ_n, namely thus: $\psi = \sum_n c_n\varphi_n$, where (in the simplest cases) n runs over the natural numbers. The main conflicting interpretations of this series expansion are shown in Table 4.6.

In the two main possibilist interpretations the coefficients of the expansion are probability amplitudes. In the actualist interpretation there are no probabilities: the series expansion represents the actual branching of the individual thing into infinitely many actual and noninterfering copies of it. Every branch φ_n is deemed to be actual: there is no actualization process (such as, e.g., the collapse $\psi \to \varphi_n$) for the simple reason that there is no potency to begin with. And, since these branches do not interfere with one another, there is no way of knowing that they are all simultaneously real – except of course on authority. The thing ramifies infinitely and infinitely many times, and so do any of its observers – unknown to him, as he cannot communicate with any of his copies.

TABLE 4.6
Alternative interpretations of the expansion of a state function into an infinite set of orthogonal eigenfunctions of a dynamical variable

	Possibilism		Actualism
	Operationism	Realism	(Many worlds)
ψ	Actual state before measurement	Actual state	Actual state
φ_n	Possible state before measurement	Mathematical auxiliary	Actual state
$\sum c_n\varphi_n$	Superposition of possibilities	Mathematical trick	Branching of thing into infinitely many non interfering things
$\lvert c_n\rvert^2$	Probability of finding thing in state φ_n when measuring property represented by operator	Weight of nth eigenvalue in spectrum of dynamical variable	

The obvious objections to this piece of science fiction are these. First, such infinite ramifications would violate all of the conservation laws; in particular there would not be enough energy to distribute among the infinitely many copies of any given thing. Second, the ramification is in principle undetectable, hence empirically just as irrefutable as it is unconfirmable: it takes an act of faith to accept it. Third, in the case of a dynamical variable with a nondenumerable spectrum, the world would branch into a nondenumerable set of identical copies of itself. If we wish to avoid this absurdity we must not try to interpret quantum mechanics in actualist terms and must reckon with chance propensities. We must take real possibility seriously.

7. CONCLUDING REMARKS

We have acknowledged real possibility and distinguished two kinds of it: causal disposition (e.g. fragility) and chance propensity (e.g. the propensity of an atom to occupy a definite energy level). Moreover we have regarded these two kinds of property as radically different:

whereas a causal disposition of a thing is unthinkable without a disposition in some other thing (think of the lock and key pair), a chance disposition is an irreducible property of the individual thing possessed by the latter even in the absence of an experimental set-up.

Our view on possibility is incompatible with actualism, according to which possibilities are only in the mind. We have met crypto-actualism in the guise of possible worlds metaphysics (Sec. 6.2) and open actualism in the many worlds interpretation of quantum mechanics (Sec. 6.6). A more common expression of actualism is the frequency interpretation of probability. According to the latter there is no such thing as a chance propensity for a single thing: there are only limiting frequencies defined for entire ensembles of things or for whole sets of states of a single thing, such as a sequence of throws of a coin. The phrase '$Pr(a) = b$' would then be short for something like "The relative frequency of a in a large ensemble (or a long sequence) of similar trials approaches b". This view is refuted by the existence of microphysical theories concerning a single thing, such as a single electron, to be sharply distinguished from a theory concerning an aggregate of coexisting electrons. Another example: genetics is in a position to calculate the probability of any gene combination, which, given the staggering number of possibilities, is likely to be a one time event. A relative frequency is a frequency of actuals, hence it cannot be identical with a possibility although it can measure the strength or weight of the latter. Unlike frequencies, probabilities do measure real possibilities.

If we take real possibility seriously then we must reject the narrow determinism espoused by Spinoza, Hobbes, the French *philosophes* and *géomètres*, Kant, Łukasiewicz, and many other necessitarians (as Peirce called them), to whom possibility was an epistemological category not an ontological one. (For example Kant held that all of the categories of modality express only relations to the body of knowledge: Kant (1781, p. A219). And Łukasiewicz stated that, if possibility were an ontological category, it would contradict causality and even the excluded middle principle, which he regarded as concerning actualities not possibilities: Łukasiewicz (1970, p. 35).) We have embraced instead, and tried to work out and update, the possibilism inherent in such diverse thinkers as Epicurus, Aristotle, Chrysippus, Cournot, and Peirce. However, we reject unconditional possibilism, according to which anything is possible (Naess, 1972). We have advanced rather *nomological possibilism*.

Possibilism is not only a metaphysical doctrine but, like many other ontological ideas, has implications for other disciplines, in particular action theory and ethics. Take for instance the much celebrated formula "Human freedom is the same as the knowledge of necessity", put forth by Spinoza and popularized by Engels. This formula needs correction on several counts. Firstly, by construing freedom as an epistemological category, it denies real or ontic freedom. Secondly it is obvious that knowledge, though certainly necessary to attain freedom in certain respects, is not sufficient for it. Thus the person who knows that he or she must die is not free to alter the course of events so as to avoid the final outcome. Thirdly a knowledge of real possibility is just as important as a knowledge of necessity – the more so since the latter is a particular case of the former. The person who wishes to get hold or rid of x in order to attain y will be well advised to use the bit of knowledge (or conjecture) that, in fact, the means x brings about (with a certain probability) the end y. Whether the law relating x to y is deterministic or stochastic makes little practical difference if multiple trials are allowed. What is important is that the relation exist and be known. In sum, freedom is not to be equated with the knowledge of necessity. Rather, factual knowledge of all kinds is just (and no less than) a means, among others, for attaining freedom in some respects.

So much for the concepts of possibility. We are now ready to face the general concept of change.

CHAPTER 5

CHANGE

So far we have not dealt with change. But, if we are to believe science, we must uphold the ontological postulate that all things are in flux. In fact the sciences describe, explain, predict, control or elicit changes of various kinds – such as motion, accretion, division, and evolution. Therefore ontology should analyze and systematize these various types of change.

While some metaphysicians have been busy praising change others have denied it and none have described it correctly. We shall endeavor to build a concept of change capacious enough – hence poor enough – to accommodate all of the concepts of change, particularly those occurring in the sciences, and to sketch general theories of change of some typical kinds. Such are the aims of the present chapter, devoted to change in general. The matter of qualitative change will be taken up in the companion volume, *A World of Systems*.

A change is an event or a process, whether quantitative or qualitative or both. Whatever its nature, a change is a modification in or of some thing or things: more precisely, it consists in a variation of the state of an entity. To put it negatively, there is no change separate from things – nor, indeed, are there changeless things even though some change slowly or only in certain limited respects. The world, then, consists of things that do not remain in the same state forever. This metaphysical hypothesis is an extrapolation from both ordinary experience and scientific knowledge. The contrary hypothesis, that nothing changes, is a philosophical extravagance hardly worthy of a sane person's consideration.

Since a change is a transition of a thing from one state to another, we must base the study of change on the concept of state analyzed in Ch. 3, Sec. 2. It will be recalled that a state of a thing is a list of individual properties of the thing, each of the latter being represented by a value of a state function or variable. And the collection of all possible states of a thing is called the (lawful) *state space* of the thing. Any change (of state) of a thing can be represented as a trajectory in its state space. This approach has the distinctive advantage that it does not require a detailed knowledge of the nature of the thing concerned: it is therefore ideally suited to ontology or the general theory of things. Let us then begin by recalling briefly the notions of state and state space, plunging immediately thereafter into the heart of the matter.

1. CHANGEABILITY

1.1. *Preliminaries*

Every thing is in some state or other relative to a given reference frame. And every (relative) state of a thing is uniquely determined by the properties of the latter (relative to some frame). Thus a state of a thing with n properties, each represented by a (state) function, is an n-tuple of values of the functions representing those properties. Different states correspond to (are represented by) different n-tuples. A change in the representation of properties, or in the choice of reference frame, ensues in a different representation of states. This shows that our knowledge of a state depends partly upon ourselves and the state of the art – not however that the state itself is an artifact of the beholder. States, in sum, are relative.

Pretend, for the sake of definiteness, that a certain thing x, such as a camera shutter or an electrical switch, has a single dichotomic general property: that it is either open (1) or closed (0). The possible states of x are then 0 and 1. In other words, the state space of x is $S(x)=\{0, 1\}$. Actually this is an extreme oversimplification: 0 and 1 are just the states of interest for some definite purposes. Any real thing has a large number n of properties P_i, each representable by a function F_i, where $1 \leq i \leq n$. The possible degrees or intensities of property P_i are represented as so many values of the function F_i. Hence the conceivable state space of the thing will be the cross product of the images of these functions. And the nomological state space will be a subset of the former space, resulting from the laws involving the P_i: see Figure 5.1. All of this holds, of course, for a given representation of properties, hence states.

Every point s belonging to the lawful state space $S_{\mathbb{L}}(x)$ of a thing x represents a possible state of the thing. The actual state of the thing is represented by what is called its *representative point* in the state space. An actual change of thing x is represented by a *trajectory* of the representative point; this trajectory is of course the graph of a certain function on $S_{\mathbb{L}}(x)$. It is convenient, though not indispensable, to express

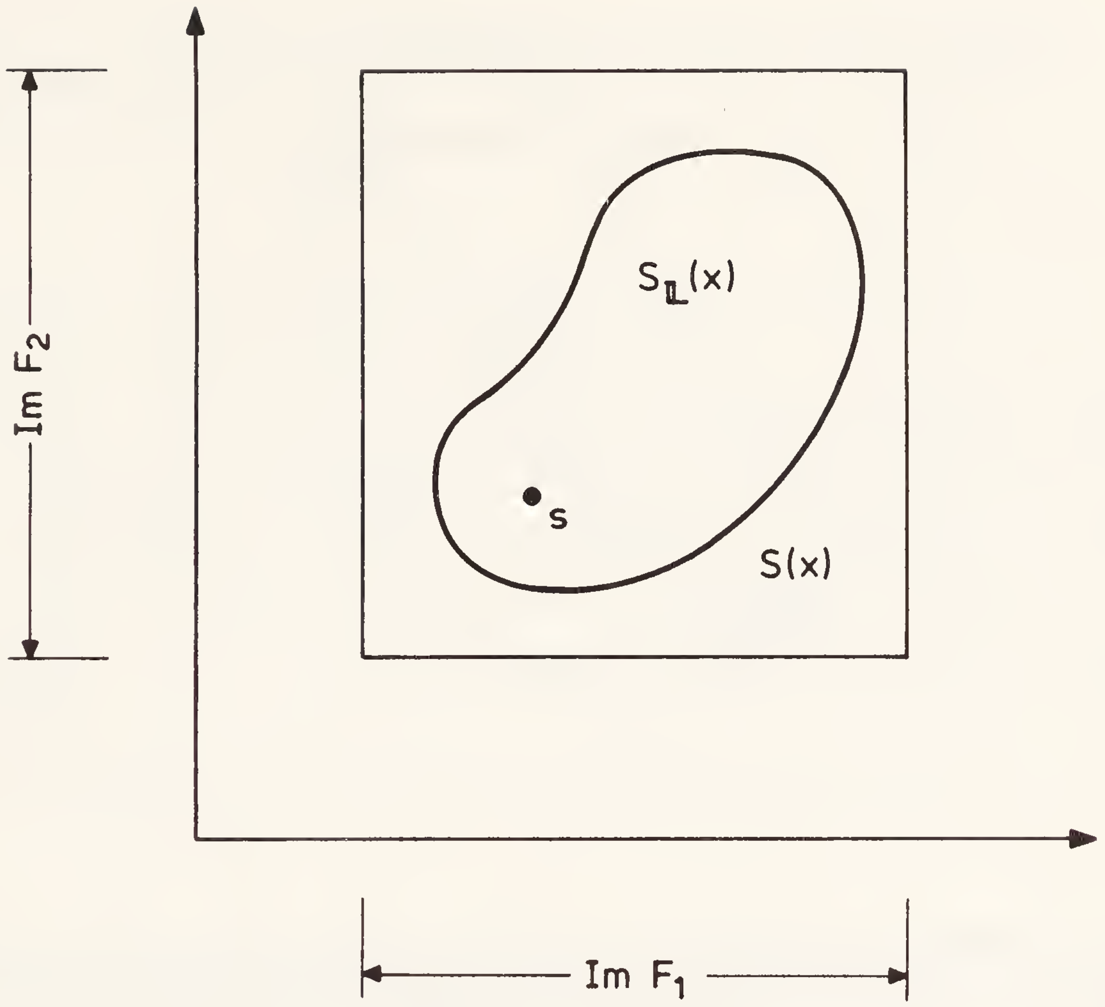

Fig. 5.1. The conceivable state space $S(x)$ and the lawful state space $S_{\mathbb{L}}(x)$ of a thing x with two properties represented by functions F_1 and F_2. '*Im F*' is read 'the image of F' and is the set of values, or range, of F.

the curve with the help of a parameter, the standard interpretation of which is time. But one of the advantages of the state space representation of change is that it requires no explicit use of the time concept.

To fix ideas consider the state space of the gene pool of a population of organisms. That set is included in the cartesian space whose axes are the gene frequencies of the pool. Every point in this space represents a possible state of the gene pool. The representative point – the one representing the actual state of the system – will remain fixed only if the organisms suffer no mutations – which is never the case, not even if the environment of the population is highly stable, such as a tropical lagoon. Otherwise the representative point moves (in state space not in ordinary space) describing a trajectory. This curve – which in the case of biological evolution has no loops – represents the genic *history* of the gene pool, or the evolution of the corresponding population at the genic level. Any segment of the total history may be called an *event* or a *process* involving the gene pool. (See Figure 5.2.)

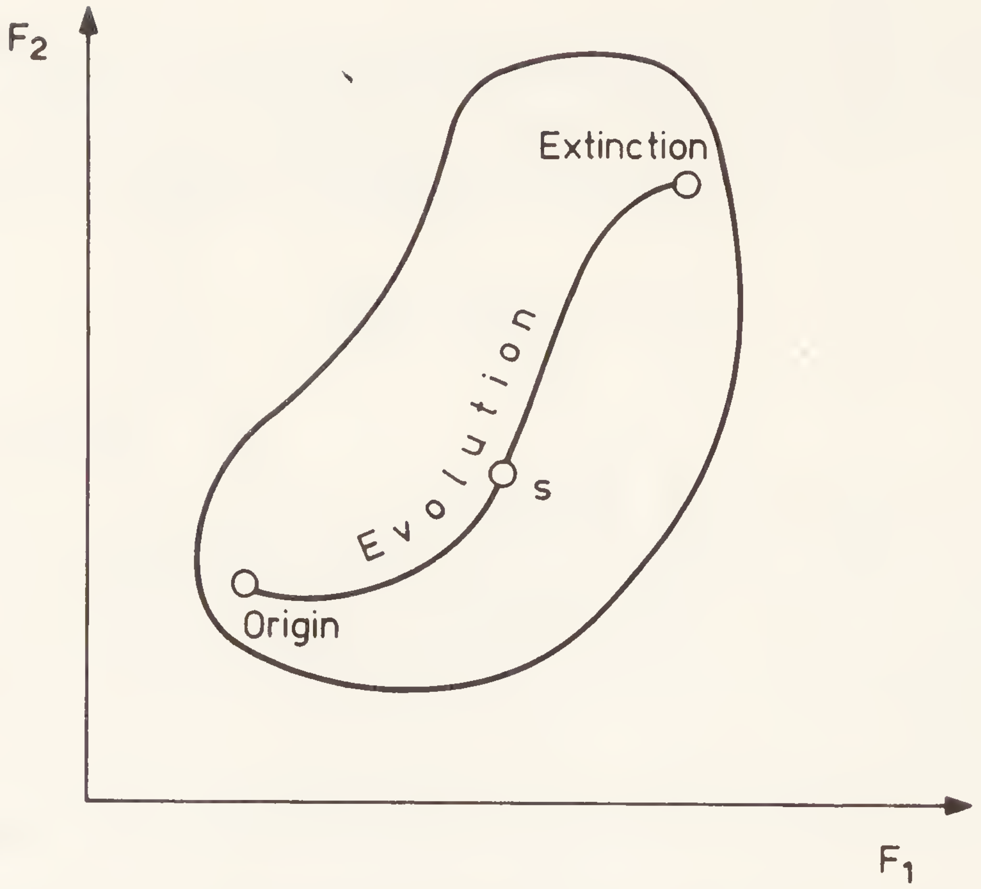

Fig. 5.2. The shifting of gene frequencies in a gene pool, in response to the joint action of mutation and selection. The end points of the curve represent the origin and the extinction of the given population.

So much for an intuitive background.

1.2. *Changeability*

Before tackling actual change we may as well elucidate the intuitive notion of mutability or changeability:

DEFINITION 5.1 Let x be a thing. Then

(i) x is *unchangeable* iff $S_{\mathbb{L}}(x)$ is a singleton for all choices of state function for x;

(ii) x is *changeable* (or *mutable*) iff $S_{\mathbb{L}}(x)$ has at least two distinct members for all choices of state function for x.

And now our first hypothesis:

POSTULATE 5.1 Every (concrete) thing has at least two distinct states, and the state space of any construct is empty. That is,

(i) if x is a thing then, for all choices of state function for x, $|S_{\mathbb{L}}(x)| \geq 2$;

(ii) if y is a construct then there are no state functions for y – or, equivalently, $S(y) = \varnothing$.

An immediate consequence of Postulate 5.1 and Definition 5.1 is

COROLLARY 5.1 All (concrete) things are changeable, and constructs are neither unchanging nor changeable.

Remark 1 We are not (yet) stating that every thing is actually undergoing some change or other, but only that it can change. *Remark 2* The second part of Corollary 5.1 states that the categories of change and of immutability do not apply to constructs. Constructs are neither eternal objects (Plato) nor changeable ones (Hegel). What do change from person to person are the brain processes occurring when constructs are thought.

Our next concept is that of overall change irrespective of the order in which it occurs:

DEFINITION 5.2 Let $S_{\mathbf{L}}(x)$ be a lawful state space for a thing x, and let $S_i(x), S_j(x) \subset S_{\mathbf{L}}(x)$ be two collections of states of x [e.g. two regions of $S_{\mathbf{L}}(x)$]. Then the *overall change* of x between $S_i(x)$ and $S_j(x)$ equals the symmetric difference between the given subsets:

$$\chi_{ij}(x) = S_i(x) \mathit{\Delta} S_j(x).$$

An overall change may be slight or large, superficial or deep. If there are considerable changes in the individual properties of a thing, but the thing neither acquires nor loses any general property, we may say that it undergoes a *large* change. If on the other hand a thing gains or loses general properties then it can be said to undergo a *deep* change. Whereas in the first case the axes of the state space remain fixed, in the second some are added or removed. We obtain a smooth description of this sort of change if we build the state space with all the necessary axes and use at any given moment only those portions of the total space that concern the properties actually possessed by the thing at the moment. In Figure 5.3 we depict the evolution of an imaginary thing undergoing a deep change. The first part of the process is described by a curve on the horizontal plane $Im\, F_1 \times Im\, F_2$; the second part is described by a curve on the vertical plane $Im\, F_2 \times Im\, F_3$. The qualitative change occurs at the junction of the two curves. The entire curve is continuous even though its tangent has a discontinuity.

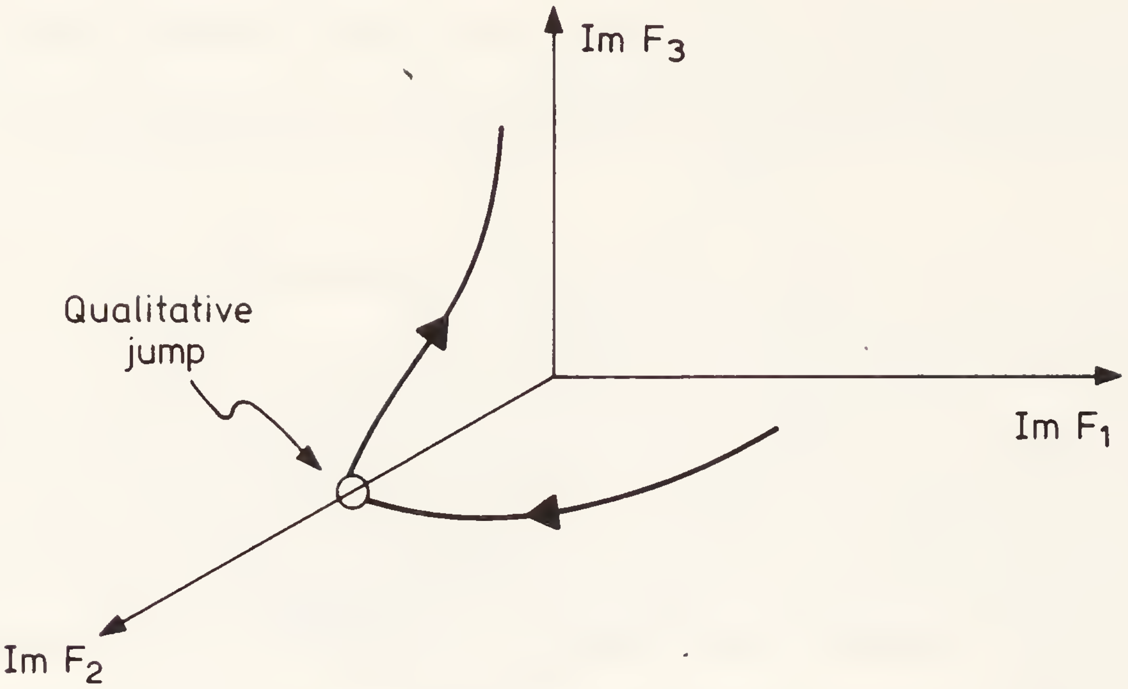

Fig. 5.3. Each arc of the curve describes a quantitative change. A qualitative jump happens at the junction of the two arcs.

In other words, we adopt

DEFINITION 5.3 Let $\mathbb{F}$ be a state function that spans the entire state space $S_{\mathbb{L}}(x)$ for a thing x. The thing undergoes a *qualitative change* iff $S_{\mathbb{L}}(x)$ equals the union of at least two subspaces, each of which is spanned by a different projection of $\mathbb{F}$. Otherwise [i.e. if none of the components can be ignored during any stretch of the process], the thing undergoes only a *quantitative change.*

An immediate consequence of this definition is

COROLLARY 5.2 Every qualitative change is accompanied by a quantitative change. [I.e., for any thing x, if x changes qualitatively then x changes quantitatively.]

The converse does not follow, which is just as well since it is false. Note that the above is not an independent ontological hypothesis but a mere corollary of a convention. The catch is that the latter has been framed so as to yield that consequence.

So much for the qualitative/quantitative distinction. The present chapter will be devoted to change in general; qualitative change will be treated in the following volume of this treatise.

2. EVENT

2.1. *The Ordered Pair Representation of Events*

Whatever changes may be thought of either as turning into a different thing or as going into a different state. In the former case the change of interest can be construed as the ordered couple $\langle x, x'\rangle$, where x and x' are the initial and the final things respectively. However, since names or singular terms such as 'x' and 'x'' are not descriptive, this representation of change is unilluminating. Besides, it forces an unnecessary multiplication of the number of things. For this reason it is not used in science and we shall not employ it in ontology.

Far more information is conveyed if the name 'x' is replaced by the sentence 'thing x is in state s', where s is a point (or a set of points) in a state space $S(x)$ for x. We can then construe a change of x as a transition from state s to some other state $s' \in S(x)$. In other words, we adopt what may be called the *principle of nominal invariance*, or permanence of names through change, and describe changes as changes of state. The principle, a designation rule, may be stated as follows:

PRINCIPLE 5.1 A thing, if named, shall keep its name throughout its history as long as the latter does not include changes in natural kind – changes which call for changes of name.

In order for this principle to work we must include in the state space of a thing all of the latter's possible states, from beginning to end. This allows us to designate a given person at age 50 by the same name as at age 5 even though in between the person may have renewed every single atom in his/her body. In short, there are no self-identical things but only constant names helping us keep track of the changes undergone by things.

As for the representation principle, a semantic assumption, it can be formulated thus:

PRINCIPLE 5.2 Let $S(x)$ be a state space for a thing x, and let $s, s' \in S(x)$ be two states of x. Then the *net change* in x from state s to state s' is representable by the ordered couple of these states, i.e. by $\langle s, s'\rangle \in S(x) \times S(x)$.

In the simplest nontrivial (yet imaginary) case, $S(x) = \{a, b\}$, and there is a single function $g: S(x) \to S(x)$ such that $g(a) = b$ and $g(b) = a$, to represent the two possible nontrivial changes of the thing, namely $\langle a, b\rangle$ and $\langle b, a\rangle$. Permanence is represented by the function $i_S: S(x) \rightarrow S(x)$ such that $i_S(a) = a$ and $i_S(b) = b$, i.e., the identity function on S.

The above principles are the clue to the theory of change to be built in the sequel. We first tackle the simpler case of the finite state space, thereafter the general case.

2.2. *The Event Space*

Let $S(x)$ be a state space for a thing x. Any pair of points in this set will represent unambiguously, though perhaps not exhaustively, a conceivable event, or change, in x. (Conceivable rather than really possible because (*a*) $S(x)$ itself is the collection of conceivable states of x, and (*b*) even if $S(x)$ is taken to be a lawful state space, not all of the transitions from or to a given state may be really possible. Just think of the state space $S(x) = \{\text{alive, dead}\}$.)

In this section we shall investigate the precise membership and structure of the space $E(x)$ of conceivable events. We start by examining the simple case of a three state thing, such as an electric switch with three states: open, closed, and transient. Calling a, b, and c the states, we have $S(x) = \{a, b, c\}$. We now form the ordered pairs

$\langle a, a\rangle$ thing x stays in state a (the identity event at a)
$\langle a, b\rangle$ thing x goes from state a to state b, etc.

Every one of these pairs represents a conceivable change in x, i.e. a conceivable event involving x. Assume further, for the sake of expediency, that in this particular case all such events can happen, i.e. are lawful. In other words, set $E_{\mathbb{L}}(x) = E(x) = S(x) \times S(x)$. We have thus 9 elementary or noncomposite events in $E(x)$:

$$\begin{array}{lll}
e_1 = \langle a, a\rangle \equiv u_a, & e_4 = \langle a, b\rangle, & e_7 = \langle b, a\rangle \\
e_2 = \langle b, b\rangle \equiv u_b, & e_5 = \langle b, c\rangle, & e_8 = \langle c, b\rangle \\
e_3 = \langle c, c\rangle \equiv u_c, & e_6 = \langle a, c\rangle, & e_9 = \langle c, a\rangle.
\end{array}$$

That is, $E(x) = S^2(x) = \{u_a, u_b, u_c, e_4, e_5, e_6, e_7, e_8, e_9\}$. The first three members of this set are nonevents or null changes. Thus u_a is the nonevent consisting in that the thing stays in state a. All others are proper events. A standard pictorial representation of this space is shown in Figure 5.4.

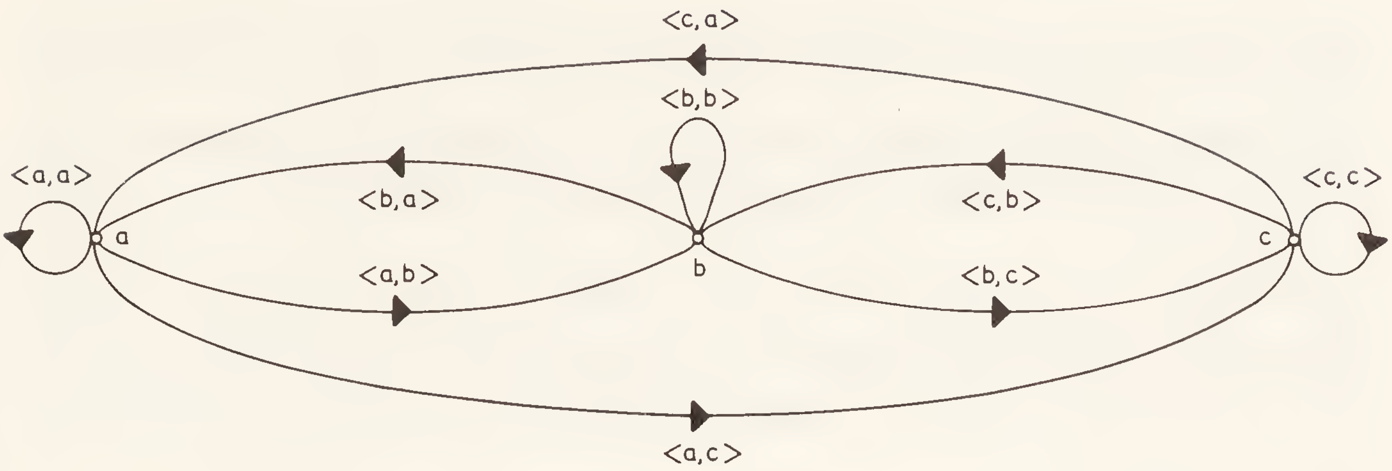

Fig. 5.4. The transition or Moore graph for a three state thing.

We assume next that the composition of certain events is possible while that of others is not. For example, event $e_4 = \langle a, b\rangle$ can be followed by event $e_5 = \langle b, c\rangle$, and the complex event may be regarded as a decomposition of event $e_6 = \langle a, c\rangle$. To symbolize the composition of events we use the asterisk $*$ and write: $e_4 * e_5 = e_6$ or, explicitly, $\langle a, b\rangle * \langle b, c\rangle = \langle a, c\rangle$. (That is, intermediate states do not show up in the net change: they are absorbed.) On the other hand the complex event $\langle b, c\rangle * \langle a, b\rangle$, which is the reverse of the former, does not occur, and so is left undefined. In other words, to represent the combination of events we introduce a (partial) binary operation $*$ in $E(x)$. If e and f are in $E(x)$, then $e * f = g$ is another event in $E(x)$ consisting in event e being *followed* by event f – with the proviso that in certain cases the composition is not defined.

The possible binary combinations of events occurring in a three state thing are shown in the following table. Every entry in this multiplication table shows the net change not the change process. But of course the

$*$	$\langle a, a\rangle$	$\langle a, b\rangle$	$\langle a, c\rangle$	$\langle b, a\rangle$	$\langle b, b\rangle$	$\langle b, c\rangle$	$\langle c, a\rangle$	$\langle c, b\rangle$	$\langle c, c\rangle$
$\langle a, a\rangle$	$\langle a, a\rangle$	$\langle a, b\rangle$	$\langle a, c\rangle$						
$\langle a, b\rangle$				$\langle a, a\rangle$	$\langle a, b\rangle$	$\langle a, c\rangle$			
$\langle a, c\rangle$							$\langle a, a\rangle$	$\langle a, b\rangle$	$\langle a, c\rangle$
$\langle b, a\rangle$	$\langle b, a\rangle$	$\langle b, b\rangle$	$\langle b, c\rangle$						
$\langle b; b\rangle$				$\langle b, a\rangle$	$\langle b,b\rangle$	$\langle b, c\rangle$			
$\langle b, c\rangle$							$\langle b, a\rangle$	$\langle b, b\rangle$	$\langle b, c\rangle$
$\langle c, a\rangle$	$\langle c, a\rangle$	$\langle c, b\rangle$	$\langle c, c\rangle$						
$\langle c, b\rangle$				$\langle c, a\rangle$	$\langle c, b\rangle$	$\langle c, c\rangle$			
$\langle c, c\rangle$							$\langle c, a\rangle$	$\langle c, b\rangle$	$\langle c, c\rangle$

table allows us to analyze certain events as processes, i.e. sequences of elementary events.

A number of regularities emerge clearly from this table. We assume that they hold for every event space and summarize them in

DEFINITION 5.4 Let $S(x) \neq \varnothing$ be a state space for a thing x and let $E(x) = S(x) \times S(x)$. The triple $\mathscr{E} = \langle S(x), E(x), *\rangle$, where $*$ is a partial (not everywhere defined) binary operation in $E(x)$ such that, for all a, b, c, d in $S(x)$,

$$\langle a, b\rangle * \langle c, d\rangle = \begin{cases} \langle a, d\rangle \text{ if } b = c \\ \text{not defined if } b \neq c, \end{cases}$$

is the *event space* of x associated with $S(x)$ iff

(i) every element of $E(x)$ represents a conceivable change of (or event in) thing x;

(ii) for any $e, f \in E(x)$, $e * f$ represents the event consisting in that event e *composes* with event f in the indicated order;

(iii) for any $s \in S(x)$, $\langle s, s\rangle \in E(x)$ represents the *identity event* (or nonevent) at s, i.e. the staying of x in state s.

An immediate consequence is that every conceivable event $\langle s, s'\rangle$, where $s, s' \in S(x)$, has a unique converse, viz., $\langle s', s\rangle$. (Which only goes to show that $E(x)$ is the totality of *conceivable* events not of really possible ones.) Another is

COROLLARY 5.3 For every state $s \in S(x)$ there is an identity event $i_s = \langle s, s\rangle$ such that, for each $e \in E(x)$ for which $*$ is defined, $e * i_s = i_s * e = e$.

In other words, the structure $\mathscr{E} = \langle S(x), E(x), *\rangle$ is a *category* with set of objects $S(x)$, set of morphisms $E(x)$, and identity morphisms i_s, for all $s \in S(x)$; the composition is $*$. The transition graph in Figure 5.6 is a vivid pictorial representation of this category in the case where $S(x)$ has only three members.

Note that in the category $\mathscr{E}$ the following holds: For any two objects (states) $s, s' \in S(x)$ there is exactly one morphism $s \mapsto s'$, namely $\langle s, s'\rangle$. This in turn implies that every morphism in the category is an isomorphism, i.e. the inverse of $\langle s, s'\rangle$ is the unique morphism $\langle s', s\rangle$. This entails

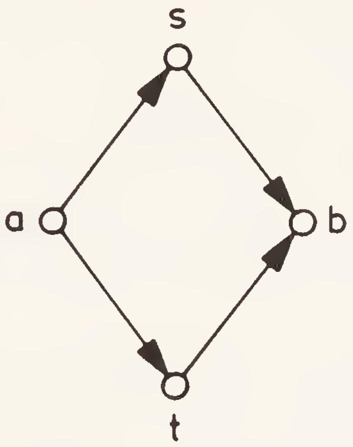
COROLLARY 5.4 Let $s, s' \in S(x)$ be states of x. Then

(i) no event other than an identity event is immediately repeatable: $\langle s, s'\rangle * \langle s, s'\rangle$ is not defined in $E(x)$;

(ii) if an event is followed by its converse then no net change results: $\langle s, s'\rangle * \langle s', s\rangle = \langle s, s\rangle$.

Hence for an event to be repeated the thing must first go back to the initial state, either through the converse event (when possible) or through intermediate events, as in the case of $\langle s, s'\rangle * \langle s', s''\rangle * \langle s'', s\rangle = \langle s, s\rangle$.

From Definition 5.4 it follows that intermediate states do not show up in the net result. Thus the two processes



are equivalent in that $\langle a, s\rangle * \langle s, b\rangle = \langle a, t\rangle * \langle t, b\rangle = \langle a, b\rangle$. Therefore we can make

DEFINITION 5.5 Two complex events (processes) in a given event space are *equivalent* iff they have the same outcome [i.e. if they relate the same initial and final states].

Hence every complex event may be construed as an equivalence class of processes, namely the set of all processes with the same end points (states).

We wind up this section by bringing to the fore two notions that have occurred tacitly in the preceding and will be of capital importance in the sequel: those of process and of precedence.

DEFINITION 5.6 A complex event [i.e. one formed by the composition of two or more events] is called a *process*.

DEFINITION 5.7 Let e and e' be two events in a given event space [i.e., e, $e' \in E(x)$ for some thing x], such that e and e' compose to form a third event $e'' = e * e'$. Then e is said to *precede* e' relative to the reference frame involved in $E(x)$:

$$\text{If } e, e' \in E(x) \text{ then } e \prec e' =_{df} e * e' \in E(x).$$

This precedence relation is irreflexive because no proper event composes with itself; it is asymmetric: if two events compose in a given order, it does not follow that they also compose in the reverse order; and it is transitive: if one event composes with another, and the latter with a third event, then the first composes with the last. In short, $<$ is a *strict partial ordering* of $E(x)$ for any thing x. (Precedence is then formally the same as $<$ in a set of numbers and $\subset$ in a set of sets.) In short, we have

COROLLARY 5.5 For any given thing x and every state representation, $\langle E(x), < \rangle$ is a strictly partially ordered set.

That every event space is ordered by $<$ means that, provided two events in it are composable, one of them precedes the other. This order is not connected: there are events in every $E(x)$ that neither precede nor succeed each other, as shown by the very definition of the composition $*$ of events as a partial operation. Also, that order is *relative* or frame-dependent instead of absolute or frame-invariant, because $E(x)$ itself is frame-dependent. Thus if e precedes e' relative to a certain frame, there may exist another frame relative to which e' precedes e – unless of course e is necessary for the occurrence of e'. Hence the importance of mentioning the space to which the events of interest belong. More on this in Sec. 2.5.

2.3. *The Representation of Processes*

The method of tracing change step by step, i.e. of collecting pairs of states, is feasible only for finite state things. (Or rather, since there are no real things with finite state spaces, we should say that the method is restricted to finite state *models* of things.) If the state space is nondenumerable like the set of reals, then there is no single state following immediately upon a given state, i.e. there is no next state. In this case, given any two states a and b of a thing, such that b follows a, there are infinitely many intermediate states following a and preceding b. In such cases then we must look for a more powerful method for representing change. We shall presently expound such a method.

In Sec. 2.1 we introduced the concept of net change. In Sec. 2.2 we noted that one and the same net change can often be effected through different intermediate states: see Figure 5.5. The net change from state s to state s' in the state space $S(x)$ can be represented by the ordered pair $\langle s, s'\rangle$. But since the change along curve f is distinct from that along

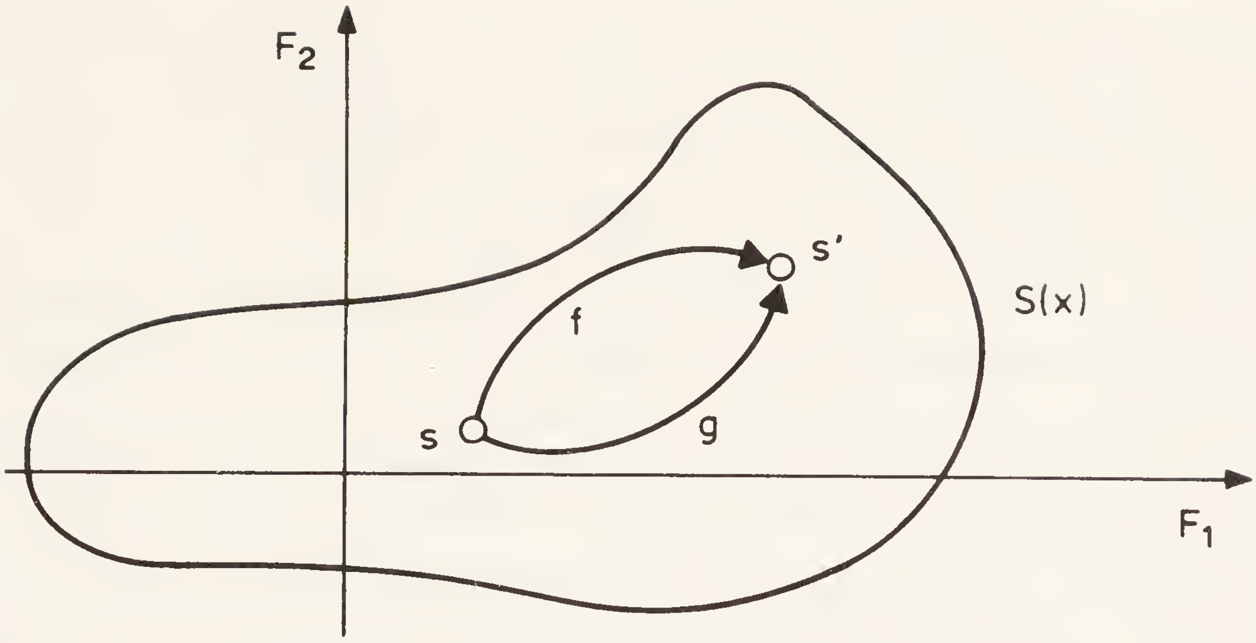


Fig. 5.5. Two different processes resulting in the same net change.

curve g, where $g \neq f$, we must represent the full events, or processes, by the ordered triples $\langle s, s', f\rangle$ and $\langle s, s', g\rangle$ respectively.

Now, the functions f and g occurring in our previous (imaginary) illustration are not supposed to be arbitrary: they must be lawful if we are to allow only lawful events and discard all the lawless (impossible) ones. In other words, f and g must be either laws possessed by the thing x concerned or transformations of the lawful state space $S_{\mathbb{L}}(x)$ compatible with those laws. (The functions need not be law functions: they may represent objective laws *cum* constraints and circumstances, such as initial conditions and boundary conditions, or they may be changes of representation leaving all the laws of the thing unchanged.) This suggests making

DEFINITION 5.8 Let $S_{\mathbb{L}}(x)$ be a lawful state space for a thing x. Then the family of *lawful transformations* of the state space into itself is the set of functions

$$G_{\mathbb{L}}(x) = \{g \text{ is a function} \mid g\colon S_{\mathbb{L}}(x) \to S_{\mathbb{L}}(x)$$
$$\& \ g \text{ is compatible with the laws of } x\}.$$

Clearly the identity transformation $i_S\colon S_{\mathbb{L}}(x) \to S_{\mathbb{L}}(x)$, where $i_S(s) = s$ for every $s \in S_{\mathbb{L}}(x)$, is a charter member of $G_{\mathbb{L}}(x)$. It represents no change and it can compose with any given nontrivial transformation.

Each such nontrivial transformation $g \in G_{\mathbb{L}}(x)$, where $g \neq i_S$, helps represent one feature of the total change undergone by x – e.g. its change of place, or of population, or of crowding. Since real changes are many-sided, they must be represented with the help of a number of different transformations composing to form the total change. Thus a thermoelectric event may be regarded as the composition of a thermal event and an electrical event – not however in the sense of 'composition' covered by the binary operation $*$ introduced in Sec. 2.2. (The acceptation of 'composition' employed in the present section is best understood by noting that $G_{\mathbb{L}}(x)$ is a proper subset of $S_{\mathbb{L}}(x)^{S_{\mathbb{L}}(x)}$, i.e. the family of all the functions on $S_{\mathbb{L}}(x)$ – not just those representing lawful changes. But the wider set has the monoid structure, since the composition of any two transformations of $S_{\mathbb{L}}(x)$ is a third transformation of the same set, and the latter includes the identity transformation.)

Now to the notion of interest:

PRINCIPLE 5.3 Let $S_{\mathbb{L}}(x)$ be a lawful state space for a thing x, and let $G_{\mathbb{L}}(x)$ be the family of lawful transformations of the state space into itself. Then a lawful event (or process) with end points s and s', where s, $s' \in S_{\mathbb{L}}(x)$, is representable as a triple $\langle s, s', g \rangle$, where $g \in G_{\mathbb{L}}(x)$ and $s' = g(s)$.

We call this the *functional representation* of change. Clearly, it subsumes the ordered pair representation, which obtains when the transformation g is fixed and the intermediate states are forgotten.

Consider the paradigmatic case of the classical model of a particle. The instantaneous dynamical state of such a (model) thing moving on a line is given by the instantaneous values of the position q and the momentum p of the particle, considered as independent variables. The nomological state space (called *phase space*) of such a thing is a subset of the cartesian plane $\mathbb{R}^2$. The transformation representing the motion can be calculated provided one knows or assumes (a) the equations of motion and (b) the forces and constraints acting on the particle. Assume, to fix ideas, that the force acting on the particle is elastic. In this case our thing is a linear oscillator and its laws are the canonical (or Hamilton) equations, which in this particular case reduce to

$$\dot{q} = p/m, \qquad \dot{p} = -kq,$$

where m is the mass of the particle and k the elastic constant. Then calling $q(t) = q$, $q(t+h) = q'$, where $h \in \mathbb{R}^+$, and similarly for the momentum, and expanding q' and p' in power series, one obtains

$$\left.\begin{aligned} q' &= q \cos ah + a^{-1} p \sin ah \\ p' &= p \cos ah - aq \sin ah \end{aligned}\right., \quad \text{with } a = (k/m)^{1/2}.$$

The value q' of the position coordinate at time $t+h$ is then a function of the earlier values of both the position and the momentum, and similarly for the momentum value p'. A transformation representing this change (motion) is called a *canonical transformation*, or a transformation satisfying the canonical equations of motion. This transformation, for a given value of the time shift h, is a map $g: \mathbb{R}^2 \to \mathbb{R}^2$ such that $g(q, p) = \langle q', p' \rangle$ as above. (There are two functions involved but they may be regarded as just two components of g.) The transformation may be regarded as a rotation in the state space, where the cartesian axes are now $x = a^{-1}p$ and $y = q$, and the rotation angle $\alpha = ah$. This transformation, far from being arbitrary, is constrained by the laws of motion. The net effect of this constraint is that the ellipse $p^2/a^2 + q^2 = 1$ is transformed into the ellipse $p'^2/a^2 + q'^2 = 1$ rather than becoming a curve of a different type.

Unless the state space happens to be one-dimensional, change will be represented by more than one function defined on the state space. Thus in the preceding example the transformation function turned out to have two components, u and v, such that $q' = u(q, p)$ and $p' = v(q, p)$. But u and v are, as noted above, the two components of a single function g mapping $S(x)$ into itself and satisfying the equations of motion.

2.4. *The Space of Lawful Events*

In Sec. 2.2 we characterized the space of conceivable net events. We now turn to a characterization of the space of really possible (i.e. lawful) events, taking into account all the intermediate states between the end points defining the net events. Recall Principle 5.3 concerning the functional representation of a full process – not just its end points – as an ordered triple $\langle s, s', g \rangle$. The collection of all such triples for a fixed transformation g may be regarded as a set of ordered couples and a subset of the space $E(x)$ of conceivable events. It represents the totality of changes of type g happening in or to thing x. And the total space of events for a given thing is the collection of all such partial event spaces. More explicitly, we propose

DEFINITION 5.9 Let $S_{\mathbb{L}}(x)$ be a lawful state space for a thing x, and let $G_{\mathbb{L}}(x) \subseteq S_{\mathbb{L}}(x)^{S_{\mathbb{L}}(x)}$ be the family of lawful transformations of $S_{\mathbb{L}}(x)$. Then

(i) the g-lawful transformations (or set of *changes of kind* g) for x, or *space of* g*-lawful events* in x, is the set of ordered pairs of states

$$E_g(x) = \{\langle s, s'\rangle \in S_{\mathbb{L}}(x) \times S_{\mathbb{L}}(x) \mid s' = g(s) \ \&\ g \in G_{\mathbb{L}}(x)\};$$

(ii) the totality of lawful transformations of x, or *space of lawful events* (in all respects) in x, is the union of all the partial event spaces:

$$E_{\mathbb{L}}(x) = \bigcup_{g \in G_{\mathbb{L}}(x)} E_g(x).$$

(We could have defined $E_{\mathbb{L}}(x)$ as the family of all $E_g(x)$'s, but then a singular event belonging to any of the latter would not belong to the former.)

Let us now relax the condition that the transformations of the lawful state space be lawful themselves, and consider the space of conceivable events. We are now in a position to generalize the result obtained in Sec. 2.2 concerning net events. Consider the events $\langle s, s', g\rangle$ and $\langle s', s'', h\rangle$, where $s, s', s'' \in S_{\mathbb{L}}(x)$, and $g, h \in G(x) = S_{\mathbb{L}}(x)^{S_{\mathbb{L}}(x)}$. That is, we consider two conceivable processes occurring in one and the same thing. Because the transformations g and h compose, the events compose in the indicated order:

$$s \overset{g}{\mapsto} s' \overset{h}{\mapsto} s''$$

to produce the net change $\langle s, s'', h \circ g\rangle$, where '$\circ$' stands for function composition. In the particular case where $h = i_S$ (identity) we get

$$s \overset{g}{\mapsto} s' \overset{i_S}{\mapsto} s'$$

which reduces to $\langle s, s', g\rangle$. This shows that the space of conceivable events is a category. More precisely, we have proved in all generality.

THEOREM 5.1 Let $S_{\mathbb{L}}(x)$ be a lawful state space for a thing x, and $G(x) = S_{\mathbb{L}}(x)^{S_{\mathbb{L}}(x)}$ the totality of (lawful and unlawful) transformations of $S_{\mathbb{L}}(x)$. Moreover let '$\circ$' designate the composition of transformations (functions) in G. Then the triple $\mathscr{E} = \langle S_{\mathbb{L}}(x), G(x), \circ\rangle$, called the *conceivable event space* of x, is a category. The objects of this category are all the states $s \in S_{\mathbb{L}}(x)$ of the thing, the morphisms all the transformations $s \overset{g}{\mapsto} s'$ with $g \in G(x)$ and $s' = g(s)$, and the identities the functions $s \overset{i_S}{\mapsto} s$.

This result (obtained with the help of Arturo Sangalli) is not terribly important because it concerns the structure of the space of conceivable events not that of the lawful events. Nevertheless it exhibits the structure in which the lawful event space $\mathscr{E}_{\mathbb{L}}(x)=\langle S_{\mathbb{L}}(x), G_{\mathbb{L}}(x), \circ\rangle$ is embedded. Besides it teaches us how to compose full events rather than just net events. In fact we have learned that the composition of events proceeds as indicated by

DEFINITION 5.10 Let $S_{\mathbb{L}}(x)$ be a state space for a thing x, and $G_{\mathbb{L}}(x)$ the corresponding set of lawful transformations of $S_{\mathbb{L}}(x)$. Further, call $e=\langle s, s', g\rangle$ and $e'=\langle s'', s''', h\rangle$ two events in the lawful event space $E_{\mathbb{L}}(x)$ defined by $S_{\mathbb{L}}(x)$ and $G_{\mathbb{L}}(x)$. Then e and e' *compose* in the indicated order to form a third event e'' iff the end of the first coincides with the beginning of the second and if the two transformations compose to form a third lawful transformation. If the composition takes place then the first event is said to *precede* the second. In symbols:

(i) $\langle s, s', g\rangle * \langle s'', s''', h\rangle = \begin{cases} \langle s, s''', h\circ g\rangle \text{ iff } s'=s'' \ \& \ h\circ g\in G_{\mathbb{L}}(x) \\ \text{undefined otherwise} \end{cases}$

(ii) $e \prec e' =_{df} e * e' \in E_{\mathbb{L}}(x)$.

And now a few overdue illustrations.

Example 1 Let the thing be a conservative system with n components. Its classical state space is the $6n$ dimensional cartesian space spanned by the state function whose components are the $3n$ generalized position coordinates and the $3n$ momenta. The event space is included in the set of graphs of the canonical or contact transformations, which are those transformations of the state (phase) space that leave the laws of motion invariant. For details on the simplest case see the example in Sec. 2.3. *Example 2* The state space of a quantum-mechanical system is a Hilbert space – a certain set of functions. The operator $T=\exp(iHt/\hbar)$ defined in this space, i.e. $T\colon S\to S$, allows one to represent the changes in the states of the system. Thus if $Q(t_0)$ represents the value of a property Q of the system at time t_0, then its value at time t is $Q(t)=TQ(t_0)T^{-1}$. *Example 3* Some or even all of the components of the state function for a thing could be random variables. Then the corresponding state space would be a probability state space (Ch. 4, Sec. 4.2.) The laws of change, or at any rate some of them, would concern not the states in a direct manner but rather their probabilities or, rather, the probabilities of the various possible (lawful) state transitions. These probabilities are conditional. Consider the simple case of a state space with a finite number of points, every one of which has a definite probability. Each final state s_f can arise from (originate in) any other state s_i with a definite probability $Pr(s_f|s_i)$, which can of course be nought for some pairs of states. For a fixed i all these probabilities add up to unity. The total probability that state s_f be actualized is

$$Pr(s_f)=\sum_i Pr(s_i)\cdot Pr(s_f|s_i).$$

2.5. *Keeping Track of Changing States*

Whereas some properties of a thing, such as its composition, are frame-invariant or absolute, others – such as its energy – are frame-dependent or relative. Since every thing possesses energy, the states of every thing are relative: recall Ch. 3, Sec. 2.8. And because states are relative, so are events. True, events such as turning on a switch or kissing look absolute. But this is only because in thinking of them we focus on what seems typical, leaving aside a number of features that are frame-dependent, such as the location and speed of the thing(s) in which the events occur. A reasonably complete account of an event calls for the determination of a number of traits, most of which are bound to be relative rather than absolute. Hence

RULE 6.1 Refer every state function – ergo every state space and every event space – to some standard thing (reference frame) or other.

The explicit reference to standards serves not only as a reminder that change is relative: it can also be utilized to label states and keep track of them in a more precise way than we have done heretofore. This is in fact the point of Definition 3.14: it allows us to identify the thing states in terms of reference states, or states of a standard. Let us recall how this was done, and let us improve on that parametrization.

Let $S(f)$ be a state space of a reference frame f for a thing x with state space $S(x)$. Further, assume that the domain of the state function $\mathbb{F}$ that spans $S(x)$, far from being unrelated to the reference frame, equals the collection $S(f)$ of reference states. That is, set $\mathbb{F}\colon S(f)\rightarrow S(x)$, so that each reference state $t\in S(f)$ is paired off to a single thing state $s=\mathbb{F}(t)=\langle F_i(t)\,|\,1\leqslant i\leqslant n\rangle$, where n is the number of properties represented by $\mathbb{F}$. The state function $\mathbb{F}$ is now the list of properties of thing x *relative to* (or parametrized by) *the states of the reference frame* f. Given any reference state t, $\mathbb{F}$ picks the corresponding thing state $\mathbb{F}(t)$. And a substitution of an inequivalent frame f' for frame f will be accompanied by different values $\mathbb{F}(t')$ of the state function.

The states of a reference frame can be described with various degrees of precision. But if we are to use them for labeling or identifying thing states, then that precision must not be less than the precision employed in describing the thing states. Now, in science one usually seeks, and often attains, maximal precision, which consists in this case in assigning real values to the individual properties of things. That is, more often than not each value of the state function F_i for a given thing equals a real number r_i, so that the state of the thing at (relative to) $t \in S(f)$ is $\mathbb{F}(t) = \langle F_i(t) \mid 1 \leqslant i \leqslant n \rangle = \langle r_1, r_2, ..., r_n \rangle$. Such a high degree of accuracy calls for a similar accuracy in the description of the reference states. And such an accuracy is achieved by coordinatizing them, i.e. by assigning them coordinate values.

The coordinatization procedure is best visualized by construing $S(f)$ as a system of four cartesian axes, so that each reference state is assigned a quadruple of real numbers. That is, we single out those properties of a reference frame that can be mapped into a four-dimensional grid, leaving all other properties aside. (The points in the grid are eventually interpreted as points in spacetime.) Finally we refer the thing states not to the reference states but to their numerical labels – as when we say '*X* was dreaming at the street corner at 7:00 p.m.'. That is, we pair each thing state off to a point in the reference grid.

The coordinatization of reference states is effected by a one to one correspondence $k : \mathbb{R}^4 \to S(f)$ between ordered quadruples of reals and reference states. The composition $\lambda = \mathbb{F} \circ k$ of the coordinatization function with the state function matches each point $r = \langle t, x, y, z \rangle$ in the reference grid with a thing state s, i.e. $r \overset{k}{\mapsto} t \overset{\mathbb{F}}{\mapsto} s$, as shown in Figure 5.6 and in the commutative diagram overleaf.

Now, the reference grid is partially ordered. Indeed, if r and s are quadruples of reals, then $r \leqslant s$ iff each component or coordinate of r is smaller than the corresponding coordinate of s. That is,

$$\langle r_1, r_2, r_3, r_4 \rangle \leqslant \langle s_1, s_2, s_3, s_4 \rangle \text{ iff } r_i \leqslant s_i \text{ for all } i = 1, 2, 3, 4.$$

Consequently $\langle S(f), \leqslant \rangle$ is a partially ordered set. This order is not connected: not every pair of reference states is related by $\leqslant$: see Figure 5.7. And the same kind of order is imposed, via $\mathbb{F}$, on the set $S(x)$ of thing

$$\begin{tikzcd}
\mathbb{R}^4 \arrow[r, "k"] \arrow[dr, "\lambda"'] & S(f) \arrow[d, "\mathbb{F}"] \\
 & S(x)
\end{tikzcd} \qquad \lambda = \mathbb{F} \circ k$$

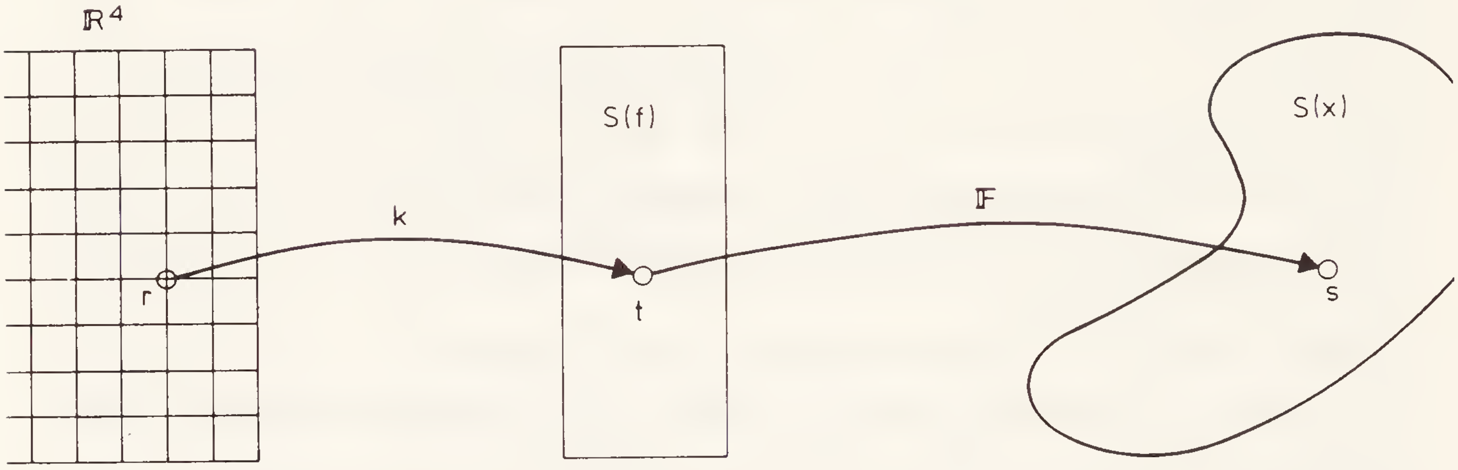

Fig. 5.6. Coordinatization of states. Each reference state $t \in S(f)$ is assigned at most one thing state $s \in S(x) \subseteq \mathbb{R}^n$ and is represented by a quadruple of reals $r \in \mathbb{R}^4$.

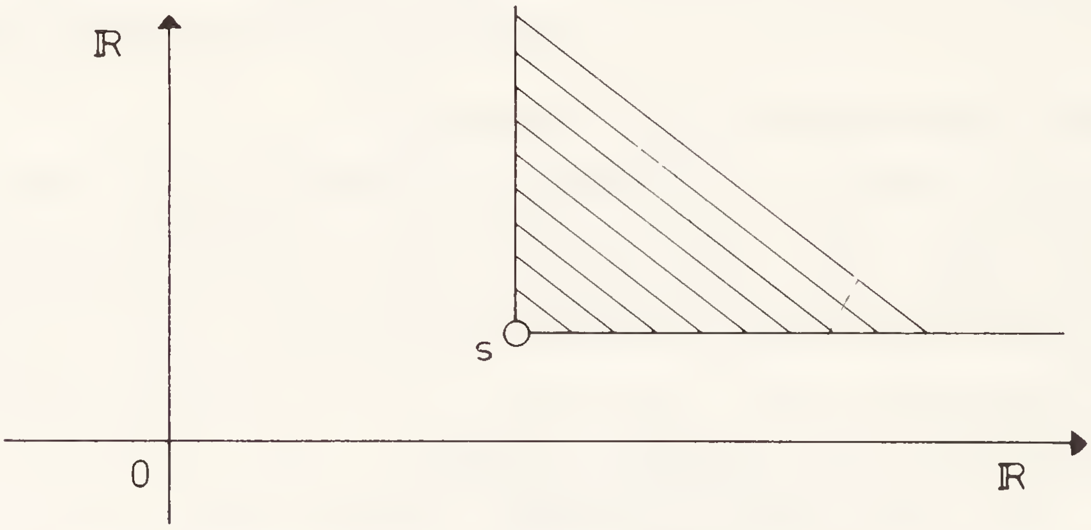

Fig. 5.7. State s precedes all others in the shaded region but none outside the latter.

states even if $\mathbb{F}$ does not take values in $\mathbb{R}^n$ – as when a mammal is said to pass through four stages of development.

The preceding considerations can be compressed into

DEFINITION 5.11 Let f be a reference frame for a thing x and let $S(f)$ and $S(x)$ be the respective state spaces. Further, assume that $S(f)$ is spanned by a four-component state function, while $S(x)$ is scanned by an n-component state function $\mathbb{F}$. Then a *coordinatization* of the states of both x and f is a $1-1$ correspondence $k: \mathbb{R}^4 \to S(f)$ such that

(i) k assigns each reference state $s \in S(f)$ a quadruple of real numbers r – as a consequence of which each thing state $s \in S(x)$ is identified as the n-tuple $s = (\mathbb{F} \circ k)(r)$;

(ii) k is order preserving, i.e. the partial order of $\mathbb{R}^4$ induces via k the partial ordering of reference states, which in turn orders the states of the thing: for all $t_1, t_2 \in S(f)$,

$$\begin{aligned}&\text{if } r_1 \leqslant r_2 \quad \text{then} \quad k(r_1) \leqslant k(r_2) \ \& \ \mathbb{F}(t_1) \leqslant \mathbb{F}(t_2),\\ &\text{where} \quad t_i = k(r_i).\end{aligned}$$

In other words, a state coordinatization is an order preserving function labeling and ordering the thing states via the reference states:

$$\langle \mathbb{R}^4, \leqslant \rangle \xrightarrow{k} \langle S(f), \leqslant \rangle \xrightarrow{\mathbb{F}} \langle S(x), \leqslant \rangle.$$

As the reference frame passes from one state to another, so does the thing: the successive states of a thing can then be matched to, hence identified by (not *with*), the successive states of the standard. And in turn, the ordering of states induces an ordering of events (in the same thing and relative to the same frame). Hence we can make

DEFINITION 5.12 Let s, s', s'', s''' be four states of a given thing relative to a certain reference frame, such that the first two form a net event $e = \langle s, s' \rangle$ and the last two another event $e' = \langle s'', s''' \rangle$. Then

(i) $e \preccurlyeq e' =_{df} s \leqslant s'' \ \& \ s' \leqslant s'''$;

(ii) $e \sim e' =_{df} e \preccurlyeq e' \ \& \ e' \preccurlyeq e$.

The relation $\preccurlyeq$ of event order is reflexive: two events are congruent iff their corresponding initial and final states are congruent, i.e.

$$e \sim e' =_{df} s \sim s'' \ \& \ s' \sim s'''.$$

It is also clear that $\preccurlyeq$ is antisymmetric and transitive. Hence $\preccurlyeq$ is a partial order – unlike the relation introduced by Definition 5.7, which was only a strict partial order. Hence instead of Corollary 5.5 we have

COROLLARY 5.6 For every thing x and relative to any given reference frame, $\langle E(x), \preccurlyeq \rangle$ is a partially ordered set.

Our new definition of event order is more comprehensive than Definition 5.7, as it includes the particular case when e composes with e' to form a third event $e'' = e * e'$ (in which case $s' = s''$), as well as the case when they do not compose. (See Figure 5.8.) The composition of events is possible only if the precedence is proper: $e * e' = e''$ iff $s' = s''$ & $e < e'$.

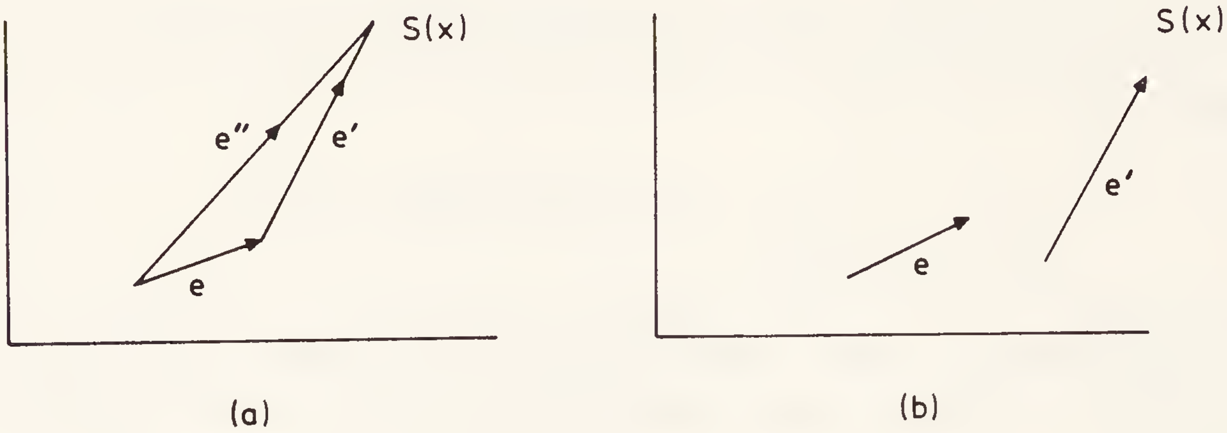

Fig. 5.8. Event order. (*a*) $e < e'$ and both compose to form e''. (*b*) $e < e'$ but they do not compose.

Consequently two events do not compose if neither precedes the other. Which is rather obvious, as the links in a chain of events are supposed to follow one another. Which in turn invites defining a *chain of events* as a denumerable and strictly partially ordered set of events $E^*(x)$ included in the event space of a thing x such that, for any $e, e' \in E^*(x)$, if $e < e'$ then the end state of e coincides with the beginning state of e', so that both events compose. More on this in Sec. 3.1.

Finally we shall proceed to formalize the notion of a variable collection, i.e. one whose membership changes as the reference states succeed one another – e.g. the population of a town. Obviously the concept of a set won't do because every set has a fixed membership. But instead of using a single set we may employ a family of sets indexed by a change parameter – call it t. Thus calling C_t a collection at t, we form the family $C = \{C_t | t \in T\}$, which may be called a variable collection. Or, equivalently, we may propose

DEFINITION 5.13 Let $t \in S(f)$ be the change parameter of frame f. Then any function

$$K: S(f) \rightarrow C, \text{ with } C = \{C_t | t \in S(f)\},$$

such that $K(t) = C_t$ for $t \in S(f)$, is called a *variable collection.*

This construal of a variable collection will be adopted henceforth, particularly in Vol. 4 of this treatise when dealing with populations of molecules, organisms, or persons – the membership of which, unlike that of a set, changes in time. It is particularly advantageous for analyzing properties of collections. Take for example the numerosity or population of a variable collection such as an ecosystem. It may be regarded as a function $p: C \to \mathbb{N}$ assigning each member of the family C a natural number $n \in \mathbb{N}$. This function composes with K to yield the function $f = p \circ K: S(f) \to \mathbb{N}$, which assigns to each reference state (or instant) $t \in S(f)$ a natural number, namely the population of the variable collection. (For discrete times the mathematical theory of sets through time is available.)

2.6. *Rate, Extent, and Change Potential*

A first notion we want to clarify is that of rate of change. Actually there is a large family of concepts of rate of change, of which we shall present only the two most common ones.

Suppose both the reference states and the thing states have been duly coordinatized (Sec. 2.5). Every reference state $t \in S(f)$ is then represented by a quadruple of reals: $t = \langle \alpha, \beta, \gamma, \delta \rangle$. Consequently the corresponding thing state is $s = \mathbb{F}(t) = \mathbb{F}(\alpha, \beta, \gamma, \delta)$. If $\mathbb{F}$ has a component F_i that is once differentiable with respect to one of the four reference parameters, say α, then the rate of change of F_i with respect to α is the partial derivative of F_i with respect to α. The thing does not change at all in the ith respect over the interval $[\alpha_1, \alpha_2]$ iff $\partial F_i / \partial \alpha = 0$ for all $\alpha \in [\alpha_1, \alpha_2]$. It changes swiftly in the same respect over the same interval if the corresponding rate of change is appreciable relative to F_i itself – otherwise it changes slowly. Needless to say, the reference parameter may but need not be the time. In sum, we can make

DEFINITION 5.14 Let the states of a thing x be coordinatized through those of a certain reference frame, so that each thing state is of the form $s = \mathbb{F}(\alpha, \beta, \gamma, \delta)$, where the arguments are the parameters identifying the reference states. Further, let the ith component of $\mathbb{F}$ be differentiable with respect to α. Then

(i) the *relative rate of change* of x in the ith respect and with respect to α is

$$V_i = \frac{1}{F_i} \frac{\partial F_i}{\partial \alpha};$$

(ii) the *relative extent of the change* of x in the ith respect, with respect to α and over the interval $[\alpha_1, \alpha_2]$, is

$$\Delta_i(\alpha_1, \alpha_2) = \frac{\ln F_i(\alpha_2) - \ln F_i(\alpha_1)}{\alpha_2 - \alpha_1} \quad \text{provided } F_i(\alpha_1), F_i(\alpha_2) > 0.$$

If the thing changes periodically with period $[\alpha_1, \alpha_2]$, the extent of its change over an integral multiple of the period is nil. This provides a definition of the concept of *cyclic change*.

The preceding definition is of no use in the case of a probability state space the points of which are not paired off to any reference frame. In this case we are interested in global changes that are frame invariant. The rate of change from state s_i to state s_j may be taken to be the conditional probability of s_j given that s_i has been actualized, i.e. $Pr(s_j|s_i)$. The rationale behind the choice is this. Think of a complex thing, n_i components of which are in state s_i, n_j in state s_j, and so on. Then $n_i Pr(s_j|s_i)$ will measure the most probable number of components jumping from state s_i to state s_j. The larger this product the greater the rate of change. The stochastic matrix $\|Q_{ij}\| = \|Pr(s_j|s_i)\|$ represents then the global rate of change of the thing. If the matrix is diagonal, i.e. if $Pr(s_j|s_i) = \delta_{ij}p_i$, where δ_{ij} is the Kronecker delta and p_i the probability of state s_i, then the thing does not change. The larger the change the larger the corresponding off-diagonal terms of $\|Q_{ij}\|$. And the extent of change, also called the *mobility*, equals the sum of the products of the off-diagonal terms by their symmetrical counterparts. We compress all this into

DEFINITION 5.15 Let $\langle S(x), Pr\rangle$, where $S(x)$ is a denumerable state space for a thing x, and Pr a probability measure on $S(x)$, be a possibility field for x. Then

(i) the *global rate of change* of x is the stochastic matrix

$$\|Q_{ij}\| = \|Pr(s_j|s_i)\| \quad \text{with} \quad s_i,\ s_j \in S(x),$$

where $Pr(s_j|s_i)$ is the probability of state s_j given that state s_i has been actualized;

(ii) the *extent of change* (or *mobility*) of x is

$$\Delta = \sum_{i \neq j} Q_{ij} \cdot Q_{ji} = \sum_{i \neq j} Pr(s_j|s_i) \cdot Pr(s_i|s_j).$$

The latter is a measure of the changeability of certain things in certain respects, namely those describable with the help of denumerable possibility fields. But it is not a measure of the overall changeability of an arbitrary thing. Just how changeable (in all respects) is an arbitrary thing? Equivalently: How big are event spaces? To answer this (imprecise) question consider the set of *all* properties of any real thing and a realistic theoretical model of such a thing – say, the relativistic theory of the electron, or of the gravitational field. Such a model, or functional schema, is based on a certain set on which an n-component state function $\mathbb{F}$ is defined, every component of which represents a (changeable) property of the thing. At least some of the components of the state function are bound to be continuous with respect to some of the "independent variables". Call F_i any such continuous state variable. As the thing changes, the values of F_i vary continuously (or at least piece-wise continuously) even if those of some other components of $\mathbb{F}$ change by jumps. (Think of a thing that gains or loses quanta of electric charge, or people, while losing or gaining momentum.) See Figure 5.9. Clearly, the (state) space spanned by $\mathbb{F}$ is nondenumerable.

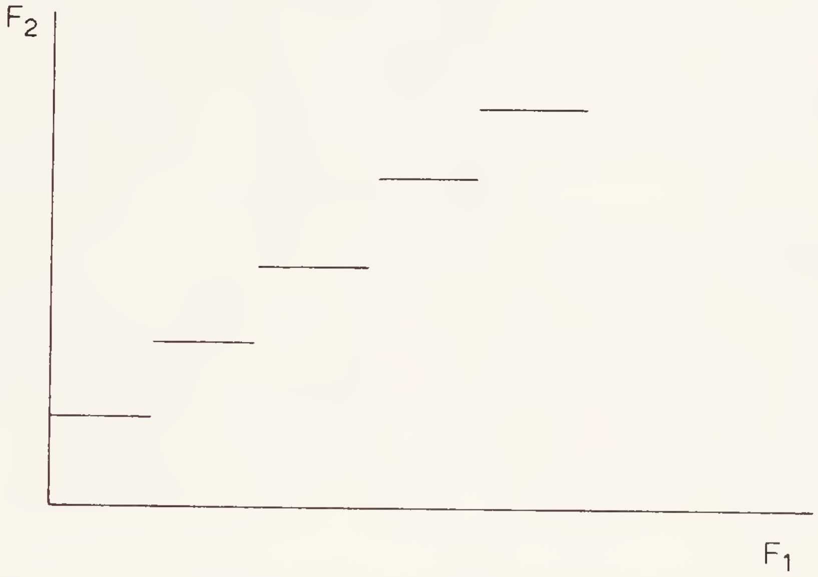

Fig. 5.9. A state space with a continuous axis (F_1) and a discontinuous one (F_2). The broken line represents the evolution of the thing. The totality of states is nondenumerable.

We assume that every thing has at least one property that changes continuously with respect to some variable or other – the "independent variable" being usually a time coordinate or a space coordinate:

POSTULATE 5.2 Every [realistic] state function has at least one continuous component.

Since a state space is the set of points scanned by the tip of the state function, we have

COROLLARY 5.7 Every [realistic] state space is nondenumerable.

And from the way events are built we also infer

COROLLARY 5.8 Every [realistic] event space is nondenumerable.

True, we often build models of things (model objects) whose state spaces are denumerable or even finite. But this is done for the sake of expediency rather than truth – i.e. because we are interested in just a few aspects of the whole thing. Thus, even though automata theory models certain machines as having only a finite number of states, the actual design and construction of such machines presupposes theories involving nondenumerable state spaces such as those analyzed in Ch. 3, Secs. 2.4, 2.5. Even if the universe were to consist of just two things in relative motion (e.g. one diatomic molecule), the world event space would be nondenumerable. In conclusion, realistic event spaces are as big as any subset of the real line can be: they all have the power of the continuum.

Because all realistic event spaces are equally bulky (Corollary 5.8), they do not supply a suitable measure of the change potential of real things. We must look elsewhere for such a measure. If we scan the factual sciences in search for a property shared by all things, regardless of kind and related to their changeability, we find but one universal property – namely, energy. Moreover energy has the property that it is greater the more complex the thing, hence the greater its potential for change. In fact, energy is strictly additive for noninteracting things, i.e. when the total state space of the compound equals the union of the partial state spaces (recall Ch. 3, Sec. 2.7). We therefore make

POSTULATE 5.3 There is exactly one property possessed by all things, that is additive for thing aggregates composed of detached parts. That is, if Θ is the class of things and F that of reference frames, then there exists one and only one real valued function $\varepsilon : \Theta \times F \to \mathbb{R}$ such that, for any x and y in Θ such that $x \rceil\!\!\lfloor y$,

$$\varepsilon(x \dotplus y, f) = \varepsilon(x, f) + \varepsilon(y, f) \text{ for all } f \in F.$$

This function ε is called *energy*, and its value at $\langle x, f \rangle$ – namely *the energy of x relative to f* – measures the *changeability of x relative to f*.

(*Energeia* was an ontological concept before being absorbed and transformed by modern physics. It is still sometimes regarded as a metaphysical notion though for the wrong reason, namely because it does not represent a perceptible property. The general concept of energy *is* a genuine ontological notion for a different reason, namely because it designates a universal property. For this reason it occurs everywhere in science, even though in some areas – particularly geography and history – it has entered only recently. In any event it is nice to see the concept of energy back in the philosophical fold. Because we now understand that energy is a property of things, there is no danger of it being reified, let alone be made into the only existent, as it was by the energetists of the turn of the century – e.g. Ostwald, 1902.)

It may be objected that Postulate 5.3 is not precise enough to define the energy concept. To this it may be rejoined, first, that science does not supply a definition of the general concept of energy. Second, to a physicist Postulate 5.3 is enough to *identify* ε as the energy function, for it is the only quantitative (and approximately additive) property all things have. (For things with interacting parts, the energy is slightly subadditive.) All our axiom states is that *all things have energy*. It does not supply a method for computing the energy of any thing in particular: this is a task for science. And no science can accomplish this task without some precise information (or conjecture) about the kind of thing, its structure, interactions, and circumstances.

One can conceive of certain properties that come in infinite degrees. For example, if the universe happens to be infinite in extension, then there are things that are infinitely distant from one another. On the other hand the energy of a finite part of the universe is normally taken to be finite. (True, both in classical and in quantum physics there are theories containing theorems – never axioms – according to which certain things, such as electrons and plane electromagnetic waves, have infinite energies. However, these formulas are regarded as blemishes of the theories not of nature, and several tricks are resorted to in order to avoid them.) We are therefore justified in adopting

POSTULATE 5.4 The energy of any thing composed of a finite number of things, and relative to any reference frame, is finite.

An important consequence of the finite energy (or potential for change) of every finite thing is that the pace and the extent of every change are bounded. (See Figure 5.10.) For example, the speed of a

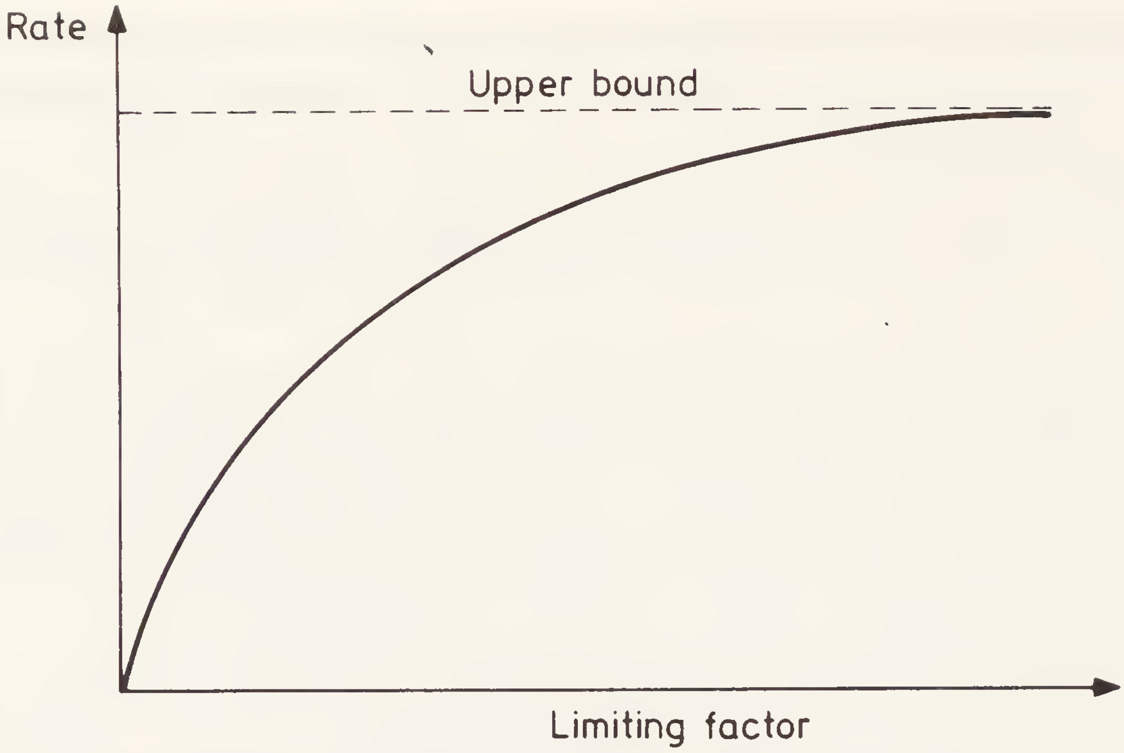

Fig. 5.10. Rate of process vs. intensity (or concentration) of a "limiting factor" such as energy.

body cannot exceed a certain limit precisely because it has a finite amount of energy. Likewise the limited energy resources of the biosphere – in particular of the soil – place a limit on human population. (For further examples and principles see Booij and Wolvekamp 1944.) All such particular statements concerning so-called "limiting factors" can be deduced from formulas regarding the energy of the particular system concerned. We compress them into

POSTULATE 5.5 The rate and the extent of every change in any thing composed of a finite number of things, are bounded.

(The restriction to finite things is due to the need for not excluding the possibility of the ceaseless expansion of the physical universe.)

An immediate consequence of the above postulate is that there is an end to every change. But this matter will be taken up in the next section.

Before closing this section we must ward off a possible misunderstanding concerning universal properties. It is often claimed that information constitutes an even more universal property than energy. However, not all things are information systems: only those constituted by an information source, an information channel, and an information receiver qualify as information systems, i.e. systems capable of generating, transmitting, and receiving information. Secondly, rather than being (relative to every reference frame) an intrinsic property, like energy, information is a mutual property in the sense that it is always an amount of information transmitted by an information carrier: change the channel (e.g. make it less noisy) and the amount of information will change. A cursory look at the basic assumptions and definitions of statistical information theory (e.g. Luce, 1960) will suffice to bear out our contention. Thirdly, while there can be energy exchanges without any information transmission – e.g. in atomic collisions – every transmission of information requires some energy. The fact that information theory pays no attention to the physical basis of an information process, hence to the energy exchanges underlying the transmission of information, does not annihilate that basis. We shall return to this matter in Sec. 4.4.

3. PROCESS

3.1. *Serial Change*: *Types*

Heretofore we have studied change in general. In this section we shall analyze a particular kind of change, namely serial change or process. Not every old set of states or of events constitutes a process. For example an arbitrary collection of events occurring in different things that are comparatively isolated from one another does not constitute a process even if it is ordered in time. For a set of events to constitute a process it must satisfy two conditions:

(i) the events must involve or concern just one thing, however complex, and

(ii) the events must be ordered intrinsically.

In sum a process may be envisaged as a directed tree, in particular a chain, in some event space.

Before laying down general principles we may as well get hold of a stock of typical examples. We shall resort to these examples several times in the course of this work, so we had better display them ostensibly.

(*a*) *Chain*

The simplest process kind is the chain formed by a denumerable set of states, or of events, in a given thing. In this particular case we can formalize the notion of a process as a *sequence*, i.e. a function defined on the set $\mathbb{N}$ of natural numbers. More precisely, we can make

DEFINITION 5.16 Let $\mathbb{F}$ be a state function, and $S(x)$ the corresponding state space, for a thing x relative to a certain reference frame. Then x undergoes a *chain process* iff $\mathbb{F}: \mathbb{N} \to S(x)$, where $\mathbb{N}$ is the set of non-negative integers. In this case the process is represented by

$$\pi(x) = \langle \mathbb{F}(n) | n \in \mathbb{N} \rangle,$$

where $\mathbb{F}(n)$ is the nth *stage* of the process.

A finite segment of such a process is the restriction of the state function to a finite subset of natural numbers. The *length* of such a finite chain is of course the number of stages in it.

Example A population of unstable particles, or organisms, or any other things that come into and go out of being, will undergo a discontinuous process as far as the population number is concerned. If the rate of destruction is balanced by the rate of emergence, a steady state prevails in the given respect.

Discontinuous processes, though common and of great heuristic importance, are not universal. An even when they do take place it is worth while to try to analyze them further instead of taking the component events *en bloc* as was done above. This need not be done in the preliminary stages of a science – e.g. in learning theory at the present moment – but it is an ultimate desideratum. Finally because discontinuous processes do not exhaust the process genus, it makes no sense to ask about the number of events that have occurred during the history of the universe – not even during the last second of its existence.

(*b*) *Continuous process*

An obvious generalization of the denumerable chain is obtained by substituting an arbitrary directed set for the set of natural numbers in the previous definition. More exactly, we propose

DEFINITION 5.17 Let $\mathbb{F}$ be a state function, and $S(x)$ the corresponding state space, for a thing x relative to a certain reference frame. Then x undergoes a *serial change* iff $\mathbb{F}: T \to S(x)$, where T is a directed set [i.e. if $\mathbb{F}$ is a *net*]. In this case the process is represented by

$$\pi(x) = \langle \mathbb{F}(t) | t \in T \rangle.$$

Serial changes are often gapless or continuous, as when the state function is a continuous function of a parameter such as time. We need therefore

DEFINITION 5.18 Let $\pi(x) = \langle \mathbb{F}(t) | t \in T \rangle$ be a serial change in a thing x. Then $\pi(x)$ is *continuous* over the interval $U \subseteq T$ iff U is nondenumerable and $\mathbb{F}$ is a continuous function on U. And the process is *piece-wise continuous* over T iff T equals the union of finitely many nondenumerable sets, and $\mathbb{F}$ is continuous over every one of them.

Example 1 A reversible chemical reaction

$$A \underset{k_-}{\overset{k_+}{\rightleftharpoons}} B$$

in a closed reactor is described by the rate equations with positive coefficients

$$\frac{dA}{dt} = -k_+A + k_-B, \qquad \frac{dB}{dt} = k_+A - k_-B$$

subject to the closure or conservation condition $d(A+B)/dt = 0$. The state space of the whole thing is the $\mathbb{R}^+ \times \mathbb{R}^+$ plane and the evolution of the system is represented by an arc of a continuous curve in this plane.

Example 2 The trajectory of a particle that collides with other particles is broken but continuous even though the particle velocity changes abruptly at each collision. The simplest case is that in which the particle is initially at rest and obtains a constant velocity at $t=0$ upon being pushed by another particle:

$$\dot{x}(t) = \begin{cases} 0 & \text{for} \quad t < 0 \qquad \therefore \quad x(t) = a = \text{const.} \\ 1 & \text{for} \quad t \geqslant 0 \qquad \therefore \quad x(t) = a + t. \end{cases}$$

It is sometimes claimed that continuity is more basic than discontinuity – and at other times that the converse is true. There seems to be no firm ground for either hypothesis, whence we shall adopt neither. We only seem to know that (*a*) both hypotheses have been ontologically and scientifically stimulating; (*b*) continuity hypotheses are empirically irrefutable or nearly so, and (*c*) while some properties (hence some processes) are continuous, others are not – at least according to contemporary science. For these reasons, instead of committing ourselves to either hypothesis we propose the more fertile heuristic

PRINCIPLE 5.4 Try to resolve every discontinuous change into a continuous process, and watch for discontinuities in every seemingly continuous process.

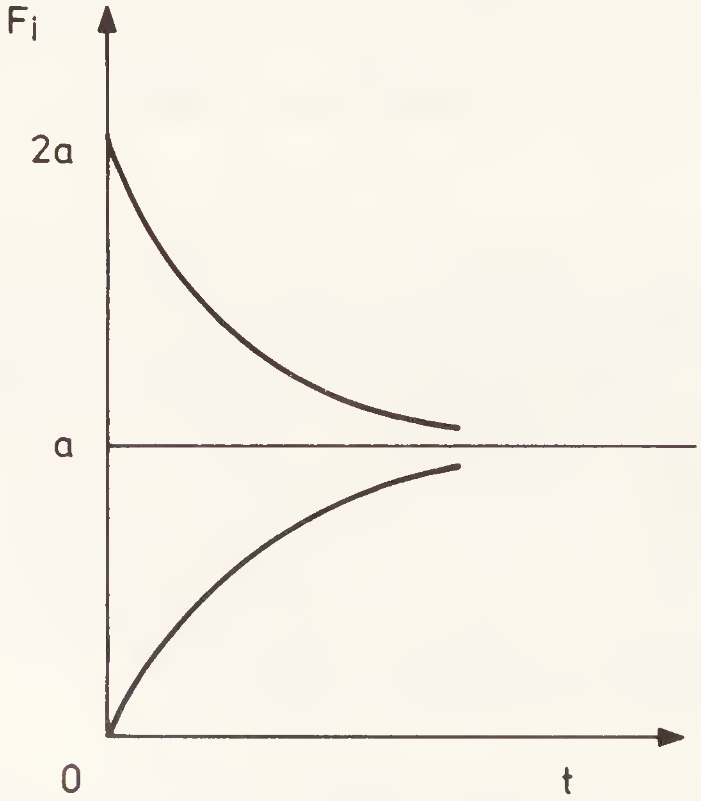
(c) *Path independence*

Whereas the outcome of some processes depends critically upon the precise trajectory in state space, others are *path independent* or nearly so. A particular case of great interest in all fields of inquiry, from physics to sociology, is that of equifinality, or same final state. The precise concept is elucidated by

DEFINITION 5.19 Two serial changes are *equifinal* iff their end states are the same.

Equifinality has been claimed to prove finality or goal-directedness, for it seems as if the system concerned – e.g. an organism – strives to attain a given goal by whatever means it can. However, equifinality is not evidence for teleology unless the existence of a purpose can be proved, for equifinal processes are common among physical things. For example, all closed thermodynamic systems approach a state of equilibrium.

Example Let the instantaneous value of a property F be given by one of the following functions on $\mathbb{R}^+$:



$$F_1(t) = a(1 + e^{-kt})$$
$$F_2(t) = a$$
$$F_3(t) = a(1 - e^{-kt})$$
with $a, k \in R^+$.

Fig. 5.11. Three different ways of reaching the same final state or asymptotic value $X_\infty = a$: starting from a, advancing to it, or declining to it.

(*d*) *Memory*

Suppose the state of a thing depends not only upon a parameter t (the phase of the process) but also upon some preceding state or states. In this case one says that the thing has a *memory* of some of its past states, or that it undergoes a *hereditary* process. Thus the elastic state of a piece of steel, the magnetic state of a magnet, and the genic state of an organism, all depend on their previous histories. In a number of cases such dependence can be expressed by a formula of the type

$$\mathbb{F}(t) = \int_0^t \mathbb{F}(\tau - t) \cdot M(\tau) \cdot d\tau,$$

where M is the memory function. (The process is memoriless iff $M = \delta$, or the Dirac delta.)

The general concept is clarified by

DEFINITION 5.20 Let $\mathbb{F}$ be a state function and $S(x)$ the corresponding state space, for a thing x relative to a certain reference frame. Further, call $t \in T$ the state parameter, where T is a directed set. Then x undergoes a *hereditary process* iff every one of its states $\mathbb{F}(t) \in S(x)$ is a functional of some other states $\mathbb{F}(\tau)$ with $\tau < t$.

There are two important species of hereditary process: (*a*) the memory is kept fairly intact throughout the process, and (*b*) the memory fades away until it disappears practically after a certain time called the *relaxation time*. Systems with weakly interacting components, such as non-ionized gases and extended empires, have short relaxation times. On the other hand organisms have long genetic and ontogenetic relaxation times. For example, malnutrition and deprivation of sociality in the early life of a mammal are separately sufficient to seriously impair some of its abilities for life.

(*e*) *Reversibility and irreversibility*

Some processes, particularly on the microphysical level – and probably only such – are reversible; all known macroprocesses are irreversible. The latter may be regarded as a generalization of a theorem proved in statistical mechanics. A system is called *ergodic* if it eventually scans its entire state space – or, more precisely, if, when left undisturbed (isolated), it occupies successively every state consistent with its total energy.

Until 1913 most authors asserted that, since individual particles move reversibly, every collection of particles must have the reversibility property and, moreover, must be ergodic. That year A. Rosenthal and M. Plancherel proved independently that, if the system satisfies the canonical equations (Ch. 3, Sec. 2.6), then it is not ergodic. That is, they proved that there are no classical-mechanical ergodic (or fully reversible) systems. Hence even if the universe were a huge aggregate of particles (which it is not) it could not retrace all of its steps. There is no eternal return.

Finally we note that in microphysics most, but by no means all, processes are assumed to be *stochastically reversible*, in the sense that the probability of an elementary process and that of its reverse are the same. This allows for momentary deviations from the general trend, i.e. for isolated events in which some states become overpopulated or underpopulated. However, certain microprocesses, notably radioactivity and, in general, transmutation processes, are irreversible.

All this invites

DEFINITION 5.21 Let $\pi(x) = \langle \mathbb{F}(t) | t \in T \rangle$ be a serial process in a thing x. Further, let $\bar{T}$ be the same set as T directed in the opposite way (e.g. $\langle \mathbb{R}, > \rangle$ instead of $\langle \mathbb{R}, < \rangle$). Then $\pi(x)$ is *reversible* iff $\bar{\pi}(x) = \langle \mathbb{F}(t) | t \in \bar{T} \rangle$ is just as possible (i.e. lawful) as $\pi(x)$.

If both $\pi(x)$ and its reverse $\bar{\pi}(x)$ can be assigned probabilities, one can think of defining the *degree of reversibility* of a process as the ratio of its probability and that of its reverse, or $r = \bar{p}/p$. For a fully reversible process, $r = 1$; for a fairly reversible process, $0 \ll r < 1$; for a nearly irreversible process, $0 < r \ll 1$; and for a fully irreversible process, $r = 0$. Such a concept might be useful in a number of fields, particularly in statistical mechanics.

It is common to declare a process to be reversible just in case its laws are invariant under time reversal. This is a mistake, because processes depend on circumstances as well as laws. For example, although the basic laws of radioactive disintegration (chiefly Schrödinger's) are T-invariant, the boundary conditions are such that the probability for a disintegration fragment to reenter the nucleus vanishes.

Finally, note that, while all reversible processes are cyclic, the converse is false. In fact most cycles are not reversible – i.e. they do not leave things as they were. For example, the water cycle and the nitrogen cycle on our planet are not reversible, as they are accompanied by energy degradation (entropy increase).

(*f*) *Random process*

A conspicuous kind of serial process, and one of great philosophical interest, is that of a random process. (For a definition of randomness see Ch. 4, Sec. 6.4.) A random or stochastic process is one described by a state function that is a random "variable", i.e. a function every value of which has a definite probability or probability density. In the simplest case the values s_i of the state function $\mathbb{F}$ form a discrete sequence $\langle s_i | i \in \mathbb{N} \rangle$, such as the times of arrival of customers at a counter. In this case the function f such that $f(s_i) = Pr(\mathbb{F}(t) = s_i) = p_i$, where Pr is a probability measure and p_i the probability that x happens to be in state s_i, is called the *probability distribution* of $\mathbb{F}$. (See e.g. Feller, 1968, Ch. IX.)

Many substantial properties, at all levels, must be represented by random "variables". Hence any real process – in contrast to an idealized model of it – is likely to have at least one random aspect. Therefore, instead of defining the concept of a real process (as is usual in the literature on stochastic processes) we prefer to adopt

DEFINITION 5.22 Let $\mathbb{F} = \langle F_1, F_2, \ldots, F_n \rangle$ be a state function for a thing x undergoing a serial change $\pi(x) = \langle \mathbb{F}(t) | t \in T \rangle$. This process is said to be *random in the ith respect* iff the component F_i of $\mathbb{F}$ is a random variable.

(*g*) *Stability*

A thing is said to be stable if its representative point in state space remains confined within a "small" region. More precisely, we can make

DEFINITION 5.23 Let $G_{\mathbb{L}}(x)$ be the set of lawful transformations of the state space $S_{\mathbb{L}}(x)$ of a thing x. Then x is *stable in the region* $A \subset S_{\mathbb{L}}(x)$ iff, for all $s \in S_{\mathbb{L}}(x)$, $g(s) \in A$ for every g in $G_{\mathbb{L}}(x)$.

In other words a thing is in a state of *dynamical equilibrium* if all the changes it undergoes send it to a fixed subset of its state space. If this subset reduces to a point then the thing is said to be in *static equilibrium* or not to change at all. In other words, a thing x is in static equilibrium at a state $a \in S_{\mathbb{L}}(x)$ iff a is a fixed point under every transformation of the state space into itself – i.e. if $g(a) = a$ for all g in $G_{\mathbb{L}}(x)$. In short, just as fixed subsets of the state space represent dynamical equilibrium, so fixed points represent states of static equilibrium.

States of static equilibrium can only be temporary. On the other hand dynamical equilibrium can be lasting. Figure 5.12 exhibits the states of

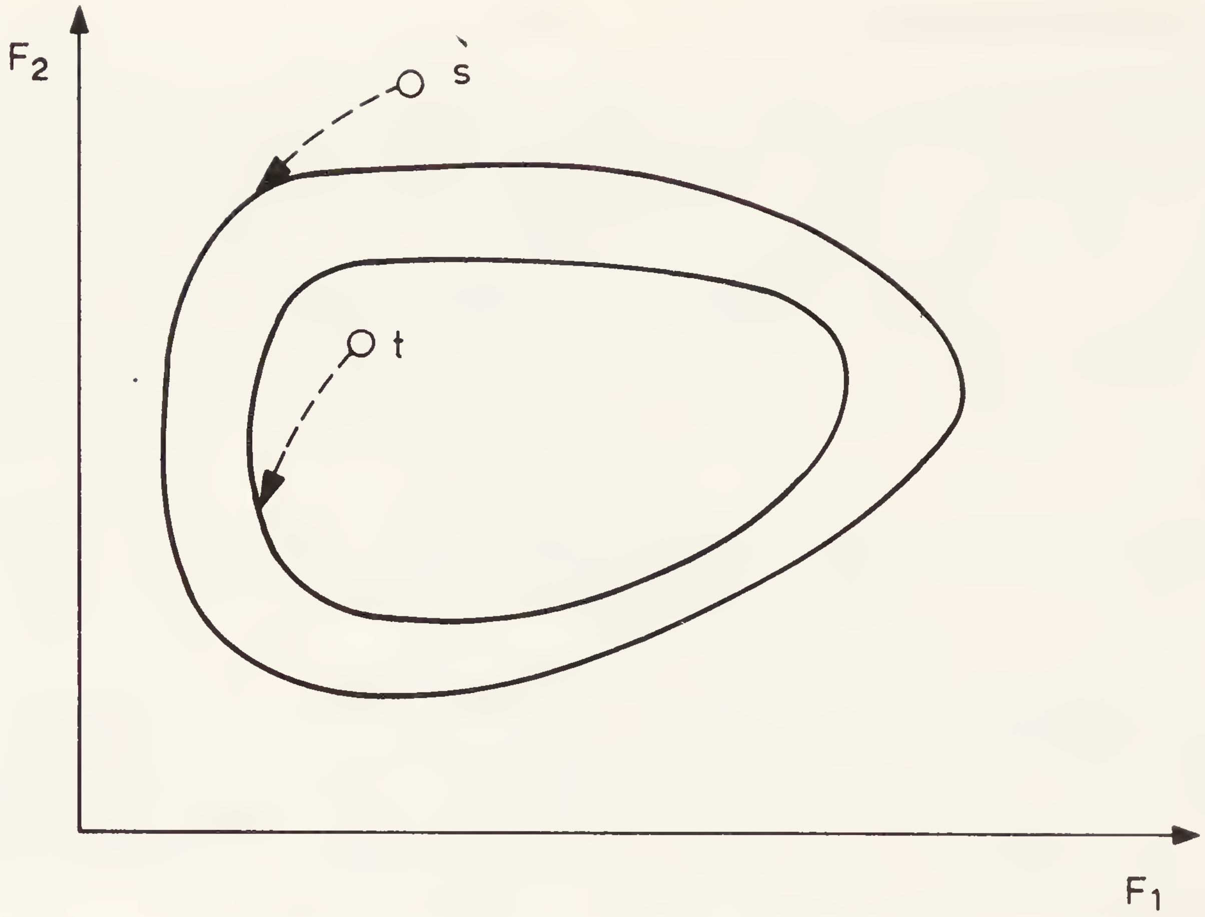


Fig. 5.12. Ecological equilibria are dynamical. If an external perturbation, such as farming or a draught, sends the representative point to s, or to t, the point eventually moves to an equilibrium orbit. (See e.g. Pielou (1969).)

dynamical equilibrium of an ecosystem consisting of two competing populations. Each curve represents a cyclic process – an oscillation in the population numbers. Each point lying on one of the closed curves represents a stable state of the system. If the populations are displaced – e.g. by some external disturbance – to values not too far from equilibrium, they tend spontaneously to return to an equilibrium point.

So much for special types of process. Let us hasten to warn that, in our view, no real process is of a pure type. This is because any (realistic) state function has a number of components of different kinds – some discrete, others continuous, some random, others nonrandom, and so on. In other words, call

$$\pi_k(x) = \langle F_k(t) | t \in T\rangle, \quad \text{with} \quad 1 < k \leq n,$$

the kth *component* of the serial process represented by $\pi(x) = \langle \mathbb{F}(t) | t \in T\rangle$. Then $\pi(x)$ will have at least one continuous component, at least one random component, and so on. In short, pure process types are ideal types: real processes are impure. We defer an exact formulation to the next subsection.

We first turn to some generalities that can be formulated in fairly exact terms.

3.2. *General Concepts and Principles*

In the previous subsection we discussed a few typical kinds of process. In the present one we shall treat processes in general, using some insights gained in the study of special process types. From that study it is apparent that a process may be regarded either as a *sequence of states* or as a *sequence of events*. In the former case we can describe a process in a thing x with the sole help of a state function $\mathbb{F}$ for it: our task boils down to following the wanderings of the tip of $\mathbb{F}$ – a task greatly facilitated by parametrizing the states $\mathbb{F}(t)$ relative to the states of a suitable frame. If on the other hand we construe a process as a sequence of events, then we must be given not only $\mathbb{F}$ but also the entire state space $S_{\mathbb{L}}(x)$ spanned by $\mathbb{F}$ as well as the totality $G_{\mathbb{L}}(x)$ of lawful transformations of the state space into itself. This alone allows us to form the individual events $\langle s, s', g\rangle$ and thereupon the whole event space $E_{\mathbb{L}}(x)$.

Each of these alternative construals has its advantages and disadvantages. The successive states approach is mathematically simpler, if only because the state space is n-dimensional whereas the corresponding event space is $2n$-dimensional. On the other hand the successive events approach, though mathematically clumsier, is philosophically more perspicuous. We can use either approach interchangeably and shall do so. In the present subsection we shall discuss some general principles in terms of events, but shall end up by introducing a notion of history based on the successive states approach.

First the general notions of process:

DEFINITION 5.24 Let $E_g(x)$ be the space of events of type g in thing x, for g in the set $G_{\mathbb{L}}(x)$ of lawful transformations of the state space chosen for x, and let $E(x)$ be the union of all $E_g(x)$'s, i.e. the total event space of x [Definition 5.9]. Further, let $<$ be the precedence relation [Definition 5.10]. Then

(i) a *process of type* g in thing x is a strictly partially ordered set of events of kind g:

$$\pi_g(x) = \langle E_g^*(x), <\rangle \quad \text{with} \quad E_g^*(x) \subseteq E_g(x) \subseteq E_{\mathbb{L}}(x);$$

(ii) a *process* in x is a strictly partially ordered set

$$\pi(x) = \langle E^*(x), <\rangle \quad \text{with} \quad E^*(x) = \bigcup_{g \in G_{\mathbb{L}}(x)} E_g^*(x).$$

Since as a matter of fact every aspect g is related to some other aspect, we may safely surmise that there are no processes of a single type but only idealizations that single out now one feature of the thing of interest, now another. (Recall the end of the last subsection.) That is, we assume

POSTULATE 5.6 Every real process has more than one aspect.

And from the assumed lawfulness of the transformations in $G_{\mathbb{L}}(x)$ it follows that every process involving a given thing satisfies all of the laws possessed by the latter:

COROLLARY 5.9 Every process is lawful.

Note that lawfulness is predicated of processes, i.e. intrinsically ordered sets of events, not of arbitrary sets of events. The latter, particularly if they occur in unrelated things, or in things with weakly coupled components, are not necessarily lawful even though every component is assumed to have a lawful behavior line. This is the ontological ground of the methodological rule employed tacitly by historians intent on discovering general historical trends or even laws – namely to focus on processes of a definite kind occurring in social systems instead of just looking for time series, which are bound to be erratic or lawless (see Braudel, 1969).

Remember however that chaos is not the same as randomness: whereas the former is lawless the latter possesses stochastic (probabilistic) laws such as those of quantum mechanics and genetics. Therefore we adopt an axiom employing Definition 5.22 of a process random in some respect:

POSTULATE 5.7 Every process is random in at least one respect.

Next we distinguish two important members of a process:

DEFINITION 5.25 Let $\pi(x) = \langle E^*(x), <\rangle$ be a process in a thing x. Then

(i) $\pi(x)$ *begins* at an event $b \in E^*(x)$ iff b is a lower bound of the set $E^*(x)$ [i.e. if every other member of $E^*(x)$ follows b];

(ii) $\pi(x)$ *ends* in an event $e \in E^*(x)$ iff e is an upper bound of the set $E^*(x)$ [i.e. if all the other members of $E^*(x)$ precede e].

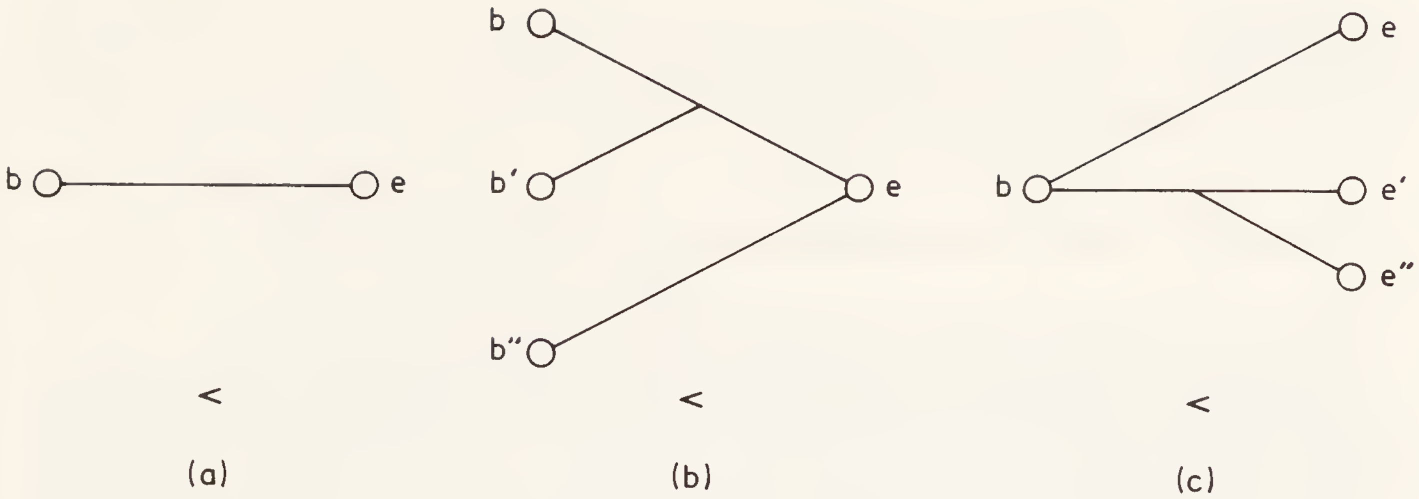

Fig. 5.13. Three kinds of process as to beginning and end. (*a*) Chain or linear process. (*b*) Converging or branching-in process. (*c*) Diverging or branching-out process.

A process may have no single beginner or single stop: see Figure 5.13. In other words, there may be multiple beginnings or multiple ends. We assume that every single process is bounded both below and above:

POSTULATE 5.8 Every process has beginning(s) and end(s). [I.e., if $\pi(x)$ is a process going on in a thing x, then $\pi(x)$ has at least one beginner and at least one end point.]

This hypothesis does not entail that there are absolute beginnings (i.e. processes starting out of the blue) and dead ends (i.e. processes that, on ending, do not start any other processes). Indeed the postulate is compatible either with a creationist and eschatologist cosmology or with the assumption that every process in a given thing, though bounded both below and above, is preceded and followed by some other processes either in the same thing or in other things. We adopt the latter hypothesis because it is the one supported by science. But first we need

DEFINITION 5.26 Let $\pi(x) = \langle E^*(x), \prec \rangle$ and $\pi'(x) = \langle E'^*(x), \prec \rangle$ be two processes in a thing x, such that $E^*(x) \cap E'^*(x) = \varnothing$. Then $\pi(x)$ *precedes* $\pi'(x)$ iff every event in the former precedes every event in the latter. Symbol: $\pi(x) \prec \pi'(x)$.

We are now ready for

POSTULATE 5.9 Every process is preceded and followed by other processes. More precisely, every thing x has parts y and z, not necessarily different from x, each of them equipped with its own event space, such that

$$\pi(y) < \pi'(x) < \pi''(z).$$

Since the world is the aggregation of all things, it follows

COROLLARY 5.10 The world has neither beginning nor end.

Remark 1 Like many another axiom of our ontology, the previous one is a sort of generalization of all we know. An ancient paradigm is of course the birth-growth-final disintegration process every metazoan undergoes. A simpler and more modern paradigm is that of the photon emitted by a star, travelling through interstellar space, and ending up trapped by a molecule or turning into a pair of electrons of opposite charges. *Remark 2* At one point some cosmologists wishing to save the steady state cosmology introduced the *ad hoc* hypothesis of the spontaneous creation of hydrogen atoms in empty space. This conjecture was not accepted because it clashes with the conservation laws (Bunge, 1962) – and anyway the steady state theory, which it tried to save, was eventually refuted by astronomical evidence. *Remark 3* Corollary 5.10 was first formulated by the Presocratic philosophers and was adopted by Aristotle. It would seem to contradict the "big bang" hypothesis of the "origin" of the universe, nowadays almost universally favored. However, this cosmological conjecture – which explains the expansion of the universe – does not illustrate creation *ex nihilo*, for it presupposes that the universe had been in existence – in a highly condensed state – before the expansion started. Nor does the old "thermal death" hypothesis (nowadays almost forgotten) illustrate absolute annihilation: all it asserts is the end of macrophysical motion once a closed system has attained thermal equilibrium.

So much for our general concepts and principles concerning process. Let us now adopt the successive states approach and introduce one more key notion that will prove indispensable in the sequel, namely that of history.

Recall that the states of a thing x can be coordinatized relative to the states $t \in S(f)$ of a reference frame f, by defining the state function as a mapping of $S(f)$ into $S(x)$, and by construing $S(f)$ as a four-dimensional grid conceptualizing a physical reference frame (Sec. 2.5). As the reference state t "moves" so does the tip $\mathbb{F}(t)$ of the thing state function. This invites

DEFINITION 5.27 Let $\mathbb{F}$ be a state function for a thing x relative to a reference frame f with states t in $S(f)$, and let the latter be coordinatized by a certain function $k: \mathbb{R}^4 \to S(f)$. Then the *history of x relative to f* is the set of ordered pairs

$$h(x) = \{\langle t, \mathbb{F}(t)\rangle \mid t \in S(f)\}.$$

This is an elucidation of the concept of a life line, behavior line, or trajectory. The history of a thing is regarded as the succession of its states but, instead of being represented by a line in the n-dimensional state space spanned by $\mathbb{F}$, it is represented as a curve in the $(n+4)$-dimensional space $\mathbb{R}^4 \times S_{\mathbb{L}}(x)$. (The dimensionality of this space can be reduced by 3 if we are interested only in the time coordinate, i.e. if t is construed as an instant of time rather than as a point in the spacetime region attached to the given frame.)

The above definition covers the most usual notions of history employed in the sciences. In particular it fits in with the notion of history occurring in one of the most fundamental theories in physics, namely quantum mechanics. Indeed in this theory the evolution operator for a thing is defined as

$$S(t_0, t) = \exp\left(-\frac{i}{\hbar}\int_{t_0}^{t} du\, H\right),$$

where H is the hamiltonian of the thing. The history of the latter is then

$$h(x) = \{\langle t, S(t_0, t)\psi(t_0)\rangle \mid u \in [t_0, t] \ \&\ \psi \in \text{Hilbert space of } x\}.$$

The broad concept of history adopted above may puzzle and even infuriate those scholars in the humanities who still regard man as supernatural. Until about the mid 19th century it had been tacitly assumed that all history is human history. Thus Hegel, for all his dynamicism, denied that nature has a history. That view changed with the revolutionary discoveries in geology and biology, to the point that Engels declared each science to be the history of something (Engels, 1878). Since then it is usually taken for granted that ***every thing has a history*** – i.e. that, for every thing x, $h(x)$ is bigger than a singleton.

Let us now apply the concept of history to a characterization of the notions of action and interaction.

4. ACTION AND REACTION

4.1. *Induced Change*

So far we have been concerned with change without regard for its sources. Now, a thing may change either by itself or under the influence of some other thing, i.e. spontaneously or by induction. We must therefore study the concepts of spontaneity and induction. To do this we shall avail ourselves of the concept of history (Definition 5.27 in Sec. 3.2) and of Leibniz' law (Ch. 2, Sec. 3.2).

Two different things of the same kind may be described with the help of the same functional schema $\langle M, \mathbb{F}\rangle$, hence of the same state space, though of course adding individuating circumstances in each case. In other words, the states of different kindred things may be represented in one and the same state space. Also: every state space, far from being owned by a single thing, may be assigned a reference class constituted by a more or less numerous equivalence class of things. Now, Leibniz' law (Postulate 2.5 or Corollary 2.1) states that different things have different properties. Hence even if a given state function describes adequately two things, they cannot occupy exactly the same states – for, if they did, they would be one. Consequently we have the following rephrasing of Leibniz' law:

COROLLARY 5.11 Different things have different histories.

Surely a thing can occupy now exactly the same state another thing was in a moment ago, but no two things can occupy exactly the same state at the same time – or, more generally, for the same value of the change parameter. (See Figure 5.14.)

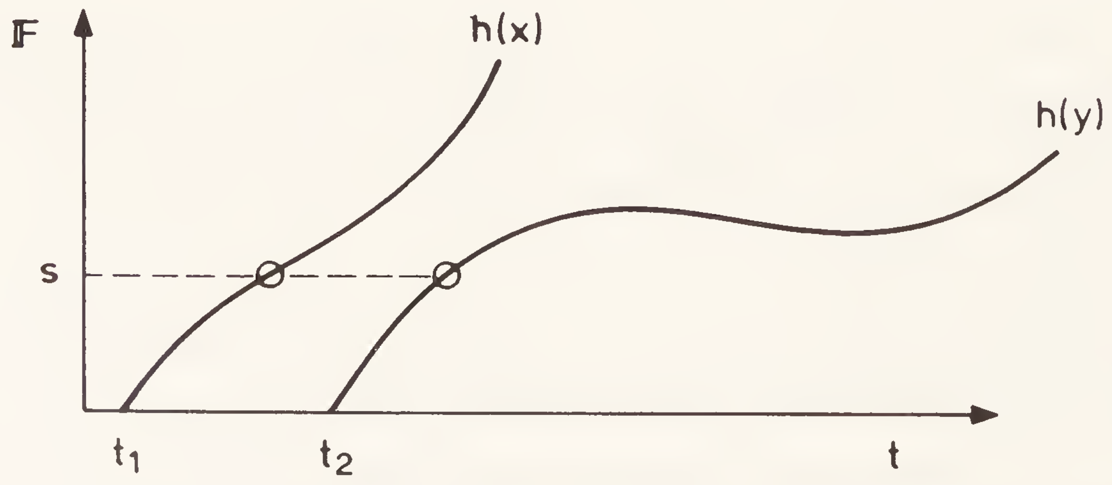

Fig. 5.14. Different things can occupy the same state provided they do it at different times.

Corollary 5.11 is our present version of Leibniz' *principium individuationis* and it supplies the clue to what we are after. Indeed, if a thing is under the action of another thing, then its history must differ from the history when free from such action. (See Figure 5.15.) (This is what scientific experiment, as different from observation, is all about, namely the deliberate switching on and off of actions or influences to compare the forced behavior of a thing to its free behavior and thus to assess the importance of the variable that is being manipulated.)

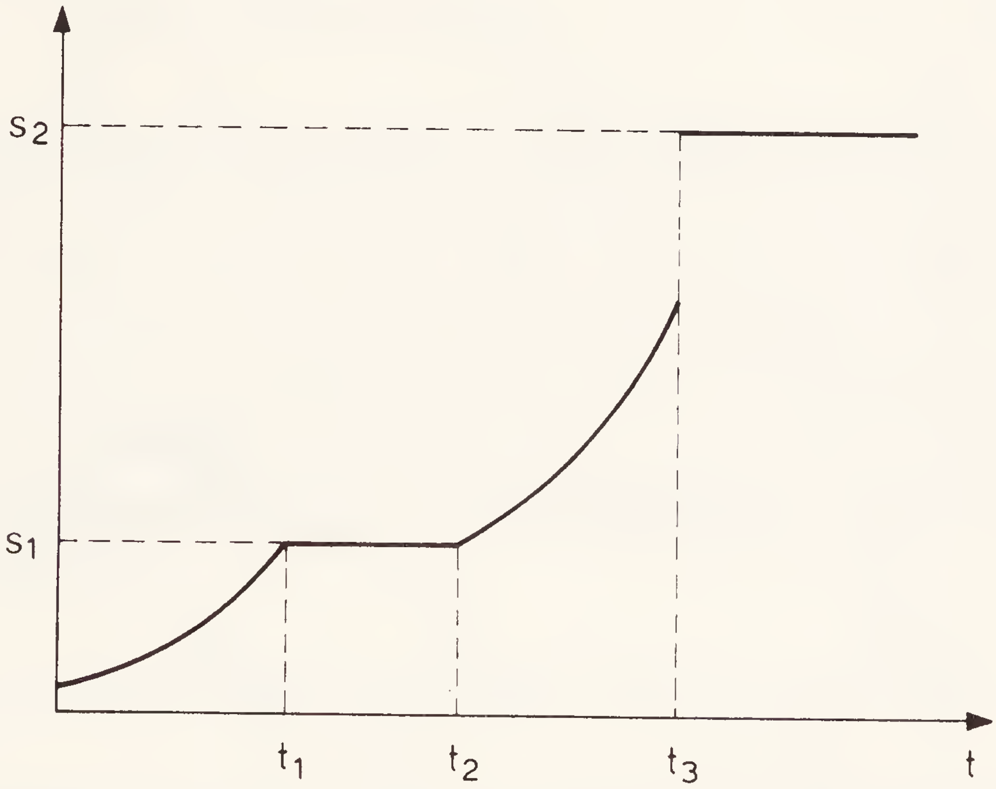

Fig. 5.15. Imaginary example of an action. The agent, by acting during the $[t_1, t_2]$ interval, forces the patient to remain in state s_1. The external action resumes at time t_3, forcing the patient to jump to state s_2.

In the absence of any actions of the agent x upon the patient y, the history of their physical sum or juxtaposition $x \dotplus y$ equals the union of their individual behavior lines. In other words, we have

DEFINITION 5.28 Thing x changes by itself, or *spontaneously*, iff $h(x)$ is not a singleton and, for any other thing y,

$$h(x \dotplus y) = h(x) \cup h(y).$$

Clearly, if one of the things acts upon the other, then while the behavior line of the agent remains unaffected, that of the patient becomes, as it were, the history of a different thing, namely the thing-acted-on-by-the-agent. (See Figure 5.16.) More exactly, we make

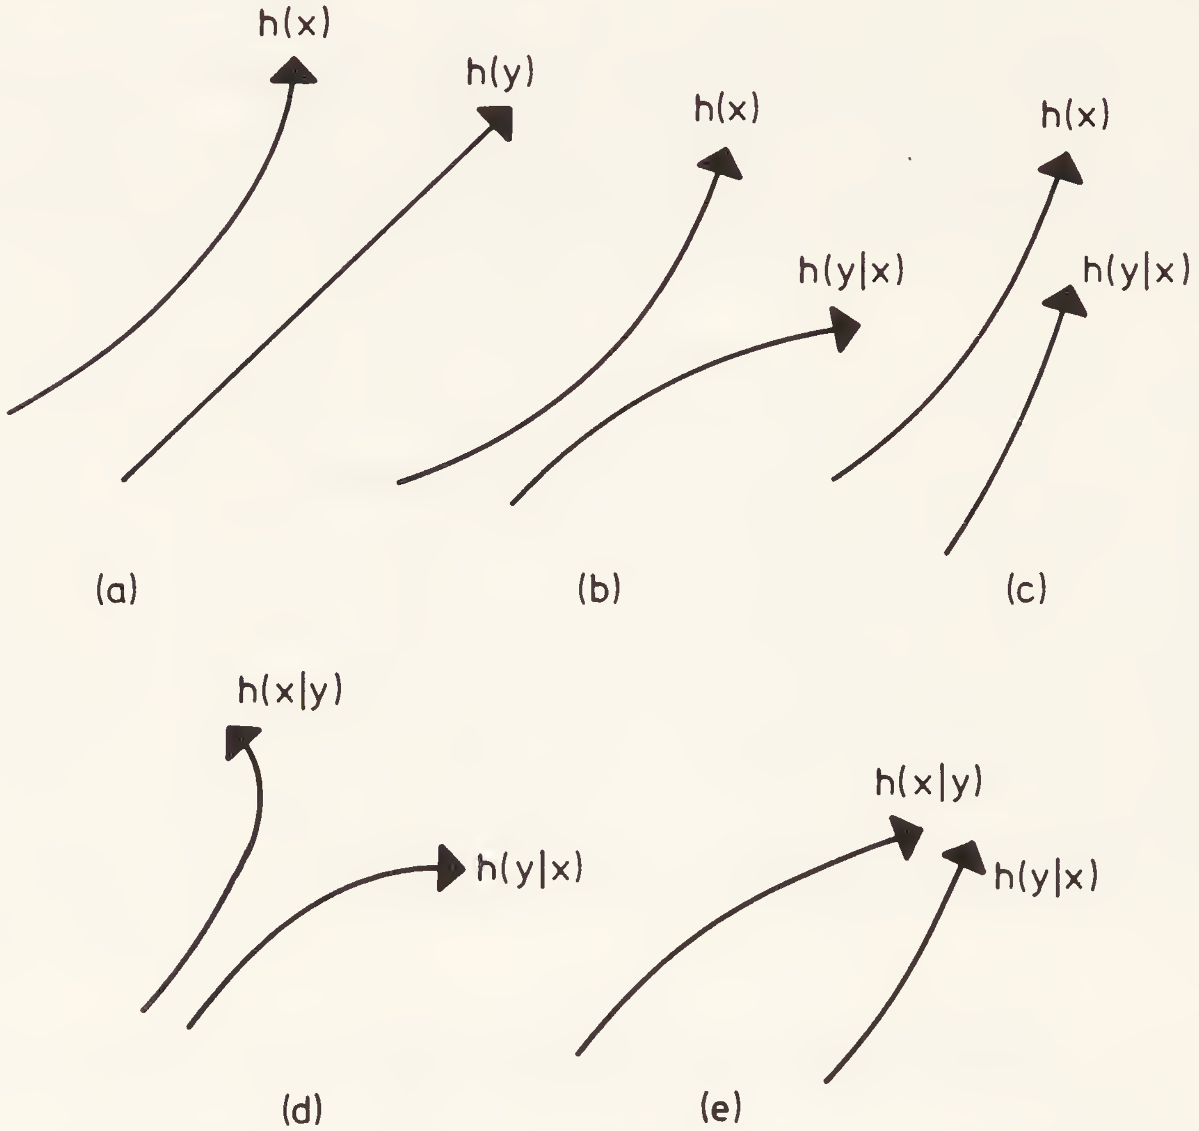

Fig. 5.16. Induced change. (*a*) No action: spontaneous change of both x and y. (*b*) Pushing action of x on y. (*c*) Pulling action of x on y. (*d*) Pushing interaction. (*e*) Pulling interaction.

DEFINITION 5.29 Let x and y be two different things with state functions $\mathbb{F}$ and $\mathbb{G}$ respectively relative to a common reference frame f, and let

$$h(x)=\{\langle t, \mathbb{F}(t)\rangle | t \in S(f)\}, \qquad h(y)=\{\langle t, \mathbb{G}(t)\rangle | t \in S(f)\}$$

be their respective histories. Further, let $\mathbb{H}=g(\mathbb{F}, \mathbb{G}) \neq \mathbb{G}$ be a third state function, depending on both $\mathbb{F}$ and $\mathbb{G}$, and call

$$h(y|x)=\{\langle t, \mathbb{H}(t)\rangle | t \in S(f)\}$$

the corresponding history. Then x *acts on* y, or $x \rhd y$ for short, iff, for some state function $\mathbb{H}$ determining the trajectory $h(y|x)$, $h(y|x) \neq h(y)$.

We may now rephrase Definition 5.28 of spontaneity: A thing *changes spontaneously* iff it changes and if there is no other thing that acts upon it. And, from the hypothesis of Definition 5.29 (in particular, that $x \neq y$), it follows that *nothing acts upon itself.*

The definition of reciprocal or mutual action is now obvious:

DEFINITION 5.30 Two different things x and y *interact* iff each acts upon the other. In symbols:

$$x \rhd\!\!\lhd y =_{df} x \rhd y \;\&\; y \rhd x.$$

Experimental scientists assume tacitly (a) that all things are studiable, (b) that there are no totally isolated things – i.e. that every thing acts on, or is acted upon by, some other thing, and (c) such actions are the basis of empirical knowledge. Indeed if a presumed thing does not act on any of our observation means then we cannot observe it; and if some putative thing is not acted upon by any of our experimental means then we cannot experiment on it. In either case we won't bother with "it". In short, the following axiom belongs to the ontology inherent in science, so we adopt it:

POSTULATE 5.10 Every thing acts on, and is acted upon by, other things.

This assumption should not be mistaken for the far stronger, and false, hypothesis that any two things interact – let alone with the same intensity. We do not react back to the light activity of the sun, even less to that of an extinct star. In other words, the universal interaction principle, first suggested by the Stoics and much favored during the acme of Newton's gravitation theory, is false.

The effects of an interaction may be lasting, even in the case of microthings. Thus if two microthings interact for a while and then cease to do so – e.g. by becoming widely separated in space – they will continue to be correlated. Hence observing one of them may yield information about the other – just as observing the behavior of a divorced person may shed light on his/her former mate. In the jargon of quantum mechanics, such things are said to be *non-separable*, or to exhibit an EPR correlation. (This is what the Einstein–Podolsky–Rosen paradox seems to be all about. More in Sec. 4.2.)

We need a qualitative concept of the size of an action or an interaction. This is given by the amount of the distortion effected by the agent(s) on the behavior line of the patient. In other words, we make

DEFINITION 5.31 Let x and y be two things, and let $h(x)$ be the history of x, and $h(x|y)$ the history of x when acted upon by y, and similarly for x. Then

(i) the *total action* or *effect* of x on y equals the difference between the forced trajectory and the free trajectory of y:

$$A(x, y) = h(y|x) \cap \overline{h(y)};$$

(ii) the *total reaction* of y upon x is the difference between the free trajectory and the forced trajectory of x:

$$A(y, x) = h(x|y) \cap \overline{h(x)};$$

(iii) the *total interaction* between x and y is the union of action and reaction:

$$I(x, y) = A(x, y) \cup A(y, x).$$

If $A(x, y) = \varnothing$ we can say that x exerts the *null action* on y.

Since the action of x on y is a set of events in y, this set cannot be the same as the reaction of y on x, which is a set of events in x. Therefore we have

COROLLARY 5.12 No action equals the corresponding reaction. I.e., for any things x and y, $A(x, y) \neq A(y, x)$.

This result is not inconsistent with the third law of Newtonian particle mechanics. Indeed this law does not state that actions and reactions are the same but that their strengths (the corresponding forces, or else torques) are equal. Anyway the law does not hold in other theories, such as electrodynamics.

Now, actions may exist in certain respects but not in others. That is, the action of thing x upon thing y may affect only some of the components of the state function of y. Hence we may analyze the total action into partial actions, namely thus:

$$A(x, y) = \bigcup_{i=1}^{m} A_i(x, y),$$

where m is the number of mutually independent actions that x exerts on y. Similarly for the reaction of y on x and for their interaction.

This distinction allows us to supplement Postulate 5.8 with

POSTULATE 5.11 Every thing changes spontaneously in some respects, inductively in others.

Finally, the concept of action permits us to elucidate the important distinction made in Ch. 2, Sec. 5.1, between a relation that affects its relata and one that does not. (See Figure 5.17.) The difference is rendered precise by

DEFINITION 5.32 Two different things are *bonded* (or *linked* or *coupled*) together iff at least one of them acts upon the other. In symbols: If x and y are things, then

$$Bxy =_{df} x \rhd y \quad \text{or} \quad y \rhd x.$$

Note that we are not including the condition that the bond be attractive. Two enemies are just as bonded as two friends.

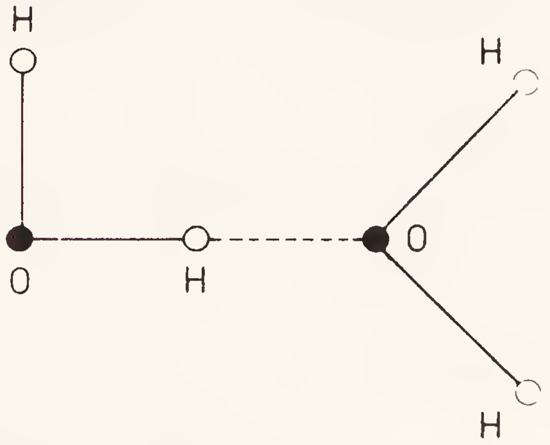

Fig. 5.17. Three different relations between two water molecules. (a) The valence bonds between the atomic components of each molecule (full lines); (b) the hydrogen bond between both molecules (dotted line); (c) the relation of being to the left (or its converse). Both (a) and (b) are bonds, links, or couplings, whereas (c) is a nonbonding relation.

The collection of bonds among members of an arbitrary set T of things deserves a special name:

DEFINITION 5.33 The *bondage* of a set T of things is the set $\mathbb{B}_T$ of all bonds among members of T.

In principle $\mathbb{B}_T$ includes couplings of all n-arities – dyadic, triadic, and so on. In practice the dyadic or binary bonds are by far the most important. If only binary bonds are taken into account, the above definition reduces to

$$\mathbb{B}_T = \{B_i \in \text{Binary relations on } T \mid (\exists x)(\exists y) \\ (x, y \in T \;\&\; B_i xy \;\&\; 1 \leqslant i \leqslant m\},$$

where $m \geqslant 1$ is the number of kinds of binary bond [or of action] holding among members of T.

It will be recalled that we assumed that there are finitely many general substantial properties (Postulate 2.3). Therefore we have

COROLLARY 5.13 The bondage of any set of things is finite.

The class of all nonbonding (or "mere") relations among T's will be designated by $\bar{\mathbb{B}}_T$. And the union of $\mathbb{B}_T$ and $\bar{\mathbb{B}}_T$ equals of course the set of all relations on T. This concept will become crucial in our treatment of the concept of a concrete system in Vol. 4, Ch. 7, so it invites

DEFINITION 5.34 Let T be a set of things and $[T]$ its aggregation [physical sum]. Then the *structure* of $[T]$ equals the totality of relations, both bonding and nonbonding, on T:

$$\mathcal{S}([T]) = \mathbb{B}_T \cup \bar{\mathbb{B}}_T.$$

We shall use the concept of a bond to characterize systems and reference frames.

4.2. *Aggregates and Systems*

We shall now employ the concepts of bond and history to clarify the distinction between a heap or aggregate, on the one hand, and a whole or system, on the other. Obvious examples of systems are atoms and molecules. On the other hand the nucleons and electrons composing an atom are not systems since they have no separable components. Another example of a nonsystem is the aggregate formed by a thing and a reference frame. Since reference frames are supposed to record without either influencing or being influenced, the history of a thing-frame compound must reflect that independence. How this is done will be seen in Sec. 4.3 once we have properly introduced the notion of a system.

An analysis of the histories of the members of a set of things should help us discover whether or not the aggregation of the set constitutes a system, i.e. whether or not its components are bonded. Indeed, the history of an aggregate of noninteracting things is uniquely determined by the histories of such components: it is just their union. Not so in the case of a system: here the history of every component is determined at least partly by the states other components are in, so that the history of the whole does not equal the sum of the individual histories. An example or two will help bring this point home.

Think of the histories of a moth and a candle before and after the former spirals into the latter. If a more distinguished example is needed, think of a system composed of two electrons close enough to interact appreciably, as is the case with those of a helium atom. This system is described by a Schrödinger equation (classically by two coupled equations of motion) jointly with the Pauli exclusion principle. The latter selects those state functions that are odd (antisymmetric) in the coordinates of the electrons. (That is, the additional law is: $\psi(x, y) = -\psi(y, x)$, where x and y are the position coordinates of the electrons. It follows that $\psi(x, x) = 0$, i.e. the two entities cannot coexist at the same point – unless they have different spins.) The Pauli principle expresses a global or systemic property, one that the individual components fail to possess, whence it cannot be represented in the partial state spaces. Therefore the construction of the state space of the system must proceed from scratch rather than on the sole basis of the state spaces of the individual electrons. (Fortunately the Pauli principle does not hold for the entire universe but only for certain parts of it, namely the subsystems formed by half integral spin components. Otherwise there would exist no fairly isolated systems in reality. (Cf. Margenau (1966).) What holds for state spaces holds a fortiori for histories.

We summarize and generalize the preceding remarks into

DEFINITION 5.35 Let X be a thing composed of parts X_i for $1 \leqslant i \leqslant n$. Then X is an *aggregate* (or *conglomerate* or *heap*) iff, in every representation of X (i.e. for every choice of state function), its history $h(X)$ equals the union of the partial histories $h(X_i)$. Otherwise X is a *system*.

The cautious phrase 'in every representation', occurring in the preceding convention, is due to this. It is often possible to choose a representation of a thing wherein the mutual actions of its components are "absorbed" in the latter. In other words one can often model the real system as a conceptual aggregate of noninteracting components. But this trick does not work for every representation.

Recalling the Definitions 5.31 of action and 5.33 of bondage, we obtain

COROLLARY 5.14 Let X be a thing with composition $\mathscr{C}(X)$. Then X is a *system* iff the bondage of $\mathscr{C}(X)$ is not empty, i.e. $\mathbb{B}_{\mathscr{C}(X)} \neq \varnothing$.

Now, the universe or world is that thing which is composed of all things (Postulate 3.3); and by Postulate 5.10 every thing – hence every component of the world – is bonded to some other thing. Hence

COROLLARY 5.15 The world or universe is a system.

By Definition 5.35 it follows in turn that the history of the world is not equal to the union of the histories of its parts.

What happens if a system breaks down, e.g. if its components fly apart and cease to interact? It would seem that, when this happens, the history of the aggregate does equal the union of the histories of the former components, which are now free from one another. This is not necessarily so. In fact the famous Einstein–Podolsky–Rosen paradox of quantum mechanics may be interpreted as follows. If two quantal things interact at any given time then, even after they have ceased interacting, they are still correlated in the sense that the history of each is affected by what happens to the other. (Equivalently: the state vector of the whole does not equal the direct product of the state vectors of the parts.) Thus interaction at some time is sufficient to induce a correlation that is reflected in the nondecomposability of the total state space, and a fortiori in the nonseparability of the partial histories. If this interpretation is correct, then the above definitions may be kept but a new assumption must be added: *Once a* (*micro*)*system always a* (*micro*)*system*. However, this is still debatable, so we shall not incorporate it into our system.

4.3. *Reference Frame*

Another important application of the notion of an aggregate is to the characterization of a reference frame. This concept is of paramount importance not only in physics but also in our ontology, for in real cases states are frame dependent. (The paradigm is of course the state of motion of a body: its track in state space is frame dependent. So much so that it won't move at all relative to a frame rigidly attached to itself.)

One condition for a thing to qualify as a reference frame for another is that the two not influence each other, so that their respective states be neatly separated. (To indulge in anthropomorphism: a reference frame must be an impartial spectator. But this is just a didactic prop: we must not mistake frames for observers.) Another condition is that the states of the reference frame for a given thing be utilizable for parametrizing the states of the thing of interest, in the sense that, for every state t of the reference frame, the thing is in a given state $s = \mathbb{F}(t)$, where $\mathbb{F}$ is the n-component state function for the thing. (See Figure 5.18) These two conditions – independence and parametrizability – will be taken to be jointly necessary and sufficient to characterize the general concept of a reference frame. (Each scientific theory may define its own specific concept of a reference frame by adding its own additional conditions – usually that certain laws be satisfied relative to the frame. See Bunge (1967b)). In sum, we make

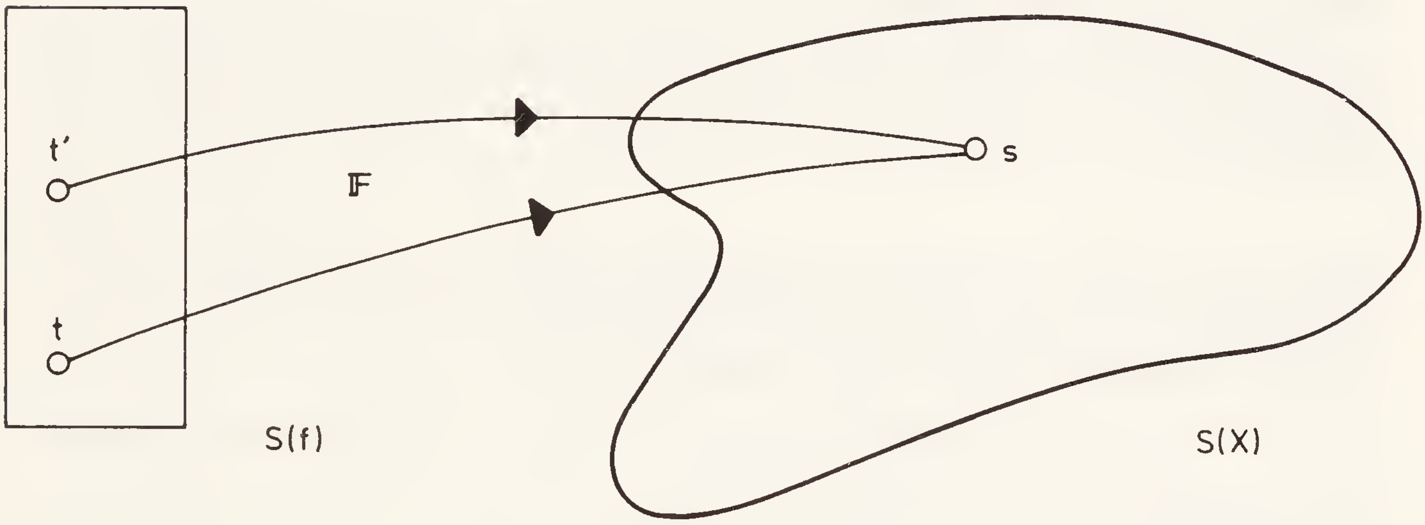

Fig. 5.18. The mapping $\mathbb{F}: S(f) \to S(X)$ of reference states onto thing states. $\mathbb{F}$ need not be 1–1: two different reference states may correspond to a single thing state, as in periodic motion. But $\mathbb{F}$ must be onto: each thing state must be paired off to at least one reference state.

DEFINITION 5.36 Let X be a thing represented by the functional schema $X_m = \langle M, \mathbb{F} \rangle$ and let f be another thing with states in $S(f)$. Then f is a *reference frame* for X iff

(i) $f \dotplus X$ is an aggregate, so that $h(f \dotplus X) = h(f) \cup h(X)$, and

(ii) the domain of the state function of X equals the state space of f, i.e. $\mathbb{F}: S(f) \to S(X)$, whence $M = S(f)$.

Remark 1 We have defined a reference frame as a concrete thing of a certain kind. Because every reference frame can be *represented* by a coordinate patch in a manifold, the misconception has spread that reference frames are identical with their conceptual representatives. That this is mistaken is realized upon recalling that frames are assigned substantial properties, such as velocities, which would be impossible if they were concepts. *Remark 2* A reference frame need not be a perfectly rigid body. This is so firstly because there is no such thing as a rigid body in the real world, secondly because a frame must have moveable parts if it is to function as a (natural or artificial) clock. A frame can be a field (Dehnen, 1970).

The concept of a reference frame allows us to elucidate the notion of a thing's being in a given state relative to some frame. In fact we can introduce

DEFINITION 5.37 Let f be a reference frame for a thing X represented by the functional schema $X_m = \langle S(f), \mathbb{F}\rangle$. Then

(i) the *state of X at $t \in S(f)$ relative to f* is

$$s = \mathbb{F}(t) = \langle F_i(t) | 1 \leqslant i \leqslant n\rangle;$$

(ii) the *state space of X relative to f* is

$$S(X) = \{s = \mathbb{F}(t) | t \in S(f)\} = \mathbb{F}(S(f)).$$

Because there is an unlimited number of reference frames, and the choice of functional schema to represent a thing is partly conventional, states can be parametrized in a number of ways. Some such representations are equivalent – as when the frames are inertial in a certain sense – while others are not. This does not entail that actually states are absolute (frame independent) and that we should blame our own cognitive limitations for the relativity of states. Except in the highly artificial case when all the components of a state function are assumed to be invariant under all possible frame substitutions, *the states themselves are relative.* This is enough to regard with suspicion all the philosophical theories that employ absolute state descriptions such as "Thing X is in state s" or, worse, "The state of the world at a given instant is such and such". (Possible worlds metaphysics and inductive logic abound with such curiosities.) But relativity must not be mistaken for subjectivity: that every state of a thing is relative to a frame does not entail that it is the private state of a subject – unless of course one manages to confuse thing states with reference states or states of a standard of reference, and frames with subjects or observers. (For criticisms of such confusions see Bunge, 1967b, 1973b.)

So much for technicalities. Let us now turn to a few rather nontechnical yet important matters of principle.

5. PANTA RHEI

5.1. *Fact*

Having now at hand exact definitions of a state (Ch. 3, Sec. 2) and of a change of state, or event (Sec. 2), we can make full sense of Definition 4.3 of a fact. We can now say that *a (real) fact is either the being of a thing in a given state, or an event occurring in a thing.* The following comments spring to mind.

Firstly, the above definition of a fact applies also the case of the conversion of one thing (e.g. a caterpillar) into another (e.g. a butterfly), provided we construe both things as a single thing in two successive stages of development. In fact, as suggested in Sec. 1.2, all we have to do is to feign that we are dealing with one and the same thing whose representative point moves now in one state space (e.g. the caterpillar state space), now in another (e.g. the butterfly state space), the two state spaces being correctly assembled.

Secondly, constructs – such as concepts and propositions – do not qualify as facts since they are neither states of things nor changes in things. Hence it is mistaken to call a true factual proposition *a fact.* At most, a proposition might be regarded as a certain equivalence class of mental states – but a class is a concept not a thing. Hence it is mistaken to identify the two.

Thirdly, our construal of facts is objective. We do not define a fact as "anything that may be observed" because (*a*) microphysics, megaphysics and the physiology of perception teach us that most facts remain beyond human observation (though not therefore beyond comprehension), and (*b*) not all observations are reliable: some correspond to no external facts, whence reports on them, unless critical, are false.

Fourthly, the same applies, *mutatis mutandis,* to the semantic definition of a fact as "the kind of thing that makes a proposition true or false" (Russell, 1918, in Marsh, Ed., 1956, p. 183). And this for the following reasons: (*a*) unless one wishes to construct a subjectivist ontology (as was the case with Russell (1914), Whitehead (1919), Carnap (1928), and Goodman (1951), one will refrain from defining ontological concepts in semantical, epistemological, or psychological terms; (*b*) most factual propositions are at best partially true rather than wholly true; (*c*) the semantic definition of a fact commits one to asserting that there are negative facts (those verifying negative statements) and general facts (those confirming general statements). The weird metaphysics of negative and general facts is avoided if, contrary to the early Wittgenstein and the Russell of logical atomism, one drops the assumption that propositions and facts stand in a 1–1 correspondence. The correspondence cannot be such because all facts are "positive" and singular. (Recall that a fact is either the being of a thing in a state, or the occurrence of a change of state of a thing.) The nonoccupancy of a state and the nonoccurrence of an event are not facts. Thus not having been inoculated against smallpox is not an event, hence it does not count as a cause of smallpox. And since we do not countenance negative events, we avoid talking of "logical events" such as "*e* or not-*e*", and so we do not have to worry about their causes. We take this to be a distinctive advantage over the probabilistic theory of causality (Suppes, 1970), where any element of a probability space qualifies as an event and where the causal relation is assumed to hold among possible events, even negative ones, rather than among actual events. In short it is false that whatever makes a proposition true or false counts as a fact.

Fifthly and lastly, facts, whether possible or actual, are objective but – pace Wittgenstein (1922) – they do not constitute the world. The world is not the totality of facts but the totality of things, i.e. concrete individuals endowed with all their properties, some of which consist in their being able to change in definite (though possibly randomly) lawful ways. This is how both physical cosmology and our ontology construe the term 'world'. Wittgenstein's construal requires either dispensing with things altogether – an awkward situation for science – or attempting to define them in terms of facts – which attempt has not even been broached. More on this in Sec. 6.

5.2. *Dynamicism*

Ours is a world of things – but of changing things not quiescent ones. Indeed, according to Postulate 5.11 in Sec. 4.1, every thing has a nontrivial history. In other words *every thing changes*. This is our version of the Heraclitean *panta rhei.* Note that we are not yet taking a stand concerning the stronger ontological hypothesis that every thing changes *incessantly*: we do not have yet a suitable concept of time. For Postulate 5.11 to hold it is necessary and sufficient that every thing changes at least once – i.e. that the history of every thing consists of at least two states or, equivalently, of one event.

We take change – not its concept – for granted rather than either deny or justify it. What has got to be justified in each case is not change but any assumption, or pretence, to the effect that a certain thing fails to change in some respect. We do this kind of thing all the time, by saying that certain changes, though real, are small, or that they consist in nothing but relative motion, etc. Moreover we explain permanence (in certain respects) in terms of insulation, or isolation, or a balance of forces, or what not. Statics is a particular case of dynamics, electrostatics of electrodynamics, and so on. The most powerful and deep theories of contemporary science are theories of change not theories of being: permanence is a particular, exceptional, temporary case of change. To deny that all things are restless, to deny that universal change is objective – as Weyl (1949), Costa de Beauregard (1963) and Grünbaum (1967) – have done is an exercise in sophistry.

The dynamicist view inherent in contemporary science, and adopted by our ontology, contrasts not only with Parmenidean staticism but also with the Aristotelian and Thomist hypothesis that rest, rather than motion, is the "natural" state of things. Our version of dynamicism goes also one step beyond Democritus', for whom atoms themselves were subject to no changes. Both high and low energy physics suggest that not even the "ultimate" components of things – "elementary particles" and fields – are quiescent. There is no inert matter, no perpetually unchanging stuff that can be disturbed only by external influences but is otherwise passive. As Bolzano saw, such external influences and the resulting relative motions could not be explained "if no change could take place in the interior of the simple substances themselves"; hence "the capacity for change through mutual influence" must be attributed to all substances, whether complex or simple (Bolzano, 1851, §§ 50, 51). The "immutable pole" exalted by some poets and philosophers is not a thing or a set of things but the set of basic objective laws.

Our view is definitely dynamicist but not excessively so; we assume that every thing changes in some respect or other but refrain from asserting that it changes in every respect, let alone incessantly. Science does not seem to support such an exaggeration: it shows that some traits remain invariant throughout certain changes. (The constants of the motion of a physical system are among such invariants.) Moreover change in some respects is possible only on account of permanence in others. (Thus, life processes are impossible unless homeostasis is maintained.) Likewise whatever is permanent (invariant, unchanging) is so relative to (under) some specific set (groupoid, semigroup, or group) of transformations. Consequently the invariants of any one such structure may not be the same as those of a different set of transformations.

What holds for every single thing – namely that it is changeable – is true of the thing composed of all things, namely the universe. That is, the world as a whole is in flux – though not as a single well integrated system or cosmos. The universal flux is a huge bundle of processes some of which intertwine (influence each other) while most probably do not. Hence it is mistaken to speak of "the world series of events" – as if it were something like an oversized world baseball series. A fortiori it is mistaken to affirm or to deny that such a series has a beginning or an end. There just *is* no world series of events. Because the precedence relation among events is local (bound to some reference frame or other), the totality of events has no overall order. All we can assert – and have in fact asserted in Postulate 5.9 – is that every single process is preceded and succeeded by other processes. Hence although the world as a whole is not engaged in a relay race, every bit of it does participate in some local relay race or other.

5.3. *Interconnectedness*

Postulate 5.10 in Sec. 4.1 states that every thing influences, or is influenced by, some other things. In other words, nothing – except for the universe as a whole – is totally isolated. If this is so then the world is an interconnected whole, i.e. a system rather than an aggregate. (Recall Definition 3.12 in Ch. 3, Sec. 2.7.) However, it is not a very tightly knit one.

The hypothesis that the world is a system is weaker, but presumably nearer the truth, than the organicist cosmology of Plato, the Stoics, or Hegel, according to whom every thing is bonded to everything else, so that the world as a whole is an "organic whole". If this other hypothesis were true then it would be impossible to study any particular thing without taking cognizance of every other thing, and it would be impossible to act on any particular thing without disturbing the entire universe.

Both contemporary science and our ontology steer a middle course between the extremes of organicism ("Everything hangs together forming a solid block") and atomism ("Everything goes its own way"). No part of the universe is isolated (or entirely free from bonds) but every thing is isolated in some respects from some other things. This *partial interconnectedness* of the parts of the world renders their study possible, for the study of every thing is partial and rests on the possibility of making contact with the thing.

Moreover, Postulate 5.10 supplies the existence criterion commonly used in the sciences, to wit: *Whatever exists (really, physically) is influenced by, or influences, some other things.* To repeat:

CRITERION 5.1 For any object x other than the world, *x exists really* iff there is a thing y other than x such that y acts on x or x acts on y.

If the thing y that acts on or is acted upon by the putative thing x, is controllable by an observer, then x is a subject of experimental research. But such possibility of effective control is sufficient, not necessary, to conjecture existence.

In short, our ontology includes the thesis of the limited or partial interconnectedness of all the parts of the universe.

5.4. *Three Misconceptions*

We have defined change with reference to concrete objects or things. Every collection of events is a set of changes in some thing or other. We have found no use for the fiction that there are changes that fail to consist in modifications of the states of some thing or other. Anyone claiming that there are such changes in reality should exhibit empirical evidence to this effect and proceed to build a theory of such thingless (or immaterial) changes.

Nevertheless once in a while philosophers and even scientists are found claiming that there are such thingless changes. Let us examine briefly the claims for three such items. One of them is the information process, sometimes regarded as not being based on the transport of matter or the propagation of fields. The reason for this misconception is that statistical information theory is a black box or phenomenological theory so general that it disregards the precise kind of signal carrying the information, the information transmission mechanism, and the kind(s) and quantity of energy involved. For this reason information theory is a nonphysical theory: it is instead a theory qualifying as a piece of scientific metaphysics, since it deals in an extremely general way with a genus of concrete things. But, of course, information is a property of certain physical (or chemical or biological) processes, namely signals, which are processes of a kind. No signal, no information transmission. And signals, let us repeat, are chains of events occurring in concrete things: the transmission of information consists in events propagating across space and carrying energy. Remove such real processes and only parapsychological anecdotes remain.

Another alleged example of a nonphysical yet real change is the parallelistic thesis that psychical or mental ("behavioral") events are not to be conceived of as changes in the nervous system of the animal concerned. If this is a point in methodology, it may have been sound in the beginnings of experimental psychology. But it has now become obnoxious for it blocks research in physiological psychology, and it is absurd when taken metaphysically, i.e. as restating the moth-eaten dogma that the soul is above matter. There is no evidence whatever for brainless ideation, whereas on the other hand there is definite evidence that every mental event is an event in the brain of some animal. We defer the detailed investigation of this matter to Vol. 4, Ch. 10.

A third point of incidence of immaterialism is the standard quantum mechanical theory of measurement (von Neumann, 1932). According to it the most striking difference between quantum physics and classical physics is that, while the latter treats measurement processes as purely physical processes, according to quantum mechanics they are not because of the intervention of the observer's mind and his decisions. So much so, it is alleged, that only natural processes obey the Schrödinger equation (but then they are unobservable) whereas measurement processes obey a separate theory centered on a different postulate, namely the projection postulate. This interpretation is not accepted by the orthodox followers of Bohr, according to whom *all* quantum events (which they call 'phenomena'), not just those controlled by measurement devices, involve observation acts. According to this alternative view there would be no spontaneous (unprovoked and unobserved) microevents ("quantum phenomena"). Realists reject of course Bohr's thesis as well as von Neumann's (Bunge, 1973b). One argument for the realist stand is that, while it is true that every measurement process is designed, executed and interpreted by some person (eventually with the help of automatic devices), it is a strictly physical process so far as the measured and the measuring things are concerned. So much so that (*a*) some measurement processes can be completely automated and (*b*) none of the existing measurement theories includes any mental variables. But even if the larger system including the observer and his staff had to be considered, this would not render measurement a nonphysical process – unless of course the mind were construed as an immaterial substance in the style of Aristotle and of the public (not the secret) Descartes. But modern physics need not ally itself with an obsolete metaphysics.

6. Concluding remarks

A basic polarity in traditional metaphysics is that of being and becoming: event is opposed to thing, process to stuff, change to structure. This opposition makes no sense in our system, where every change is the transformation of some thing or other, and every thing is in flux. This view, incompatible with much of traditional metaphysics, is consistent with science: the latter provides no ground for hypothesizing the existence of thingless events any more than it suggests that there might be changeless things. Surely the formulas of theoretical science do not always contain thing variables in an explicit way, but the context – what is sometimes called "the prose identifying the variables" – usually makes it clear that the formulas refer to things of some kind or other. The precise description of every event requires mentioning the thing or things subject to the change in question. This is why any correct axiomatization of a scientific theory starts by making assumptions concerning the kinds of thing the theory refers to, and ends up by characterizing events as changes in some of the properties of such referents. (See e.g. Bunge, 1967b, 1973b.) The converse course, namely that of starting with events and ending up by defining things, has been suggested as a program (e.g. by Russell (1914) and Whitehead (1929)) but never actually carried out. Let us take a glimpse at it.

Some process philosophers – anxious to flog the dead horse of Parmenidean ontology – have gone to the point of postulating that the being of an entity consists in its becoming – that "the actual world is a process" (Whitehead, 1929, pp. 29 and *passim*). Likewise the physicist Fokker characterized reality as a stream of events (Fokker, 1965, p. 1).

A few other physicists have reinvented this idea and even denied the existence of things (Bohm, 1970; Finkelstein, 1973; Stapp, 1976). This idea, that events and processes are the stuff the world is made of, has been encouraged by a misleading terminology introduced by some workers in relativistic physics, who call any point in spacetime an *event*, whether or not the point happens to be occupied by some thing. Further, they call *world* the set of all such "events" – even for a hollow universe. In this way the world is regarded as a set of events and the things that change are lost sight of.

In point of fact not the world but just a *world line* or tube or history – the region of spacetime scanned by some thing – qualifies as a sequence of events or process. (See Figure 5.19.) What can be said is that any region of spacetime is the seat of *possible* events occurring to things (particles, fields, etc.) that might exist within that region. But this is a far cry from identifying an event with a quadruple of real numbers.

In any case we need not spend more time with the quaint version of process metaphysics that dispenses with the thing concept, because it is logically untenable. Indeed, it is circular to define a *thing* as the

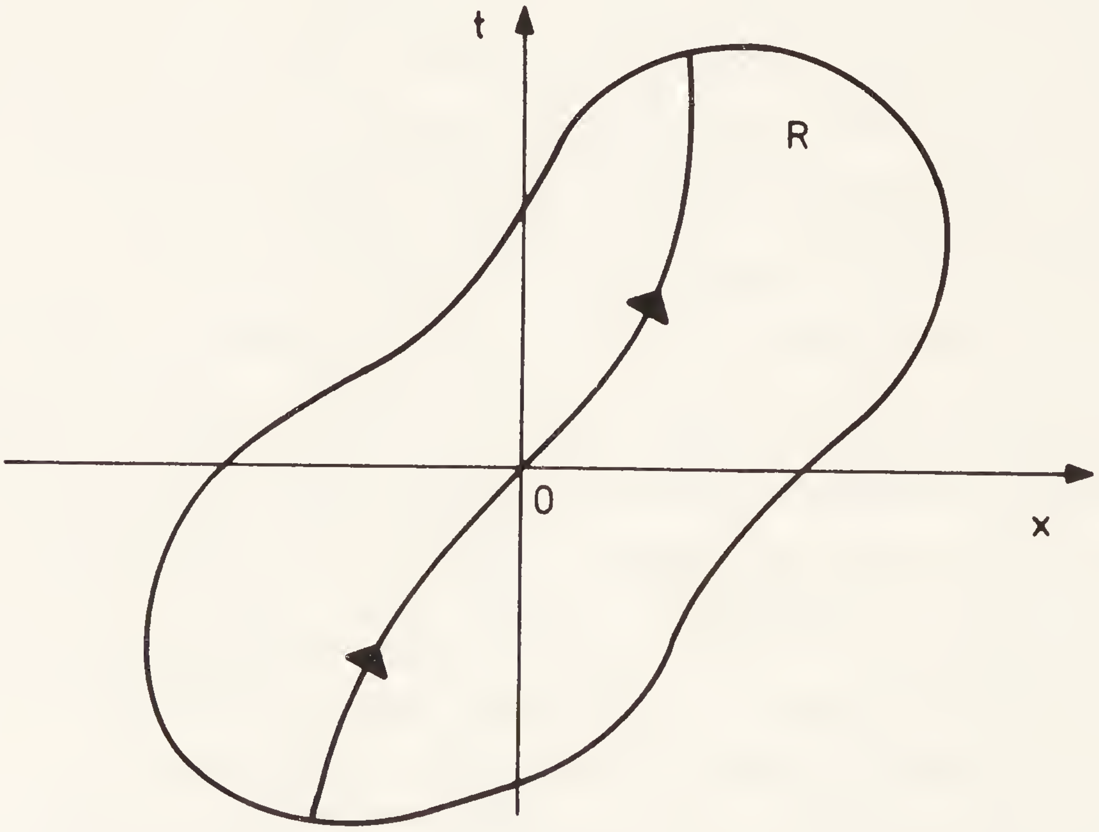

Fig. 5.19. The spatiotemporal track of a point particle (or world line of the latter) is a process in spacetime. Unless there are actually other things in the spatiotemporal region *R*, all the points other than those constituting the world line of the particle are uneventful and therefore do not deserve being called 'events'.

collection of events occurring in the *thing*. This is why our study of change was preceded by an examination of the concept of a thing.

The dual of process metaphysics is of course being metaphysics. One version of it is structuralism, currently fashionable in France (cf. Lévi-Strauss, 1958). Just as traditional metaphysics opposed being to becoming (or thing to process), and even extolled one of them at the expense of the other, so structuralism tends to oppose structure to change and to divorce the former from things. Just as the extreme dynamicists speak of thingless events, so structuralists speak of structures in themselves and concentrate their attention on structural permanence amidst flux. This too is mistaken: except for pure mathematics, where there are structures in themselves – e.g. Boolean algebras – every structure is the structure *of* some (complex) thing – atom, molecule, cell, organ, organism, community, ecosystem, or what have you. (Recall Definition 5.34 of the structure of an aggregation of things.) We do not say of a certain physical object that it *is* a rotation group but that a certain property of it (e.g. the energy) has rotation symmetry, or is invariant under rotations (members of the rotation group). Likewise we do not say of a community that it *is* a social structure but instead that it *has* such a structure. Moreover given the changeability of all things it is unlikely that there be anything with a permanent structure. In short, structure is a property – and a changeable one.

In conclusion, neither processism nor structuralism are viable alternatives to our metaphysics of changing things. Becoming is not pure flux but consists of things' being in successive states, or of successive things. (Remember Aristotle's *Physics*, Bk. III, Ch. 1, Sec. 1: "there is no such thing as motion *over and above* the things".) And structures are not just fickle but also lacking in independent existence: they are structures of things, features of concrete objects. In sum change and structure are so many distinct but interlocked features of changing things endowed with some structure or other. Therefore the traditional metaphysical poles, namely process metaphysics and being metaphysics, have each a grain of truth and both are overcome by our ontology.

We come to the end of our study of change in general. We have formed the main building blocks for constructing the concepts of time and space. Once these have become available we shall be able to give a more detailed account of change – in particular qualitative change, which will concern us in Vol. 4, Ch. 8. We proceed then to a study of extension and duration.

CHAPTER 6

SPACETIME

Science takes space and time for granted. Although not every scientific theory makes detailed assumptions about space and time, these two are usually regarded as constituting an independently existing framework allowing one to locate things and date events. So much so that facts are said to be or to happen *in* space and time even when we do not care for their precise spatiotemporal characteristics. So much are space and time taken for granted in science that most descriptions of things are effected in terms of space or time – i.e. space and time coordinates are used as independent variables. Moreover space and time are usually regarded as external to things and their changes: they are taken to constitute a fixed scenario.

True, on the relativistic theory of gravitation things influence the structure of spacetime: they distort its metric, hence its intrinsic curvature. But they do not create the basic manifold. (Indeed, setting the matter tensor equal to zero in the gravitational field equations one is left with equations describing a riemannian space.) In other words, even the general theory of relativity is consistent with – although it does not necessitate – a modified absolute theory of spacetime, i.e. one according to which spacetime has an independent existence instead of being a mesh of relations among facts. (The revision required by general relativity is this: the metric is not a priori, or purely geometric, but depends upon the momentary distribution of matter and fields. Hence spacetime is homogeneous just in case that distribution is itself homogeneous – i.e. actually never.) In sum science tells us what the structure of spacetime is but not what spacetime is.

This procedure, though legitimate in science, is unsatisfactory in philosophy. Here we cannot take space and time for granted because philosophy takes for granted nothing but the existence of the whole universe. In philosophy we must ask 'What are space and time?': we must attempt to understand how they come about, what their roots in things and events are. For, in the absence of things, there should be no spatial relations; and in the absence of change there should be no temporal relations. Indeed, it takes at least two things to make sense of 'here', 'there', 'to the left', and the like. And it takes at least two different states of a thing to make sense of 'before', 'after', 'meanwhile', and their kin.

Therefore instead of assuming that space and time are absolute (autonomous, self-existing) or even mildly absolute (influenced but not created by the furniture of the world), we should try and construct them out of facts. Philosophers are not interested in the empirical question 'Where and when did x happen?' They are interested instead in the question 'Do facts give rise to space and time, and if so how?' It behoves them to characterize the gross – algebraic and topological – structure of space and time, if possible in terms of factual items. Once this task has been accomplished, the philosopher should step aside and let the scientist investigate the fine structure – in particular the metric – of spacetime. It would be presumptuous of him to legislate that spacetime is – or is not – euclidean: this is a matter for the scientist to investigate. The philosopher will not try to compete with the scientist unless he is intent on being beaten by him.

From a methodological point of view the situation is this: there are three kinds of geometry – mathematical, physical, and ontological. *Mathematical geometry*, or geometry for short, is the collection of theories defining spaces of all kinds, where by 'space' is meant an arbitrary set endowed with a minimal structure, namely a topology. This structure can be modest or rich, and it may or may not depend upon the nature of the elements of the set. For example let S be a two member set $S=\{a, b\}$ – never mind what these elements are. Form the power set of S, i.e. $\tau=2^S=\{\varnothing, \{a\}, \{b\}, \{a, b\}\}$. Then S is said to be *topologized* by τ. Equivalently, the ordered couple $\langle S, \tau\rangle$ is called a *topological space* – or space for short. A theory of a mathematical space is said to be "concrete" if the nature of the elements of the base set S is specified – e.g. if the members of S are n-tuples of real numbers. Otherwise, i.e. if the "points" of the space are faceless (unspecified individuals), then the theory is said to be abstract, or to define an abstract space.

A *physical geometry*, on the other hand, is a theory purporting to represent things and events in physical space (or in spacetime). It consists of a mathematical geometry of the "concrete" type (i.e. interpreted in mathematical terms) enriched with semantic assumptions ("correspondence rules") specifying the referents of the theory (e.g. light rays) and what properties of such referents (e.g. their mutual separation) those concepts represent. For example, in such a geometry a (physical) triangle could be determined, say, by three intersecting light rays, and the length of its sides could be equalled to the times of flight of the photons constituting such rays. That is, the objects of a physical geometry are physical objects and as such subject to measurement at least in principle.

Finally we shall call *philosophical geometry*, or *chronotopics*, the set of theories explaining the deep structure, i.e. the factual support, of spacetime. (A philosophical geometry is a part of both philosophy – in particular ontology – and the general foundations of physics. It should not be mistaken for the philosophy of geometry, which is a metatheory concerned with the nature of geometric objects, the kinds of geometric argument, the relation of mathematical geometry to factual science and to reality, and so on.) Chronotopics makes use of both ontology and pure mathematics, and it intends to underpin physical geometry. It attempts to lay bare the ontic substratum of spatiotemporal relations in order to answer the philosophical questions that neither mathematical nor physical geometry answer, namely 'What are space and time?'. The subject of the present chapter is precisely chronotopics. And our answer to the question formulated a wink ago will be this: Space and time are what chronotopics say they are. Or, in a less sibylline way: *Spacetime is the collection of facts together with their separations* – where "separation" is construed in terms of facts only. Precisely how it is construed will be seen shortly. But before embarking on the construction of the theory we must examine the kinds of theory we might build.

1. CONFLICTING VIEWS

1.1. *The Three Main Views*

There are three main views on the nature of space and time: we call them the container, the prime stuff, and the relational views. (For a history of these ideas see Jammer, 1954.) Here they are in a nutshell:

(i) *The container view*: space and time constitute the fixed stage where things play out their comedy. Physical objects exist in space and time, which in turn are not physical objects. Moreover a physical object may be defined as anything occupying a region of space and a stretch of time. The container exists by itself (is absolute), hence it would continue to exist if all things contained were to change radically in kind or even were to pass out of existence. Not being a physical thing or a relation among physical objects, the supreme container cannot be described in physical terms: space and time have got to be described in purely mathematical terms without even the assistance of concept-fact bridges or semantic assumptions. Thus instead of stating that a certain geometry represents physical space we must say that the two are identical. Such a view is compatible with both the objectivist conception invented by the Greek atomists, and refined by Newton, and the subjectivist conception of space and time as the intuitive scaffolding necessary for human experience (Kant).

The container view of space and time is strongly suggested by the way science uses these concepts most of the time. Thus one calculates or measures the place or time *at* which something happens, and one computes or measures spatial and temporal intervals regardless of the kind of fact involved. However, the fixed framework view has been shaken by the relativistic theory of gravitation, where the very structure of spacetime is influenced (though not determined) by the things contained. (As you turn the pages of this book you modify, albeit by tiny amounts, the distances between neighboring objects as well as the trajectories of the light rays reaching your eyes.) Besides, the doctrine is philosophically unsatisfactory because it does not really answer – except metaphorically – the question 'What are space and time?'. It is particularly unacceptable to any ontology which, like ours, has no room for objects that are neither things nor properties of things nor relations among things. Therefore we cannot accept the container view even though we may feign to do so in everyday life.

(ii) *The prime stuff view*: spacetime is the elementary substance of which every physical object is made. Whatever is part of the world is a chunk of spacetime, and every substantial property is a property of a chunk of spacetime. Hence everything physical ought to be explained in spatiotemporal terms – be it Anaximander's *ápeiron*, Clifford's space hills, or Wheeler's wormholes. Physics becomes geometry and moreover a geometry in no need of physical interpretation, as it generates its own interpretation. Geometric monism is substituted for the spacetime-matter dualism of the container view: space and time are not just experientially and epistemically prior (as for Kant) but also ontologically primary (as for Alexander). Indeed, every physical object is regarded as a local warping of space (or of spacetime). Thus an electrically charged particle is said to be identical to a wormhole in the basic spacetime manifold. (See Wheeler, 1962.) In short, on this view space and time are just as absolute as on the container view, in so far as their properties depend on nothing. The difference is that, according to the prime stuff view, things are not in spacetime but instead the latter constitutes the former.

This fascinating theory is unfortunately semantically and ontologically too simple to be true. Semantically because the mathematical formalism is declared to be in no need of semantic hypotheses ("correspondence rules"). Thus instead of saying that a certain figure in spacetime *represents* a black hole one simply *calls* that surface a black hole: definitions take the place of semantic assumptions, hence the border line between formal science and factual science disappears – perhaps also that between constructs and things. And the theory is ontologically too simple because it attempts to reduce the entire variety of kinds of stuff to extension and shape (in four dimensions) alone. This Cartesian reduction to *figures et mouvements* does not account for the varieties of elementary particles and fields.

(iii) *The relational view*: space and time are not self-existing objects but a network of relations among factual items – things and their changes. What is assigned mathematical (topological, affine, or metrical) properties is not spacetime itself but the set of things – atoms, fields, etc. – and their changes. No changing things, no spacetime. Of course things may be said to have spatiotemporal properties – but the latter boil down to relations among things or events. The concepts of space and time used in science should result (and also be made more precise) upon one's abstracting from the facts, as when "Point x is included in sphere s with center at the origin of coordinate system k" is abstracted from "Thing X is inside ball S centered at the origin of the material frame of reference f (represented by coordinate system k)". Likewise "Instant t_1 precedes instant t_2 in the four-dimensional coordinate system k" should be construed as an abstraction from "Event e_1 precedes event e_2 in reference frame f (represented by the four-dimensional coordinate system k)".

The relational view has been expounded, with various degrees of clarity, by thinkers as diverse as Aristotle, Lucretius, Augustine, Leibniz, Lambert, Lobachevsky, Riemann, Engels, Mach, Whitehead, Robb, van Dantzig, Fokker, and Penrose. It was best summarized by Leibniz in oft quoted words: space is an *order of possible coexistents* and time an *order of successives* (Leibniz, 1956, II, p. 1083). Hence talk of space or time is elliptic talk of facts (Mach, 1872, 1883). When saying

'The position of thing X' we actually mean "The position of thing X relative to thing Y", where Y is either a reference frame or just the environment of X. And when saying 'The state of thing X at time t' we actually mean "The state of thing X when the chosen reference frame (or the environment) is in state t". However, *pace* Mach it does not follow that the concepts of space and time are dispensable: elucidating is not necessarily explaining away or eliminating. We cannot afford such a luxury because mention of space and time landmarks amounts to a public and global, hence objective and economical, reference to the state of the environment – of any environment, of any kind. Moreover there is no better way of getting quantitative precision than to fix the spatiotemporal coordinates of a thing or an event. But this is a methodological point: what matters to ontology is that space and time are not self-existing (absolute) objects of uncertain ontological status (neither things nor thing properties). The relational view is that *spacetime is the basic structure of the totality of possible facts*. But, unlike the prime stuff view, which eventually developed into a full fledged theory (geometrodynamics), the relational view has heretofore remained at the heuristic stage. The subsequent sections will see us through a hypothetical-deductive system spelling out the basic intuitions of the relationist thinkers. But before piling up bricks let us take a look at architectural styles.

1.2. *Approaches to Chronotopics Building*

There are two epistemological approaches to the problem of building a relational chronotopics: the subjectivist and the objectivist ones. In the former one takes the cognitive subject and his experiences as the point of departure, whereas in the second case one proceeds from a consideration of the things themselves. The subjectivist approach has been tried by Whitehead, Nicod and Basri among others. Let us glance at these attempts.

Whitehead (1919) assumes that space is euclidean and tries to define in experiential terms all the concepts that euclidean geometry takes as primitive. (There is an echo of the Berkeley–Mach program in Whitehead's attempting "the deduction of scientific concepts from the simplest elements of our perceptual knowledge": Whitehead, 1919, p. vii.) Thus Whitehead's is not really a radical construction but a reconstruction with a strong a priori component, namely a particular mathematical conponent, and an equally strong philosophical bias, namely radical empiricism. Because of that a priori element Whitehead's theory of space and time is incompatible (by design) with the two theories of relativity and therefore hopelessly obsolete at birth and beyond repair. And because of its pronounced subjectivism the theory is inconsistent with the epistemological outlook of science, which is realist and the one adopted in this work. (Recall our Rule 7 for philosophizing: Introduction, Sec. 4.) Lucas' more recent attempt (Lucas, 1973) is subject to similar criticisms.

Nicod's (1923) venture was more radical though technically far less accomplished than Whitehead's and just as far removed from the science of his time. It was more radical because Nicod started from (imaginary) experiences and attempted to build geometry out of them without imposing any a priori structure on space. (One is reminded of Condillac and his statue.) In other words Nicod – following leads from Mach and Russell, and independently of Carnap's similar attempt – tried to build physical geometry out of (common sense) psychology. As a matter of fact he delivered nothing of the sort: he did not even produce a theory of any of the perceptual spaces such as the visual or the acoustic space. (Neither he nor Whitehead realized the differences between physical space and the perceptual spaces.) Like Whitehead's, Nicod's was a scientific and philosophic failure. (For detailed criticisms see McGilvary, 1951 and Vuillemin, 1971.)

Finally the most recent work along the Mach-early Russell–Whitehead–Carnap line, namely Basri's (1966), is just as subjectivistic but on the other hand it has the merit of being admirably rigorous and of respecting the formulas of relativistic physics. However, it does not serve as a foundation for the latter because it violates the spirit of the two relativities, which are field theories (Basri admits only particles) and moreover observer-invariant ones (Basri's is observer-bound). And although this theory professes to be concerned with human observers and their sensations and operations, it makes no contribution to the physiology or the psychology of space and time perception. In short, since the theory is subservient to an unscientific philosophy – namely empiricism – it serves neither physics nor psychology.

The subjectivistic approach cannot yield what we want in scientific ontology, namely an objective chronotopics compatible with physics but soft enough that the physicist may shape it according to his theories and data. And, whether subjectivist or merely conventionalist, the a priori approach to the geometry of physical space is unphysical because it assigns space a structure independent of the actual distribution of things. We must therefore try an objectivist approach, i.e. one starting with factual items as the prime stuff and postulating their spatiotemporal relations quite apart from considerations of perception and even measurement. This does not mean that the construction should proceed a priori, i.e. in advance of any experience. Quite the contrary, we shall be guided by the finding of scientific experience, that physical space is a three-dimensional connected generalized continuum. For the sake of simplicity we shall build first a geometry, then a chronology, and finally a chronotopics or philosophical theory of spacetime.

2. Space

2.1. *Interposition*

We shall build our relational theory of space using only materials elaborated in the previous chapters. In fact we need only the following background assumptions and definitions:

(i) there are concrete objects or things, none of them is a construct, and all of them exist independently of the cognitive subject;

(ii) all things can juxtapose or aggregate: if $x, y \in \Theta$, then $x \dotplus y \in \Theta$ or, equivalently, $[\{x, y\}] \in \Theta$;

(iii) the world is the aggregation of all things – i.e. $\square = [\Theta]$ – and whatever is a part of the world is a thing – i.e. if $x \sqsubset \square$ then $x \in \Theta$;

(iv) all things are, or are composed of, basic things or members of $B \subset \Theta$: for any $x \in \Theta$ there is a unique subset B_x of B such that $x = [B_x]$; and basics are elementary, i.e. have no parts: if $x, y \subset B$ and $x \sqsubset y$, then $x = y$.

(v) every thing is in some state or other relative to a given standard thing or reference frame, and the collection of really possible (lawful) states of a thing x is called its lawful state space $S_{\mathbb{L}}(x)$;

(vi) the evolution or history of every thing x is representable as a trajectory in its lawful state space: if $\mathbb{F}$ is the state function of x, and $S(f)$ the state space of reference frame f, then $h(x) = \{\langle t, \mathbb{F}(t)\rangle | t \in S(f)\}$;

(vii) a thing x acts upon another thing y iff the former modifies the history of the latter: $x \rhd y =_{df} h(x \dotplus y) = h(x) \cup h(y|x)$ & $h(y|x) \neq h(y)$;

(viii) the total effect or action of thing x upon thing y is $A(x, y) = h(y|x) \cap \overline{h(y)}$;

(ix) every change is a change in the state of some thing, and the net change of thing x from state s to state s' is representable as the ordered pair $e = \langle s, s' \rangle \in S_{\mathbb{L}}(x) \times S_{\mathbb{L}}(x)$;

(x) if $e = \langle s, s' \rangle$ and $e' = \langle s'', s''' \rangle$ are events in a thing x relative to a frame f, then e precedes e' if e composes with e' in the indicated order to form a third event in x; i.e. $e < e' =_{df} e * e' \in E_{\mathbb{L}}(x)$, where $E_{\mathbb{L}}(x)$ is the proper lawful event space of x, i.e. the set of really possible changes of x.

Our first geometrical notion is that of interposition, which we proceed to build in terms of the ontological notions occurring in the previous list. Our definition will be explicit, namely via

POSTULATE 6.1 Let R be a ternary relation among things and abbreviate "R holds among x, y, z in the given order" to $x|y|z$, where $x, y, z \in \Theta$. Then R is the *interposition* or *betweenness* relation iff, for any $u, v, x, y, z \in \Theta$,

(i) $x|y|z \Rightarrow x \neq y \neq z \neq x$ or $x = y = z$, i.e. R holds either among different things or trivially for a single thing;

(ii) $x|y|z \Rightarrow z|y|x$, i.e. R is symmetric in the outer variables;

(iii) $x|y|z \;\&\; u|x|y \;\&\; y|z|v \Rightarrow u|y|v$, i.e. whatever interposes between two given things lies also between two outer things;

(iv) $x \neq y \;\&\; x \sqsubset y \Rightarrow \neg(\exists z)(z \in \Theta \;\&\; x|z|y)$, i.e. nothing interposes between the part and the whole;

(v) $y \in B \Rightarrow (\exists x)(\exists z)(x, z \in B - \{y\} \;\&\; x|y|z)$, i.e. any basic thing can be "surrounded" by two other basics;

(vi) $\neg(x \sqsubset y) \;\&\; \neg(y \sqsubset x) \Rightarrow (\exists z)(z \in B \;\&\; x|z|y)$, i.e., there are basics interposed between any two detached things: the world is dense, it constitutes a *plenum*;

(vii) $x|y|z \;\&\; x \rhd z \Rightarrow (\exists u)[u \in A(x, y) \;\&\; (v)(v \in A(x, z) \Rightarrow u < v)]$, i.e. if y interposes between x and z, and x acts on z, then some of the effects of x on y precede all of the effects of x upon z. (See Figure 6.1.)

The first three clauses seem intuitive. The fourth is a sort of interpretation of Hilbert's second axiom group for elementary geometry – in our notation $\neg(x|y|y)$ (Hilbert, 1899). The fifth is a sort of dual of Hilbert's 4th component of the second axiom group – namely that there is a thing lying between any two distinct things. The sixth is countenanced by both gravitation theory and quantum electrodynamics: according to these theories no region of space is totally devoid of some entity or other. (This is of course the plenistic hypothesis defended by Aristotle, Descartes and Einstein among others.) And the last clause exhibits,

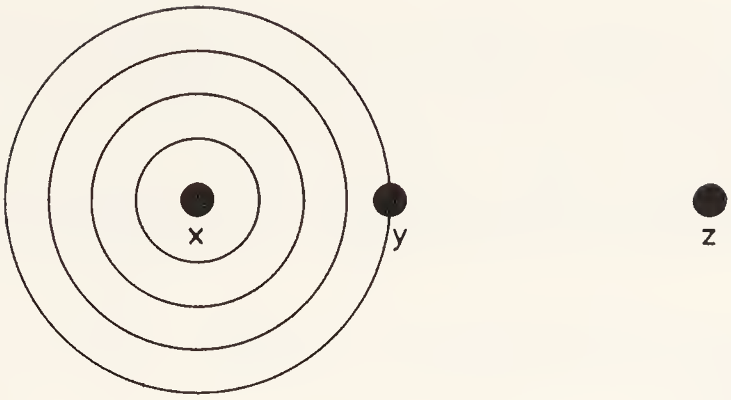

Fig. 6.1. Illustration of clause (vii) of Postulate 6.1. A spherical wave emitted by x reaches y before it does z.

perhaps even more forcefully than all the others, the material basis of the interposition relation. It would be objected to by the Leibnizians, who would argue that there would be space even in a world composed of mutually independent entities (monads), none of which acted upon any other. Maybe, but ours happens not to be such a world (Postulate 5.10). Clause (vii) suggests that the interposition relation might not even be properly definable for a changeless universe.

2.2. *A Philosopher's Space*

A basic concept in any geometry is that of separation. There are several notions of separation. One of them is the topological notion of separation between sets (Wallace 1941). We cannot use it because we wish to clarify the notion of separation between concrete things not between sets, which are constructs. Other concepts of separation are metrical or quasimetrical. Any of these consists in a real valued function d on an abstract set S obeying well known conditions. The members x and y of S are said to be separate iff $d(x, y) \neq 0$. We cannot use these notions either because it is not our purpose to compete with physicists by assigning precise quantitative measures to the separations among things. We need a more basic, qualitative notion of separation. We shall get it with the help of the concept of interposition.

We define the separation between two things as the set of things that interpose or lie between the given things. More precisely, we make

DEFINITION 6.1 Let $B \subset \Theta$ be the set of basic things. The function $\sigma: \Theta \times \Theta \rightarrow 2^B$ such that $\sigma(x, y) = \{z \in B \mid x|z|y\}$ for $x, y \in \Theta$ is called the *thing separation*.

Because the null thing is part of every thing, the separation between an arbitrary thing and the null thing is nought, i.e. $\sigma(x, \square) = \varnothing$. And because every thing is part of the world, there is no separation either between an arbitrary thing and the world: $\sigma(x, \text{▯}) = \varnothing$. These two consequences follow from Postulate 6.1 and Definition 6.1, as does

THEOREM 6.1 For any two things $x, y \in \Theta$,
(i) $\sigma(x, x) = \{x\}$;
(ii) $\sigma(x, y) = \sigma(y, x)$.

Proof The first part follows from clause (i) of Postulate 6.1. The second, from clause (ii).

Note the similarities and dissimilarities between σ and the distance (or quasidistance) functions d mentioned at the beginning of this section. Property (ii) is analogous to the corresponding properties of the d's. On the other hand property (i) is not, nor is the frame invariance of σ, which contrasts with the frame dependence of the d's.

Further, if a thing interposes between two things which in turn interpose between two other things, then the former interposes between the latter. In terms of the separation function:

THEOREM 6.2 For any things $u, v, x, y, z \in \Theta$: If $y \in \sigma(x, z)$, $x \in \sigma(u, y)$ and $z \in \sigma(y, v)$, then $y \in \sigma(u, v)$.

Proof By Postulate 6.1(iii) and Definition 6.1.

We could derive further theorems but we shall not need them for our purposes. What we do need is another property of the separation function, which the previous assumptions and definitions fail to entail. We must therefore postulate it (see Figure 6.2). More exactly, we assume

POSTULATE 6.2 Let x_1, x_2, y, z_1 and z_2 be basic things. If $y \in \sigma(x_1, z_1) \cap \sigma(x_2, z_2)$ and $x_1 \neq z_1$, $x_2 \neq z_2$, then there are basic things x_3 and z_3 such that $x_3 \neq z_3$ and

$$y \in \sigma(x_3, z_3) \subset \sigma(x_1, z_1) \cap \sigma(x_2, z_2).$$

We now have all we need to build an important notion:

DEFINITION 6.2 The set B of basic things, together with the separation function σ, is called the thing space, abbreviated $\vartheta = \langle B, \sigma \rangle$.

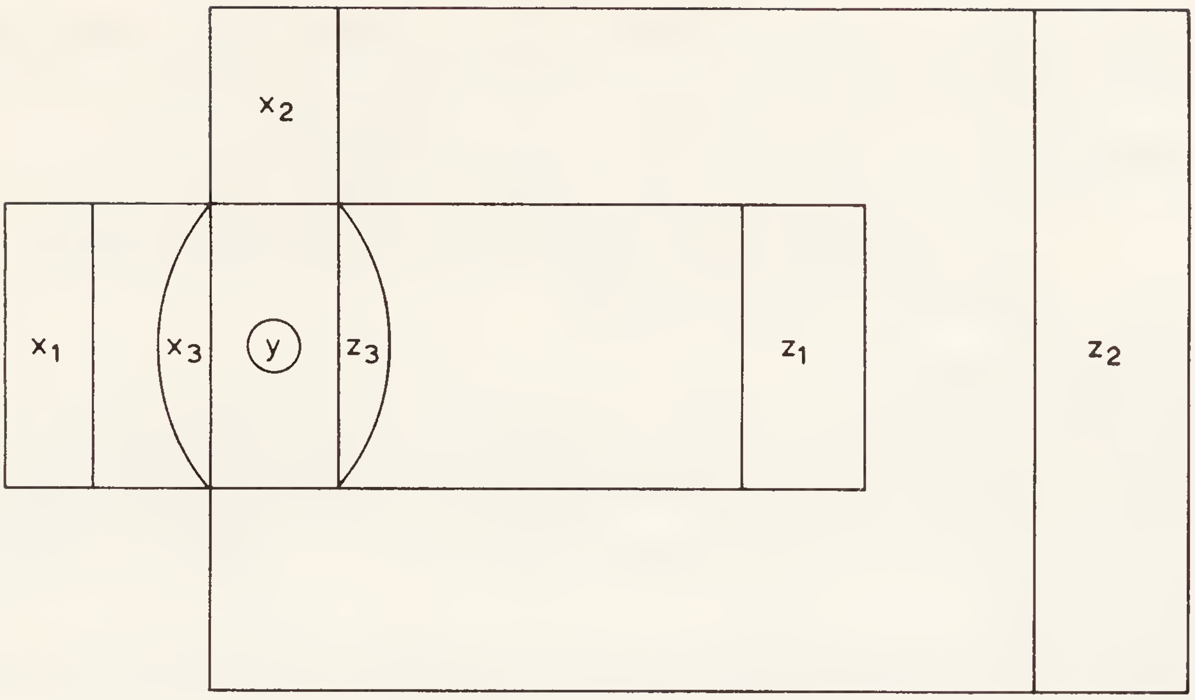

Fig. 6.2. Postulate 6.2.

In other words, the thing space is nothing but *the collection of spaced things*, or the set of things related by their mutual separations. This space deserves being regarded as a real (or ordinary or physical) space because its coordinates, B and σ, are real. Indeed, the basics have been assumed to be real and moreover the fundamental constituents of all concrete objects; and the separation function is a *relatio realis* in the sense of Ch. 2, Sec. 5.1, Definition 2.17, for σ obtains between real things.

The space ϑ is all the philosopher needs, for it has been built out of a few extremely general (ontological) concepts. We may call ϑ a *philosopher's space*, and the corresponding theory (summed up in the preceding postulates, definitions and theorems), a *philosophical geometry*, and moreover one both relational and objectivist. However, so far we have no evidence that ϑ is indeed the physical space: we have not proved that our philosophical geometry can be specified to yield a geometry utilizable by physics. This task will be taken up in the next subsection, adapted from Bunge and García Máynez (1977).

2.3. *The Physicist's Space*

The thing space introduced by Definition 6.2 would seem to have too poor a structure to qualify as physical space or even as a mathematical space. However, this is not so, as will be shown in the present subsection.

To begin with $\langle B, \sigma\rangle$ has a definite topological structure, as shown by

THEOREM 6.3 The family of sets of basic things

$$\tau = \{X \in 2^B \mid \text{For all } y \in X \text{ there are } x \text{ and } z \text{ in } B - \{y\} \text{ such that } y \in \sigma(x, z) \subset X\}$$

is a topology for B.

Proof By Postulate 6.1(v), $B \in \tau$. Besides, it is obvious that $\varnothing \in \tau$ and that every union of members of τ belongs to τ. Finally, by Postulate 6.2 the intersection of any two elements of τ is also in τ. Hence τ is indeed a topology for B.

We shall assume then that the set B of basic things, equipped with the topology τ, is or rather represents physical space:

POSTULATE 6.3 The topological space $\Sigma = \langle B, \tau\rangle$ represents physical (ordinary, real) space.

However, we have so far little justification for assuming this hypothesis aside from the fact that B is constituted by things and has a topology. For one thing we have assigned Σ no definite dimensionality, whereas we feel certain that physical space is three-dimensional. For another we want Σ to be connected (in one piece). These and other shortcomings will be remedied by foisting certain properties on Σ. That is, we shall *force* Postulate 6.3 to become true.

To begin with we define, in the usual way, closures in τ:

DEFINITION 6.3 If $A \in \tau$, then

$$Cl\,A =_{df} \{x \in B \mid \text{For all } V \text{ in } \tau \text{ containing } x,\ V \cap A \neq \varnothing\}.$$

For these closures to be of any help they must be large enough. This is ensured by a mild enough assumption:

POSTULATE 6.4 Every pair of separate basics is in the τ-closure of their separation. I.e.,

$$\text{For any } x, y \in B, \text{ if } \sigma(x, y) \neq \varnothing, \text{ then } x, y \in Cl\,\sigma(x, y).$$

By taking $x = y$ it follows immediately that every finite subset of B is closed. Now, a space with this property is called a T_1-space. In other words, we have

COROLLARY 6.1 The physical space $\Sigma = \langle B, \tau \rangle$ is a T_1-space.

We need one more assumption to convert Σ into a Hausdorff (or T_2) space. Actually Σ should have further properties: the physicist wants Σ to be a connected and metrizable space locally homeomorphic to $\mathbb{R}^3$. In other words Σ should be a Euclidean three-manifold.

Now, it has been known for a long time that it is possible to express every theorem in Euclidean three-dimensional geometry with the sole help of the concepts of sphere and of inclusion. In fact these are the sole extralogical undefined notions in the set of postulates for elementary geometry proposed by Huntington (1913). For example, a *point* is defined in this geometry as a sphere such that there is no other sphere within the given sphere. And a *segment* is defined as follows: Let a and b be any given points, i.e. minimal spheres. If x is a point such that every sphere which contains both a and b also contains x, then x is said to belong to the *segment* (ab) or (ba). (See Figure 6.3.)

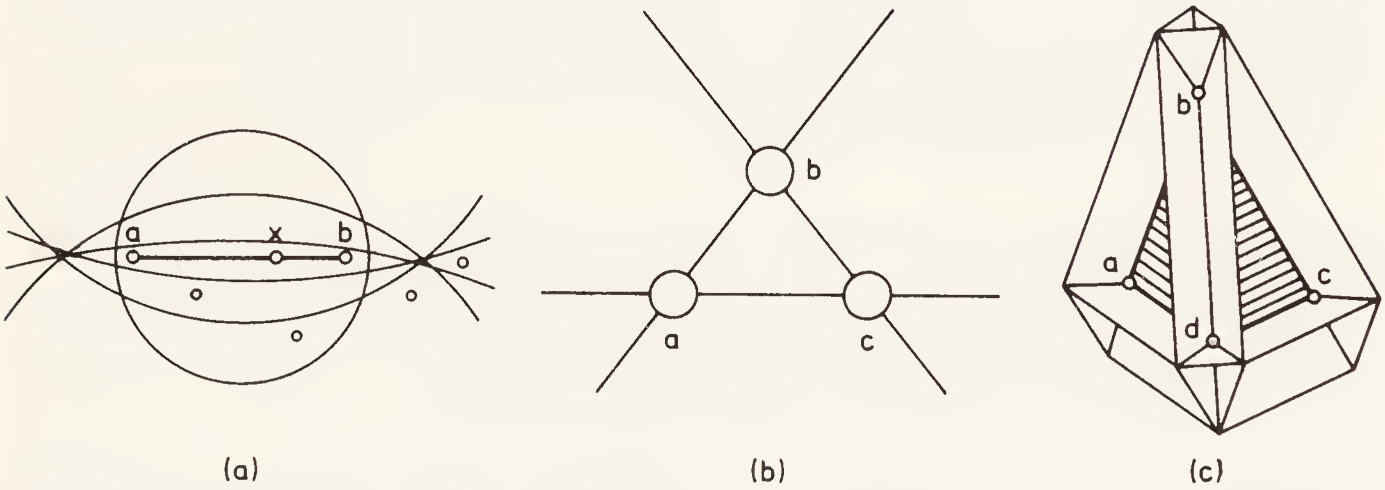

Fig. 6.3. Building space with spheres: (a) a segment, (b) a triangle, (c) a tetrahedron. From Huntington (1913), figs. 1, 3, 9.

We shall adopt Huntington's postulates but, instead of taking the notion of sphere as primitive, we shall define it in terms of some of our previous concepts. This will endow Huntington's postulates with a physical (or rather protophysical or ontological) interpretation and authorize us therefore to claim that they characterize physical space (in the small).

Our first task is then to define the concept of a sphere. We will define a sphere lying between two given things as the closure of a separation between those things. More precisely we make

DEFINITION 6.4 For any pair $x, z \in B$ of distinct basic things, the *spheres* lying between x and z are

$$Sxz = \{Cl\,\sigma(u, v) | u, v \in B \ \& \ \varnothing \neq Cl\,\sigma(u, v) \subset \sigma(x, z)\}.$$

Next we assume that these spheres satisfy Huntington's postulates:

POSTULATE 6.5 For any given pair $x, z \in B$ of distinct basics, if the spheres Sxz are nonempty, the structure $\langle Sxz, \subset \rangle$ satisfies (is a model of) the Huntington (1913) axioms.

Hence

THEOREM 6.4 The nonempty separation $\sigma(x, z)$ between two basic things $x, z \in B$ is homeomorphic to three-dimensional Euclidean space.

Proof The minimal spheres are the single points of $\sigma(x, z)$. By Huntington's (1913) Theorem 47 this collection can be topologized in such a way that it is homeomorphic to $\mathbb{R}^3$. Now, a basis for this topology consists of all the τ-interiors of elements of Sxz. Hence this latter topology is identical with the relative topology of $\sigma(x, z)$.

We are now justified in framing

DEFINITION 6.5 Every member $Cl\,\sigma(u, v)$ of the family of spheres Sxz lying between the things x and z is said to be a *Euclidean ball*.

Remember now that physical space is a T_1-space (Corollary 6.1). Since Postulate 6.5 supplies regularity we obtain

COROLLARY 6.2 $\Sigma = \langle B, \tau \rangle$ is a regular three-manifold without boundary.

We have come near the goal. We shall attain it by adding one last assumption, namely that any two basic things can be bridged by a string of spheres (Figure 6.4). More precisely, we assume

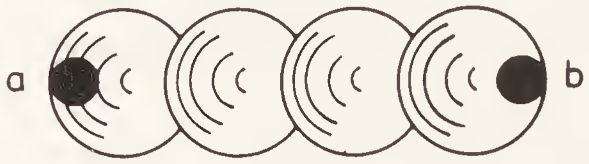

Fig. 6.4. The chain of partially overlapping spheres bridging things *a* and *b* (black dots).

POSTULATE 6.6 The set B of basics contains two sequences, $x_1, x_2, \ldots$ and $z_1, z_2, \ldots$, such that $x_i \neq z_i$ for each $i \in \mathbb{N}$ and, for every pair a, b in B, there is a simple chain

$$\langle C_i | 1 \leqslant i \leqslant n \rangle, [\text{i.e. } C_i \cap C_{i+1} \neq \varnothing, 1 \leqslant i \leqslant n-1]$$

such that $a \in C_1$ and $b \in C_n$, and every C_i is of the form $\sigma(x_j, z_j)$.

We can now prove that Σ is connected, i.e. in one piece or gapless. Moreover we shall prove in the same breath that Σ is second countable, i.e. that it has a countable basis. (A basis for τ is a subset β of τ such that each member of τ is a union of members of β, so that the latter are the building blocks of τ.) In fact we can also prove that Σ is metrizable. All of this is stated by

THEOREM 6.5 $\Sigma = \langle B, \tau \rangle$ is a connected, second countable and metrizable three-manifold without boundary.

Proof Being homeomorphic to $\mathbb{R}^3$ (by Theorem 6.4), every $\sigma(x_i, z_i)$ is connected and Lindelöf. Hence by Postulate 6.6 $\langle B, \tau \rangle$ is connected and Lindelöf. Now, every regular Lindelöf space is paracompact and every paracompact locally metrizable space is metrizable. Therefore $\langle B, \tau \rangle$ is connected, Lindelöf and metrizable. Finally $\langle B, \tau \rangle$ is second countable because, in metrizable spaces, the properties of being Lindelöf and of being second countable are equivalent. [For these notions see e.g. Gaal (1964).]

In other words, physical space is a three dimensional connected manifold. And, because Σ is metrizable, the physicist may assign it an adequate metric. We shall of course abstain from doing so because our goal was to build a concept of physical space broad enough that it can be used in the axiomatic foundations of any of the current physical theories. (Besides, the theories of relativity have taught us that any attempt to assign space a metric, independently of time, is bound to fail: only spacetime can be assigned the proper metric.)

This completes our justification of Postulate 6.3, that $\Sigma = \langle B, \tau \rangle$ represents physical space. But why should we have required Σ to have precisely the properties postulated or deduced in the present subsection? Why could we not hypothesize an entirely different set of properties of physical space? The answer to these questions depends upon the relation of one's philosophy with science, hence indirectly with reality.

In an a priori philosophy, physical space can be assigned any structure whatsoever. For example one could postulate – as Whitehead (1919) and Lucas (1973) have done – that physical space is globally euclidean. But in a philosophy that seeks to be continuous with science no such freedom exists. In any science-oriented philosophy one requires the geometry of ordinary space to agree with physics. Moreover one lets physics have the upper hand because physicists, not philosophers, are competent to decide on matters of the fine structure of physical space.

Now, physics happens to assume that physical space is a three-dimensional differentiable manifold. (See e.g. Trautman, 1965.) This is necessary to write down the basic equations of contemporary physics, though usually insufficient to solve them. (We disregard the speculative deviant theories. If any of them were shown to be true then we would have to change our geometry.) Surely most theories require some additional structure. For example classical mechanics and non-relativistic quantum mechanics require ordinary space to be globally euclidean, classical electrodynamics requires it to be an affine space, and the relativistic theory of gravitation assumes that space is riemannian. But the assumption common to all of these specifications is that physical space is a three-dimensional manifold. This being the minimal geometrical assumption, it should be a necessary and sufficient constraint for philosophy – until further notice. (Recall Rule 10 of the method of scientific ontology: Introduction, Sec. 4.)

The geometry described in the present subsection is then compatible with the mainstream of contemporary physics. A new physics might call for a new protophysical (or ontological) geometry. Two radical changes of the sort have been suggested a few times. One is that the spatial generalized continuum may have to be replaced by a discontinuous or atomic space with a fundamental length built into it. (This hypothesis is suspect because it usually has an operationalist motivation, namely the impossibility of measuring distances below a certain value, say 10^{-11} cm.) Another possibility is that our current metrics may be sorts of statistical averages of stochastic metrics describing a fluctuating spacetime. (This other hypothesis is far more plausible in view of the zero-point fluctuations of the electromagnetic field.) However none of these ideas seem to have been carried beyond the hand-waving stage. The fact is that the theories actually employed by physicists make no assumptions about physical space contradicting our results.

In sum, we may declare our ontological geometry true because contemporary physics says so. But at the same time we should be prepared to see it revised or even revolutionized by new developments in physics.

2.4. *Bulk and Shape*

Now that we have grounds for modelling physical space as a manifold we can use the latter to determine the bulk and shape of things. First we exactify the notion of the *place occupied by a thing*:

DEFINITION 6.6 Let the three-manifold $M^3 = \Sigma = \langle B, \tau \rangle$ represent physical space. Then the function $\beta\colon \Theta \to 2^{M^3}$ from things to regions of space is called the *bulk*, and its value $\beta(x)$ at $x \in \Theta$ the *bulk of* x, iff

(i) β is injective;
(ii) for every thing x other than the null thing, $\varnothing \subset \beta(x) \subseteq M^3$;
(iii) for all $x, y \in \Theta$, $\beta(x \dotplus y) = \beta(x) \cup \beta(y)$.

The first clause makes room for things, such as photons, that can share the same region of space. The second states that every real thing has a nonempty bulk – even if, as in the case of the mythical point particle, the bulk consists of a single point of space. The third, that β is additive. The three clauses together elucidate the notion of *room* or *space occupied by a thing*.

None of the above conditions presupposes or implies that all things have sharp boundaries: so far as Definition 6.6 is concerned, a thing can have "colonies", i.e. pieces outside its main bulk. Consequently nothing is implied about the measure of the bulk of a thing. Questions of measure are specific scientific questions answered by computing or measuring volumes not bulks. (And volumes, unlike bulks, depend on the interactions among the components, as well as on the reference frame.) On the other hand Definition 6.6 allows one to compare bulks. Indeed if x and y are things then we can say that x is *bulkier* than y just in case $\beta(x) \supseteq \beta(y)$.

The concept of bulk allows us to define that of shape:

DEFINITION 6.7 Let $x \in \Theta$ be a thing with bulk $\beta(x) \subset M^3$. Then x has *shape* f iff the boundary $\partial\beta(x)$ of $\beta(x)$ is homeomorphic to a piece-wise smooth function $f\colon \mathbb{R}^2 \to \mathbb{R}$.

Remark 1 The values of the shape function f depend upon the choice of reference frame, hence of coordinate system. Hence shape is frame-dependent rather than frame-invariant. (Recall the flattening of a sphere into an ellipsoid relative to a moving frame.) *Remark 2* Shape is not a universal property of things. For example electrons have no shape of their own – or, if preferred, they acquire the shape of whatever macrophysical body contains them. Nor do porous bodies and gaseous bodies have a definite shape of their own. Therefore we cannot regard shape as a basic property of all things. Hence we cannot adopt Descartes' program of explaining the world in terms of *figures et mouvements* only. *Remark 3* Shape, hardly a property of basic things, emerges rather definitely at the macromolecular level and becomes the more definite, the bulkier the thing. It is therefore a derivative property. Moreover it emerges from nongeometric characteristics. Thus the helicoidal configuration of a DNA molecule results from chemical forces such as the hydrogen bonds between an NH group and a carbonyl group, and it is influenced by the environment of the molecule – to the point that the pattern disintegrates at high temperatures. Likewise the shape of a macrobody is determined jointly by the inner stresses and the external forces. In general, shape or geometric pattern, when it exists at all, is an outcome of the interplay of internal forces and environmental constraints. *Remark 4* Although shape is a secondary property, once acquired it conditions the acquisition or loss of further properties, which are called *steric properties*. Suffice it to recall that the specific activity of enzymes depends upon their shape.

2.5. *Concluding Remarks*

We have obtained a solution to the problem we set out to solve, namely that of building a theory of physical space based on the concept of a changing thing. This does not mean that changing things are more fundamental than space: only the corresponding categories are ordered. Ours is then a full fledged relational theory – not just a program – and moreover one based on general ontological ideas and couched in strictly objective terms, as enjoined by Rule 7 of our philosophical methodology. (See Introduction, Sec. 4.)

However, ours is not the only possible relational theory of space. For example there is Basri's (1966) theory. But we rejected it in Sec. 1 for being a particle theory and therefore inconsistent with field physics, and also for being subjectivist, hence inconsistent with the epistemology inherent in the scientific approach. There is also Penrose's (1971) equally rigorous and moreover objectivist relational theory of space. But, because it is based on the concept of angular momentum, it is not general enough to serve as a foundation for all physical theories. On the other hand our own theory is based on extremely general ideas.

Our theory has one seemingly unsatisfactory feature, namely that it postulates the three-dimensionality of space instead of explaining it. (The hypothesis is contained in Postulate 6.5.) This assumption may seem arbitrary. Actually it is not, for it is suggested by the actual behavior of real things: if things were different then physical space might not be three-dimensional. In other words, the three-dimensionality of space is rooted in the laws of things. What would the dimensionality of physical space be if things possessed ("obeyed") laws different from those we know? This question can receive a partial answer, namely along the following lines. (For a detailed investigation see Penney (1965).) Take for instance the pervasive processes of propagation of waves of various kinds and write out any wave equations in spherical coordinates in an n-dimensional manifold. Any such equation will contain a radial term with a factor $(n-1)$. So, if experiment were to show that wave propagations proceed according to say, $n=4$, then we would have to conclude that physical space is four-dimensional. But of course this is not the case. In short experiment points, in however devious a fashion, to the three-dimensionality of ordinary space. (Note by the way that, on a nonrelational theory of space, one would ask instead the question: 'What would things look like if space were not three-dimensional?' But this question cannot be answered except dogmatically.) Hence in postulating that space is three-dimensional our ontology bows to experience, just as Peirce wanted.

What would become of space if all things were to go out of being? The answer is provided by the separation function (Definition 6.1). Since σ is defined only for pairs of things, and its values are sets of things, unless there are (changing) things there is no physical space, hence neither a relational philosophical geometry nor a physical geometry. That is, a hollow universe would be spaceless. Likewise a block universe, such as Parmenides' undifferentiated One, would be spaceless.

This corollary of our philosophical geometry has some bearing on the interpretation of the relativistic theory of gravitation. What happens if the matter tensor in the gravitational field equations is set equal to zero everywhere? Sure enough the solutions characterize a riemannian manifold: there would seem to be space even in the absence of things (particles, fields, etc.). Is this a physically possible solution? Not on our geometry: here, if there are no things, none of the relations among points in the manifold is a real relation. The relations involved in a riemannian geometry (e.g. the distance relation) become real to the extent that they are satisfiable by things. In short, the homogeneous equations of gravitation, corresponding to a hollow universe, are physically meaningless. (For the notion of factual content see Vol. 1, Ch. 5, Sec. 3 of this *Treatise*.) It is nice to see that ontology can be of some use to science.

Ordinary space, then, is just as real as any other real relation. (Actually space is not a relation but a set of related things or, if preferred, a relational structure: recall Definition 6.2.) But, not being a thing, physical space has no causal efficacy. In other words, the spatial relations are nonbonding relations rather than bonds or couplings. (For the concepts of bonding and nonbonding relations see Ch. 5, Sec. 4.1.) That is, just as things do not act upon space (since space is not a thing), so space does not react back on things. This is one point our theory shares with Newton's absolute view.

To the practising physicist, who takes space for granted, space is basic and things are somehow embedded in or superimposed on space. To the philosopher upholding a relational doctrine of space, neither is the more basic. In particular, on our theory things come with their mutual separations, hence neither is prior to the other: there is neither a thingless space nor a spaceless thing. This is of course in sharp contrast to the container view of space, according to which space, though not a thing, exists by itself and independently of the things it contains. According to our theory neither space nor things exist by themselves. Only mutually spaced things exist.

Moreover, the separations or spacings among things may alter with changes in the things themselves. Hence real space is as much in flux as are things. Real space is then a dynamic structure of the collection of things. Ordinary space may be pictured as an elastic net, or fluctuating lattice, the nodes of which are things. But temporality belongs in the next section.

3. Duration

3.1. *Intuitive Idea*

A duration is the duration of some event or process: a changeless universe would be timeless. Just as space is the spacing of things (Sec. 2), so time is the pace of events. (Aristotle, *Physics* IV, 11, 220a 25, called time *arithmós kinéseos*, the measure of motion.) And just as spatial distance is the separation among things, so temporal interval is the separation between different states. This is the intuitive germ of the relational theory of time.

To get an idea of this theory consider a world consisting of a single thing the states of which can be mapped on the set of natural numbers: it can be a clock or a heart. The history of such a heart is, roughly, the sequence of its heart-beats; and the life span of the heart is the total number of its heart-beats. Since there are not other hearts (or clocks) in our imaginary universe, there is no question of slowing down or quickening the pace of the heart-beats – not even of missing a heart-beat now and then. The heart-beats generate a uniform or well tempered time – i.e. same intervals between beats. The time coordinate attached to this clock is a function $t: B \to \mathbb{N}$, where B is the set of heart-beats and $\mathbb{N}$ that of natural numbers, such that $t(b) = n \in \mathbb{N}$ for $b \in B$. We interpret '$t(b)$' as the time at which b occurs. This function determines the time lapse function

$$\tau: B \times B \to \mathbb{N} \quad \text{such that } \tau(b, b') = |t(b) - t(b')| = |n - n'|$$

for $b, b' \in B$. (Clearly, the structure $\langle B, \tau \rangle$ is a metric space.) If the heart stops beating altogether then both t and τ lose their support and time ceases to "exist", i.e. the temporal relations cease to be real (to hold among real events). If we now multiply the number of time keepers it becomes possible to compare their paces and eventually to pick the most regular among them. But this is a technical point of interest to physics and astronomy rather than ontology. So much for the intuitive background.

3.2. *Before and After*

On a relational theory of time we cannot accept a purely mathematical characterization of time – e.g. as the ultimate independent variable, or as the parameter of a one-parameter continuous group of transformations. In other words there is no such thing as mathematical time in our ontology: there are only mathematical representations of time. (See however Whitrow (1961) for the concept of mathematical time.) Mathematics, unlike mathematicians, is alien to time: constructs are neither changeable nor mutable (Corollary 5.1 in Ch. 5, Sec. 1.2); hence they are neither in time nor out of it. Nor would a definition of time in terms of the bare individuals of Ch. 1 do, because no state space and a fortiori no event space can be defined for them. We need the concept of a changing thing, hence that of state, if we are to define duration as a sort of distance between states.

Our starting point is then the concept of a lawful state space for a concrete object, or thing, of any kind. (Recall Ch. 3, Sec. 2.5.) In Ch. 5, Sec. 2.5, we saw that the states of a thing can be ordered by reference to those of a standard thing or reference frame, such as a clock mounted on a ruler. That was an *extrinsic* order, i.e. one induced on the thing states *ab extrinseco* by the natural or intrinsic ordering of the reference states. But actually any thing can serve as a clock even though only a few things are good clocks. In other words, the states of every thing are ordered. Because this order is intrinsic and independent of the kind of thing, we are justified in identifying it with temporal order. More explicitly, we assume the *intrinsic* time order of thing states:

POSTULATE 6.7 For every basic thing $x \in B$ and every lawful state space $S_{\mathbb{L}}(x)$ for x, there is exactly one ordering relation $\leqslant$, connected in $S_{\mathbb{L}}(x)$, such that, for any $s, s' \in S_{\mathbb{L}}(x)$,

$$s \leqslant s' \quad \text{iff} \quad s' = g(s), \quad \text{where} \quad g\colon S_{\mathbb{L}}(x) \to S_{\mathbb{L}}(x)$$

is a really possible (lawful) transformation of $S_{\mathbb{L}}(x)$, i.e. one representing a lawful change of x.

This assumption acquires a precise ontological sense by virtue of its semantic partner:

POSTULATE 6.8 The set $S_{\mathbb{L}}(x)$ of states of any basic $x \in B$ is *ordered temporally* by $\leqslant$. Furthermore for any $s, s' \in S_{\mathbb{L}}(x)$

(i) s *precedes temporally* s' iff $s \leqslant s'$;

(ii) s is *simultaneous with* s' iff $s \leqslant s'$ and $s' \leqslant s$ (i.e. $s \sim s'$).

The basic temporal relations have been defined only for the states of a single thing. So far we do not have any concept of temporal relations between states of different (in particular distant) things. It will also be noted that the preceding elucidations depend upon the notion of lawful change but not upon that of causation. Our postulates allow for temporal relations in a stochastic universe, i.e. one in which every single law is stochastic. Causality is sufficient for temporality and it may be necessary to *ascertain* which events precede which, but it is not necessary for the relations of before and after to *obtain*. The relation between precedence and causation is this:

For all events e and e', if e causes e' then e precedes e'.

But the converse is false. Hence precedence in time is not definable in terms of causation, nor is the converse move possible. (See Bunge, 1959.) Therefore our theory of time, though relational, is not causal – unlike the theories of Robb (1914, 1921, 1936) and Reichenbach (1928, 1956). Ours is a nomological rather than causal theory of time.

The equivalence relation $\sim$ introduced by Postulate 6.8(ii) effects a partition of $S_{\mathbb{L}}(x)$ into the states which are simultaneous and those which are not. The latter are related either by the *before* relation $<$ or by the *after* relation $>$. However, if we were to consider a rather bulky thing rather than a basic component (or member of B), there might appear pairs of states which are neither simultaneous nor related by $<$ or by $>$. Such would be the states of components of a thing not connectible by light waves. This is one reason for defining temporal relations on B rather than Θ.

We can now clarify the notions of present, past, and future of a basic thing:

DEFINITION 6.8 Let $S_{\mathbb{L}}(x)$ be a state space for a basic thing $x \in B$, and call $s_0 \in S_{\mathbb{L}}(x)$, a distinguished state of x, the *origin* or *zero* state. Then

(i) the *present* of $x =_{df} \{s \in S_{\mathbb{L}}(x) | s \sim s_0\}$;
(ii) the *past* of $x =_{df} \{s \in S_{\mathbb{L}}(x) | s < s_0\}$;
(iii) the *future* of $x =_{df} \{s \in S_{\mathbb{L}}(x) | s > s_0\}$.

Obviously, we are free to choose the origin s_0 and may call it *now* if we want to – provided we do not insist that this word designates the egocentric "now". Indeed, s_0 may be chosen to be the beginner of a process in the thing concerned, and all interested observers may agree on this choice for the sake of convenience. This, *pace* Hugo Bergmann (1929) and Grünbaum (1967), does not entail that becoming is unreal, hence temporal order conventional. Likewise the relativity of the splitting of states into present, past and future, to a given thing (in the above the very thing whose states are being partitioned) implies no subjectivity. Relativity and parochialism – as shown by the special choices of thing and of initial state – are one thing, subjectivity another.

The relativity of temporal orderings to things cannot be remedied: the two theories of relativity – the special and the general – have taught us that every thing has its proper time, so that there is no universal time. (There would be one if the universe were to pulsate as a whole – but this it does not.) In other words *there is no absolute or thing-free time.* This is a generalization of the statement in relativistic physics, that time is relative to some reference frame or other. We feel justified in making that generalization because, as noted before, almost anything can be regarded as a clock since all things are assumed to tick in some way or other. Of course some things tick more regularly than others and therefore make better clocks. But this is a matter for metrologists, astronomers, and atomic physicists, not for ontologists. From the point of view of ontological principles any thing the states of which are ordered in a certain way qualifies as a clock, whether or not it is actually used as such. The order in question is the strict partial order, i.e. asymmetric and transitive, so that no two states are simultaneous. Therefore we adopt

DEFINITION 6.9 A thing $f \in \Theta$ is a *potential clock* iff every one of its state spaces $S_{\mathbb{L}}(f)$ is strictly partially ordered.

DEFINITION 6.10 Let f be a potential clock with state space $S_{\mathbb{L}}(f) = T_f$. Then

(i) T_f is called the *time span* of f;
(ii) any interval of T_f is called an *f-moment*; and
(iii) any member of T_f is called an *f-instant.*

Each thing, and in particular each clock, ticks its own way. However, things are not monads: recall Postulate 5.10 in Ch. 5, Sec. 4.1. That is, every thing is connected with other (though by no means with all) things. And some such connections or couplings are of the physical information kind, so they can establish relations among the local temporal orderings. (For example, if two bodies move with constant velocity relative to one another then their time coordinates are related by a Lorentz transformation.) This gives us a revised notion of temporal universality: time orders are universal not because they are the same for all things – which they are not – but because they are mutually translatable within bounds. The kind of translation is specified by the following convention and the subsequent axiom.

DEFINITION 6.11 Let $f \in \Theta$ be a potential clock [Definition 6.9] with state space $S_{\mathbb{L}}(f)$ and $x \in \Theta$ any thing connectible with f, with state space $S_{\mathbb{L}}(x)$. Then

(i) an *f-time assignment* to the states of x is an injection

$$\varphi_f: S_{\mathbb{L}}(f) \rightarrow S_{\mathbb{L}}(x);$$

(ii) an f-time assignment φ_f is *faithful* iff, for any $t, t' \in S_{\mathbb{L}}(f)$,

$$t \leqslant t' \Rightarrow \varphi_f(t) \leqslant \varphi_f(t').$$

The next axiom ensures that time assignments are always possible, so that every potential clock can be "utilized" by any thing connectible with it:

POSTULATE 6.9 Let $x \in \Theta$ be any thing. Then there exists a potential clock $f \in \Theta$ and a faithful time assignment φ_f: $S_{\mathbb{L}}(f) \to S_{\mathbb{L}}(x)$.

In other words, the states of any thing can be ordered by the (reference) states of a potential clock connectible with the given thing.

So much for time order and its universal translatability (universal within bounds). We proceed now to build the concept of duration.

3.3. *Duration*

Relativistic physics teaches that durations are frame-dependent. Any given process in a thing has as many durations as there are (inequivalent) potential clocks connectible with the given thing. (And the shortest of all such durations is the one relative to the thing itself or to a frame attached to it. That is, the shortest duration is the so-called *proper* duration, i.e. the one relative to the thing undergoing the process of interest.) Therefore our ontological theory of time must take into account the relativity of duration.

We assign each event or process in a thing a collection of contiguous reference states, i.e. an interval of the time span of a clock. (See Figure 6.5.) The assignment is made by

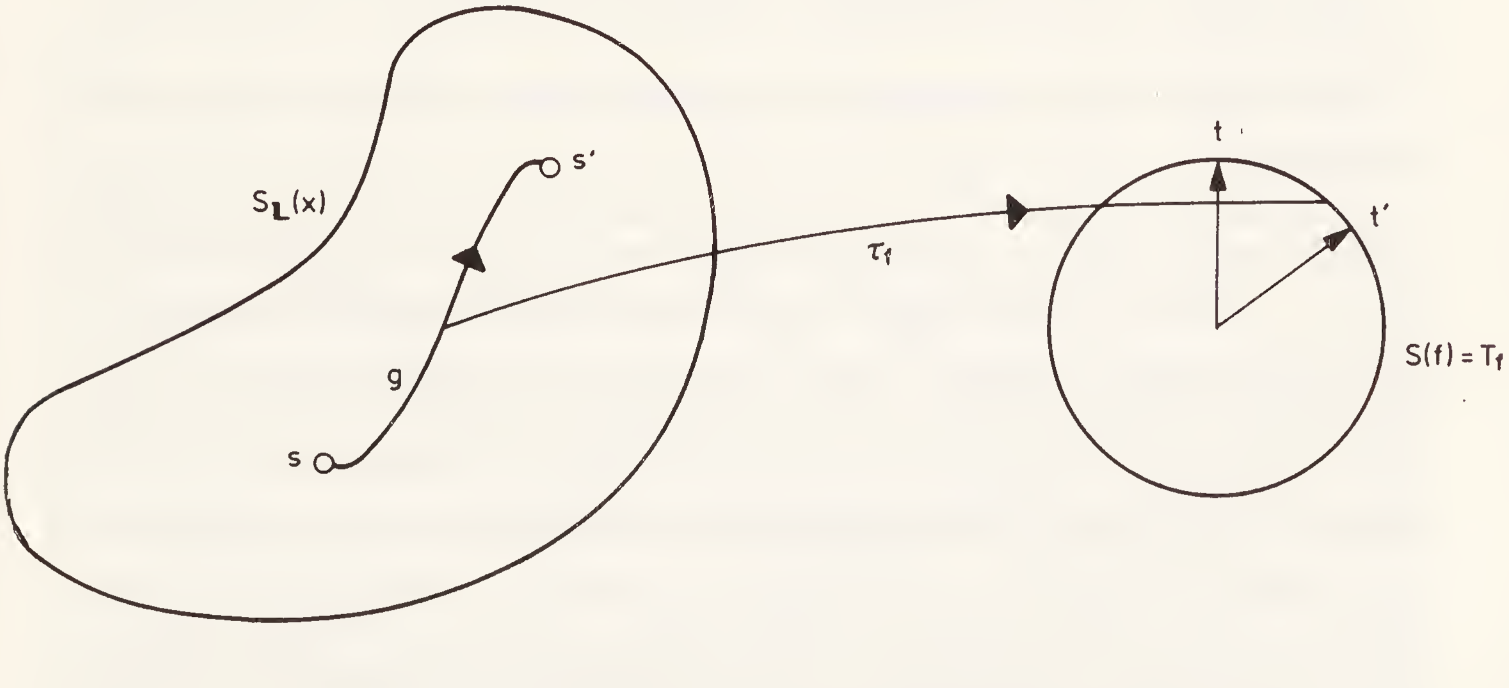

Fig. 6.5. The process $\langle s, s', g\rangle \in E_{\mathbb{L}}(x) \subseteq S_{\mathbb{L}}(x) \times S_{\mathbb{L}}(x)$ in thing x is assigned the interval $[t, t'] \subset T_f$ of reference states.

DEFINITION 6.12 Let T_f be the time span of a clock f and let $E_{\mathbb{L}}(x) \subseteq S_{\mathbb{L}}(x) \times S_{\mathbb{L}}(x)$ be an event space for a thing x connectible with f. The *duration relative to f*, or *f-duration*, is the function

$$\tau_f \colon E_{\mathbb{L}}(x) \to 2^{T_f}$$

from events to intervals of reference states such that, for any events $e = \langle s, s', g \rangle$, $e' = \langle s'', s''', h \rangle \in E_{\mathbb{L}}(x)$, where g and h are lawful transformations of $S_{\mathbb{L}}(x)$,

(i) if $s \sim s'$ then $\tau_f(e) = \varnothing$;
(ii) if $s < s'$ or $s' > s$ then $\tau_f(e) \supsetneq \varnothing$;
(iii) if e and e' compose to form $e'' = \langle s, s''', g \circ h \rangle \in E_{\mathbb{L}}(x)$, then

$$\tau_f(e) \cup \tau_f(e') = \tau_f(e'')$$

$\tau_f(e)$ is called the *duration* of e relative to f.

The duration function enables us to define in a precise (yet still nonquantitative) manner a number of notions in wide usage:

DEFINITION 6.13 Let τ_f be the duration function associated with a clock-thing pair $\langle f, x \rangle$. Then for any two events $e, e' \in E_{\mathbb{L}}(x)$ occurring in thing x,

(i) e is *instantaneous* (or a *point event*) iff $\tau_f(e) = \varnothing$;
(ii) e is *temporally extended* (or *takes time*) iff e is not instantaneous;
(iii) *e lasts just as long as e'* relative to $f =_{df} \tau_f(e) = \tau_f(e')$;
(iv) *e lasts longer than e'* relative to $f =_{df} \tau_f(e) \supset \tau_f(e')$;
(v) e and e' are *temporally contiguous* relative to $f =_{df} \tau_f(e) \cap \tau_f(e') \neq \varnothing$;
(vi) e and e' are *temporally detached* iff they are not temporally contiguous.

An identical transition $s \mapsto s$, or nonevent, is of course trivially instantaneous. But it may also happen that $\tau_f(s, s', g) = \varnothing$ even if $g(s) \neq s$. That is, there might exist instantaneous proper events, i.e. genuine changes taking no time. Whether such changes exist we do not know and we need not know for building our theory of time, because the values of the duration function are intervals between $\varnothing$ and T. Hence we do not face the difficulty met with by alternative theories of time – such as Russell's and Whitehead's – based on the assumption that all events are analyzable into point (instantaneous) events. (This is a difficulty because, according to the quantum theories, there are temporally extended elementary events.)

We have now all we need to state in a precise fashion the gist of the relational theory of time:

DEFINITION 6.14 Let x be a thing and $E_{\mathbb{L}}(x)$ an event space for x. Further, let τ_x be the duration function relative to x. [I.e., x is now its own reference frame or clock.] Then the ordered couple $\langle E_{\mathbb{L}}(x), \tau_x \rangle$ is called the *local time* in (or relative to) x.

If $E_{\mathbb{L}}(x)$ were to shrink to nought, i.e. if x were immutable, the duration function would lose its support and there would be no time left. In other words we infer

COROLLARY 6.3 There is no time where there are no changing things.

Hence we are justified in calling a thing *timeless*, or out of time, just in case it is unchanging. But by Postulate 5.11 in Ch. 5, Sec. 4.1 there are no immutable things. Hence there are no timeless things. Therefore if anything looks timeless then it has been improperly investigated.

We emphasize that, since $E_{\mathbb{L}}(x)$ is the set of lawful events in thing x, our time concept hinges on the notions of thing, change, and law. In a chaotic (i.e. lawless) thing there would be no time. (Remember the distinction between stochastic orderliness or regularity, on the one hand, and chaos on the other: cf. Ch. 4, Sec. 6.3.) If we can discern temporal relations even in an arbitrary set of events, such as those composing a slice of our experiential stream, it is only relative to some set of regular events such as those of our biological clock.

Note also that Definition 6.14 allows for as many times as there are things. The assumption that all these times are the same, i.e. that the pace of events is the same relative to all things, is the hypothesis of *universal time*. We do not adopt this assumption because we wish our metaphysics to be compatible with physics, and the latter admits only local times. However, a relational theory of time including the universal time hypothesis would still be rela*tional* though not rela*tivistic*.

So far our concepts of time are qualitative. We can easily metrize the concept of duration provided we borrow from the foundations of physics the concept of a chronometric scale-*cum*-unit system. Indeed, the precise measure of a duration depends upon the way the successive stages of a process are assigned numbers, i.e. on the chronometric system. Moreover since time units – like all units – are conventional, they can be generated *ad libitum* to form a whole set U_t. Reckoned on a certain time unit $u \in U_t$, the duration of an event $e = \langle s, s', g \rangle$ in a thing x, relative to a clock f, can be taken to be the value, at $\langle e, u\rangle$, of a certain function T_f to be defined presently, i.e. $t = T_f(e, u)$. This function is characterized by

DEFINITION 6.15 Let f be a clock and x a thing, possibly the same as f, with event space $E_{\mathbb{L}}(x)$. Further, let τ_f be the duration function for the given pair $\langle f, x\rangle$. Then the corresponding *metric duration* is the mapping

$$t_f: E_{\mathbb{L}}(x) \times U_t \to \mathbb{R}$$

satisfying the conditions that, for any fixed unit $u \in U_t$ and any two events $e = \langle s, s', g\rangle$, $e' = \langle s'', s''', h\rangle \in E_{\mathbb{L}}(x)$,

(i) $t_f(e, u) \geqslant 0$ iff $\tau_f(e) \supseteq \varnothing$;

(ii) if e and e' compose to form $e'' = \langle s, s''', g \circ h\rangle \in E_{\mathbb{L}}(x)$, then

$$t_f(e, u) + t_f(e', u) = t_f(e'', u).$$

Clearly, metric durations are frame-dependent, which is in keeping with relativistic physics. Note also that clause (i) does not exclude negative durations but states only that, if state s precedes state s', then the duration of this event is non-negative.

Clearly, for every $u \in U_t$, the structure $\langle E_{\mathbb{L}}(x), t_f\rangle$ is a metric space. This justifies our calling $t_f(e, u)$ the *metric duration* of event e, relative to frame f, in units u.

We derive a couple of immediate consequences. First

COROLLARY 6.4 The duration of a point event is nil: for any frame f, If $\tau_f(e) = \varnothing$ then $t_f(e, u) = 0$ for any $u \in U_t$.

Proof By clause (ii) of Definition 6.15 applied to the case of identical change or improper event. In fact in this case $2t_f(e, u) = t_f(e, u)$, whence $t_f(e, u) = 0$.

COROLLARY 6.5 The metric duration is an oriented interval [or directed set]: for any frame f, any unit $u \in U_t$ and all states $s, s' \in S_{\mathbb{L}}(x)$ forming the conceivable events $e = \langle s, s', g\rangle$ and $e' = \langle s', s, g^{-1}\rangle$,

$$t_f(\langle s, s', g\rangle, u) = -t_f(\langle s', s, g^{-1}\rangle, u).$$

Proof By clause (ii) and Corollary 6.4 upon setting $s''' = s$.

The last consequence expresses the so-called *anisotropy* or *asymmetry* of time, about which so much nonsense has been written. There is no mystery in it and it has nothing to do with irreversible processes.

Indeed, Corollary 6.5 is just a consequence of a convention, namely Definition 6.15, which assigns positive metric durations to changes occurring in the natural order and negative durations to their conceptual inversions. (We might as well have chosen the backwards reckoning.) More on this subject in Sec. 5.1.

4. SPACETIME

4.1. *Spacetime, the Basic Network of Events*

Since Einstein's 1905 revolution, space and time have ceased to be regarded as independent: they are now treated as two aspects of a single four-manifold called *spacetime.* The separate relational theories of space and time should accordingly be replaced by a unified theory of spacetime. According to our relational point of view this formal unification is not a mere mathematical trick but formulates the idea that spacetime is generated by changing things. Before proceeding to the mathematical development let us give an intuitive idea.

Imagine a miniature universe composed of just two particles initially superposed at the origin (see Figure 6.6). All of a sudden one of the particles, call it *p*, starts moving while the other remains at 0. (Actually since there is no third thing that can function as a reference frame they just move relative to one another.) As *p* moves the edge of

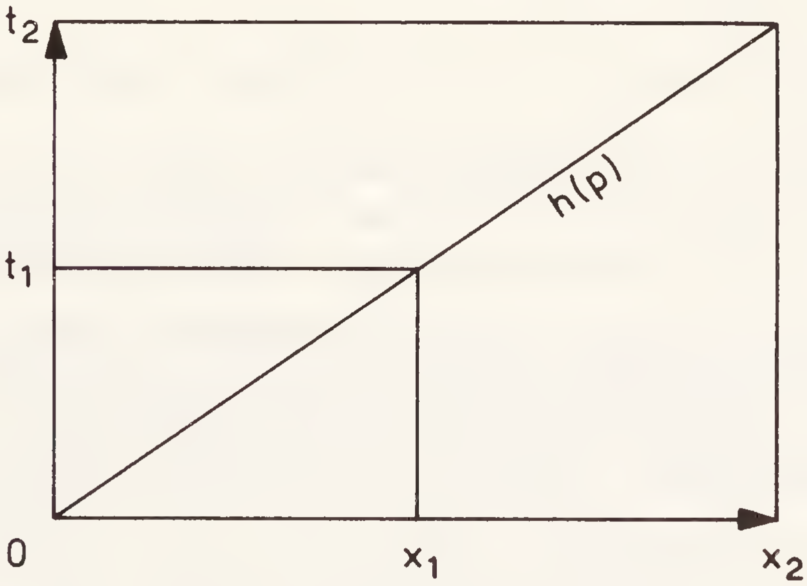

Fig. 6.6. The edge of spacetime advances as particle *p* moves away from the particle located at 0.

spacetime advances. When p reaches position x_1, spacetime covers the interior rectangle. This region expands up to the outer rectangle as p reaches position x_2. If p stops here there is no further displacement of the spacetime edge, and the outer rectangle remains frozen: the system has a past but no future.

We shall construct our view of spacetime on the basis of the concepts of event and of spatiotemporal separation between events occurring in things that may be different. Spacetime will then be defined as a certain set of events together with their spatiotemporal separations. However, this new concept of separation will be based on the concepts of thing separation (Definition 6.1) and of event duration (Definition 6.12). This strategy will allow us to advance rather quickly.

We start by defining the spatial distance between events as the separation between the things where they occur:

DEFINITION 6.16 Let $x, y \in B$ be two basic things, possibly identical, with event spaces $E_{\mathbb{L}}(x)$ and $E_{\mathbb{L}}(y)$ respectively relative to a common frame f. Moreover assume that all three things are connectible. Then the *spatial separation* between the events in x and those in y equals the separation between the corresponding things. In symbols,

$$\delta_{sf}: E_{\mathbb{L}}(x) \times E_{\mathbb{L}}(y) \to 2^B$$

such that

$$\delta_{sf}(e, e') = \sigma(x, y) \quad \text{for} \quad e \in E_{\mathbb{L}}(x) \quad \text{and} \quad e' \in E_{\mathbb{L}}(y).$$

If the things are not connectible – e.g. by signals of some kind – then the inter-event separation is not defined. And if the things coincide then the events are not spatially separated. Indeed, by Theorem 6.1(i), if $x = y$ then $\delta_{sf}(e, e') = \sigma(x, x) = \{x\}$. Note finally that the index f occurring in the event separation function is missing in the thing separation function. This is because, whereas events are relative to frames, their carriers (things) are not. Think of an emitter moving towards a stationary receiver – moving, that is, relative to a certain reference frame. The wavelength of the emitted signal differs from that of the received signal (Doppler effect). On the other hand the set of things that can interpose between the two bodies is frame-invariant.

Next we define the temporal distance between two events as the lapse between the end state of the first and the beginning state of the second. (We are presupposing here Postulate 5.8 in Ch. 5, Sec. 3.2, i.e. that every change has a beginning and an end.) More exactly, we make

DEFINITION 6.17 Let $x, y \in B$ be two basic things, possibly identical, with event spaces $E_{\mathbb{L}}(x)$ and $E_{\mathbb{L}}(y)$ respectively relative to a common frame f with states in $S(f)$. Moreover suppose that all three things are mutually connectible. Then the *temporal separation* between the events in x and those in y is the function

$$\delta_{tf}: E_{\mathbb{L}}(x) \times E_{\mathbb{L}}(y) \to 2^{S(f)}$$

such that, if $e \in E_{\mathbb{L}}(x)$ and $e' \in E_{\mathbb{L}}(y)$,

$$\delta_{tf}(e, e') = \tau_f(\text{end state of } e, \text{ beginning state of } e').$$

Now, the two separation functions δ_{sf} and δ_{tf} can be regarded as so many projections of a third function $\Delta_f = \delta_{sf} \times \delta_{tf}$ determined by the former in accordance with the following diagram:

$$\begin{tikzcd}
& E_{\mathbb{L}}(x) \times E_{\mathbb{L}}(y) \arrow[dl, "\delta_{sf}"'] \arrow[d, "\Delta_f"] \arrow[dr, "\delta_{tf}"] & \\
2^B & 2^B \times 2^{S(f)} \arrow[l] \arrow[r] & 2^{S(f)}
\end{tikzcd}$$

More explicitly, we propose

DEFINITION 6.18 Let $x, y \in B$ be two basic things with event spaces $E_{\mathbb{L}}(x)$ and $E_{\mathbb{L}}(y)$ respectively relative to a common frame f with states in $S(f)$. Moreover assume that all three things are mutually connectible. Then the function

$$\Delta_f = \delta_{sf} \times \delta_{tf}: E_{\mathbb{L}}(x) \times E_{\mathbb{L}}(y) \to 2^B \times 2^{S(f)}$$

such that

$$\Delta_f(e, e') = \langle \delta_{sf}(e, e'), \delta_{tf}(e, e') \rangle \quad \text{for} \quad e \in E_{\mathbb{L}}(x), e' \in E_{\mathbb{L}}(y),$$

is called the *spatiotemporal separation* (or *interval*).

We have now all we need to define a philosopher's relational concept of (local) spacetime:

DEFINITION 6.19 Let $B_0 \subset B$ be a set of basic things and call f a common reference frame. Furthermore suppose that all these things, i.e. $B_0 \cup \{f\}$, are mutually connectible. Finally, call E_f the event space, relative to f of the aggregation $[B_0]$ of basic things, and Δ_f the corresponding spatiotemporal separation. Then the ordered pair $\langle E_f, \Delta_f \rangle$ is called the *f-spacetime* (or *local spacetime of frame f*).

In physics a far more sophisticated structure is defined, namely a connected four-manifold M_f^4. We shall not construct M_f^4 out of the event f-spacetime. But this can be done along lines similar to those followed in Sec. 2 for building the physicist's space. In other words it is possible to map the events connectible with a frame f, and their mutual separations, on to a local spacetime chart M_f^4. And once such a chart for an arbitrary frame f has been defined, one can compose the atlas formed by all such local charts – i.e. the global or cosmic spacetime M^4.

So much for our outline of a relational theory of spacetime. Such a theory is not only relational but also compatible with relativistic physics, in that (*a*) it assumes the structure of spacetime to depend upon its furniture, and (*b*) it does not postulate a global structure. However, the theory is not *relativistic*: it does not include any of the special laws characterizing the various relativistic theories, such as for example the frame independence of the velocity of light, or the equations of the gravitational field. The relational theory of spacetime sketched above is just a component of the background of any general-relativistic theory – if one cares to add such an ontological background. Physicists usually don't: they are in the habit of postulating the four-manifold without inquiring into its roots in events. (Surely they call *events* the points of the manifold, but this is not done consistently, for such a definition presupposes a bijection between events and points in spacetime, and actually there is no such bijection, i.e. they do not mean that there is something going on at every point in spacetime.) Conversely, a relational theory of space and time may not be consistent with relativistic physics. Thus Robb's original theory (Robb, 1914), based on a set of point-like events and an absolute (frame-independent) relation of precedence, was relational but at variance with relativistic physics. In sum the theory of spacetime outlined in this subsection is relational and compatible with relativity but not relativistic. Only relativity is relativistic; and it is also relational provided it is explicitly based on a relational theory of spacetime.

4.2. *Position in Spacetime*

It is likely that events, however elementary, are not pointlike but take up nonvanishing regions of spacetime. That is, the event space E_f associated with a frame f ought to be mapped on the power set of the four-manifold M_f^4 rather than on M_f^4 itself. However, we may pretend, for the sake of simplicity, that events are pointlike, so that each event $e \in E_f$ can be assigned a point p in the corresponding local chart M_f^4. We shall make this simplifying assumption here because we are concerned only with clarifying certain ideas. The refinement is left to the reader.

We assume then that the event spacetime E_f can be mapped on a chart M_f^4. Now, by definition of a manifold, the latter can in turn be mapped locally on a set of ordered quadruples of real numbers. Consequently by composing the two maps we can assign numbers to events. This can be called a spatiotemporal coordinatization of events. The gist of it is shown in Figure 6.7, where 'N_f' designates an open subset of M_f^4.

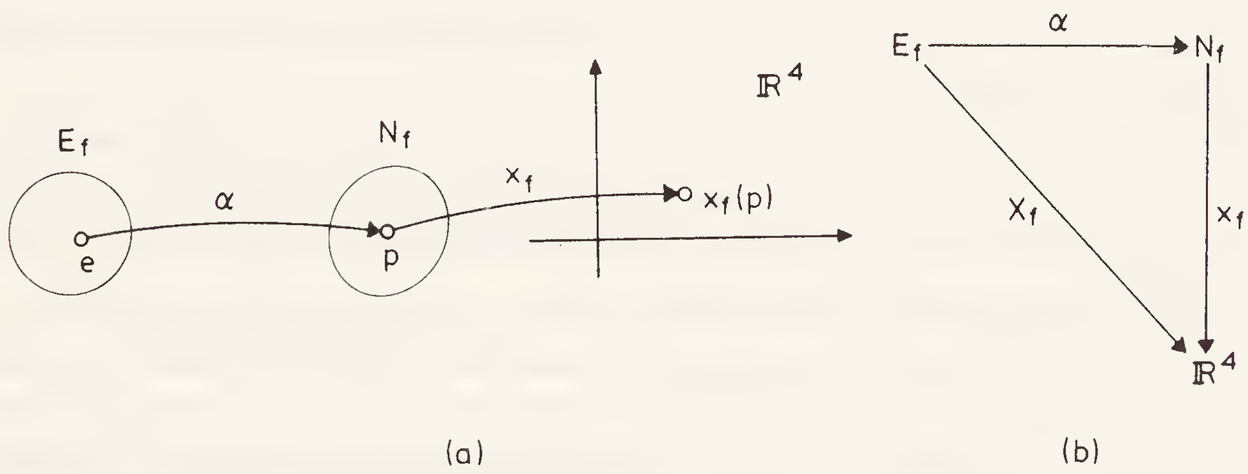

Fig. 6.7. (*a*) The mapping of the image N_f of E_f onto numbers and (*b*) the composition of the maps α and x_f to form the map X_f. The latter is a physical coordinate while x_f is a geometric coordinate. Whereas α is injective, x_f is bijective. Hence although every event is paired off to a quadruple of reals, the converse is false: there might be points in spacetime where nothing happens. (This is impossible according to our ontology, but scientific theories are partial and most of them do not assume that something is going on at every point in spacetime.)

In other words, for every reference frame f there is a coordinate system $\langle M_f^4, x_f \rangle$ representing f, where x_f, the local coordinate function, is a homeomorphism from an open subset N_f of M_f^4 into the cartesian space $\mathbb{R}^4$. This homeomorphism assigns each *point* $p \in N_f$ a quadruple of real numbers called the *coordinate values* of p relative to f:

$$x_f(p) = \langle x_1(p), x_2(p), x_3(p), x_4(p)\rangle, \quad p \in N_f \subset M_f^4.$$

(The choice of either of the four coordinate functions as the time coordinate is conventional, but one of them has got to be interpreted as the time coordinate.)

On the other hand the value of the composition of x_f and α, i.e.

$$X_f(e) = (x_f \circ \alpha)(e), \quad \text{where} \quad e \in E_f,$$

equals the spatiotemporal location of the *event e* relative to f. Note the difference – seldom recognized – between the geometrical coordinate functions x_f and the physical coordinate functions X_f. (The plural is apposite because for each f there are four coordinate functions of each kind.) The former locate *constructs*, the latter locate *events* represented by those constructs. Because α is not onto, X_f is not onto either, i.e. there are points and quadruples of reals that represent no events at all. But because α and x_f (hence also X_f) are functions, *every event is somewhere in spacetime* (*relative to a frame*). And because every event is a change in some thing, it follows that *every thing is at some place or other* (*relative to a frame*).

Nowadays we take it for granted that, even if space (and time) were absolute – i.e. self-existent –, position (in space and time) is not. But the idea that places are relative to frames has not been easy to come by. In all archaic and ancient cosmologies place was regarded as absolute and unique, every thing was supposed to occupy a definite place in space, and every event to occur at a moment of time likewise independent of any frame. These ideas are found not only in Aristotle but as recently as in Strawson (1959, pp. 22, 25–26). The credit for exactifying the notion of place relative to a coordinate system usually goes to Descartes. Galilei and his followers introduced the notion of a physical reference frame, which they dimly saw as representable by, though not identical with, a coordinate system. By the same token they showed that things and events have no absolute places – or, equivalently, that every single thing or event has as many places as there are reference frames, i.e. in principle infinitely many. These developments, stemming from Descartes and Galilei, disposed then of the principle that every thing and every event have or occupy a unique hence absolute place. In our own century Einstein crowned that development by demolishing the axiom that every fact happens relative to any reference frame (not just relative to the connectible frames) and consequently that it happens at a single absolute time irrespective of any frames.

Other developments that completed the demise of the *One fact-one place in space and time* principle were the following. First, Newton hypothesized that gravity can act everywhere, whence it has no unique or natural place. Second, Faraday showed that electricity and magnetism can likewise extend almost anywhere. Third, different bosons (e.g. photons) have been shown to be able to occupy the same place. Fourth, quantum mechanical things – whether particles or fields – seem to occupy no clear cut spatial regions, i.e. they have no sharp boundaries. These discoveries have refuted the old principles concerning place and have even diminished the importance of the category of place. Parallel developments in epistemology have devalued the notions of here and there, now and then. These have proved to be egocentric particulars (Russell, 1942) rather than objective items. That is, they are meaningful only in relation to a very particular reference frame, namely the self. Remove all subjects and no trace is left of here and there, now and then. Spacetime, on the other hand, is supposed to outlive the hecatomb for, *pace* Kant, it is not phenomenal.

Place in spacetime is then viewed as being relative to some reference frame or other. Being relative, location in spacetime is not an intrinsic property of things and events. And, being neither intrinsic nor causally effective, place in spacetime is not essential *per se*. In other words, coordinate values are rather arbitrary labels. What may be of importance is not the place that the mapping α assigns to an event nor consequently the relative positions of points and regions in the spacetime manifold, but rather the connections or bonds among things. In particular, it is irrelevant whether thing a is near thing b unless such nearness makes it possible for a to act upon b or conversely.

To sum up. Location in spacetime is both relative to a frame and objective. It is epistemologically important because it enables us to individuate or identify things and events that, aside from their distinct spatiotemporal location, might be equal (i.e. "only numerically distinct", as it used to be said). But spatiotemporal location is arbitrary to the extent that the choice of reference frame is arbitrary within broad bounds. Hence it is ontologically of secondary importance. So much so that the basic laws are invariant under changes in spatiotemporal position – which is a way of saying that coordinates are artifacts. But this is a matter for the next section.

4.3. *Change in Spacetime*

Change in general can be described without the assistance of any concepts of space and time: see Ch. 5. But specific kinds of change, such as change of place (relative to some frame) require of course some concepts of space and time. The very first thing to do in order to describe the motion (Aristotle's local change) of a thing is to model the latter either as a piece of space or as a chunk of spacetime (see Figure 6.8).

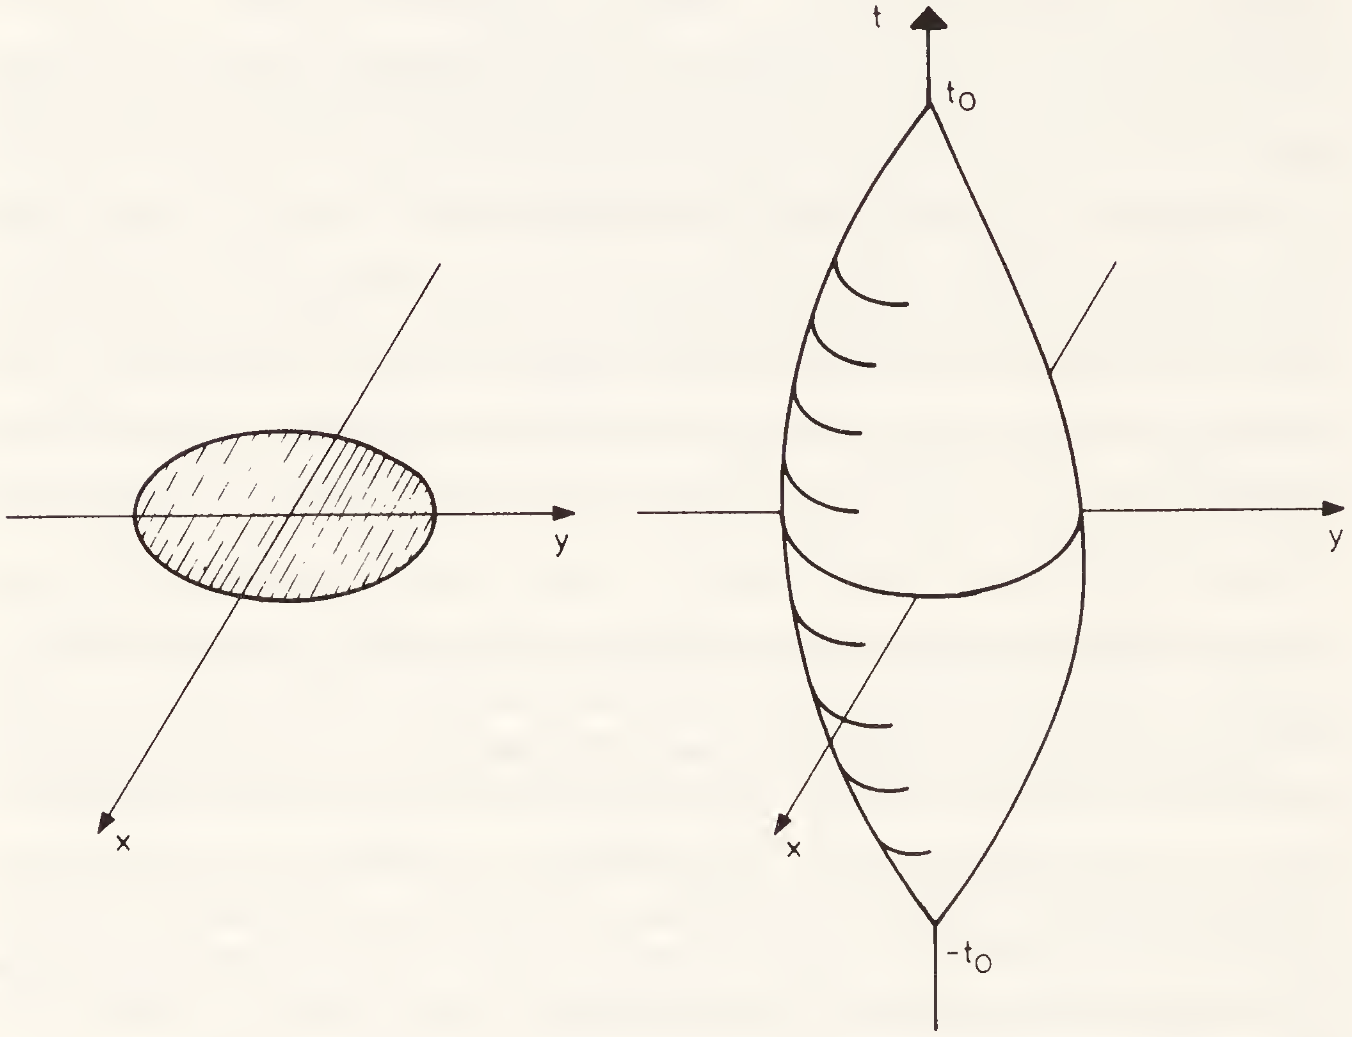

Fig. 6.8. Growth and decline of a disk-shaped thing. (*a*) Spatial representation of thing at state of greatest bulk. (*b*) Spatiotemporal representation of history of thing from birth at $-t_0$ to extinction at t_0. The thing as a whole does not move relative to the chosen reference frame.

Motion is then described as the change of place, in the course of time, of some or all of the points making up the thing – points which, unlike those of empty space, are located with the help of physical coordinate functions X_f (Sec. 4.2).

In building a model of a moving thing we start from Definition 3.6, in Ch. 3, Sec. 1.4, of a functional schema. A functional schema of a thing X

is a model thing X_m consisting in an ordered couple $X_m = \langle M, \mathbb{F}\rangle$, where M is the domain on which the state function $\mathbb{F}$ is defined. The latter is usually frame-dependent and it consists in an n-tuple of functions, usually real valued ones. We obtain a mechanical model if we equate M with space, or with spacetime, and some of the components of $\mathbb{F}$ with the physical coordinates of the thing (relative to the given frame), in the sense of Sec. 4.2. The values of these coordinate functions differ from zero only at the places (in space or in spacetime) at which the thing is. More precisely, we can make

DEFINITION 6.20 Let $X_m = \langle M, \mathbb{F}\rangle$ be a functional model of a thing X relative to a reference frame f [that occurs in the very construction of $\mathbb{F}$]. This model is a *mechanical model* just in case

(i) $M = N_f \subset M_f^4 =$ the spacetime chart attached to f;

(ii) some components of the state function $\mathbb{F}$ are physical coordinates serving to locate the parts of the thing:

$$X_f\colon N_f \to \mathbb{R}^4 \quad \text{or} \quad X_f\colon N_f^3 \times T_f \to \mathbb{R}^4$$

where N_f^3 is a three-dimensional projection of N_f.

In most theories the second choice of position coordinates is available, so that a general value of the position vector would be

$$X_f(x_f, t) = \langle x, y, z\rangle \in \mathbb{R}^3.$$

Note that the physical coordinate depends upon the geometric coordinate. The values of the two functions coincide only where the thing is. It is only in very special theories, such as classical particle mechanics, that X_f depends not on x_f but only on t.

A special kind of mechanical model is that of kinematical model: here all of the state functions are physical coordinates. That is, we have

DEFINITION 6.21 Let $X_m = \langle N_f, \mathbb{F}\rangle$, with $N_f \subset M_f^4$ be a mechanical model of a thing X. This model is a *kinematical model* iff $\mathbb{F} = X_f$.

The concept of motion, or mechanical change, may be regarded as a specification of the general concept of history introduced by Definition 5.27 in Ch. 5, Sec. 3.2, as shown by

DEFINITION 6.22 Let $X_m = \langle N_f, \mathbb{F}\rangle$, with $N_f \subset M_f^4$, be a mechanical model for a thing X relative to a frame f, and call X_f the position coordinate functions in $\mathbb{F}$. Further, call T_f the time projection of the state space $S(f)$ of frame f. Then a *motion* (or *mechanical change*) *of X relative to f* is any nonempty subset of its kinematical history

$$\mu_f(X) = \{\langle t, X_f(t, x_f)\rangle \in \mathbb{R}^5 | t \in T_f\}.$$

Spacetime is so important because it is an inescapable part of the state space of any moving thing. (The two seldom coincide, for change of place often brings about changes in other properties; or conversely. It is only in extremely idealized models, such as that of the point particle, that the history coincides with the kinematical history.) Moreover whenever there is change of any kind there is also motion, if not of the whole thing at least of some of its parts. (Think of a community established in an old town: although the town does not move relative to the earth, every member of the community moves about a great deal.) This is so important and sweeping a generalization that it deserves being conferred the title of

POSTULATE 6.10 The history of any basic thing, relative to an arbitrary frame, has a nonempty projection onto the spacetime attached to the frame.

This postulate must not be mistaken for the hypothesis that all change is reducible to motion. This other thesis, which characterizes all mechanistic ontologies, is plainly false: just think of the propagation of an electromagnetic wave or of an industrialization process. Surely the things concerned, or at least some parts of them, move in the course of such processes; but they also change in other respects. This remark too deserves being generalized and the generalization exalted to the axiom rank:

POSTULATE 6.11 Whatever changes does so in more than one respect.

The implication for epistemology is clear: no theory concerning a single type of change suffices to account for the multifarious changes of real things.

5. SPATIOTEMPORAL PROPERTIES

5.1. *Does Spacetime have any Properties*?

Spacetime is often said to have mathematical properties. According to our view only mathematical objects can have mathematical properties and, since spacetime is not such an object, it can have no mathematical properties. Not spacetime itself but rather every one of its conceptualizations, in particular the four-manifold M^4, has mathematical properties, such as that of being the carrier of continuous functions. That the distinction between spacetime and its mathematical representations is seldom made in the scientific literature should be no excuse for the philosopher's failure to draw it.

How about physical properties: does spacetime have any? On our view spacetime has no physical properties either. How could spacetime have substantial properties not being a thing but rather a (relational) property of things? Still, it is often stated dogmatically that spacetime does have certain physical properties, in particular the following three. One is that spacetime is the "carrier" of physical fields such as the gravitational field – a function formerly assigned to the ether. This is suggested by the mathematical representation of a physical field as a tensor (or spinor or vector) field over a manifold. But a mode of representation should not be identified with the object represented. Physical fields need no carrier or substrate: they are things on their own – as first recognized by Einstein. Surely we shall continue to speak of, say, the gravitational field at a given place, without however attributing places an autonomous existence nor, a fortiori, physical properties.

Another property commonly attributed to spacetime is that any given event is connectible only with events lying inside its forward light cone (see Figure 6.9). This restricted connectibility is sometimes said to be a

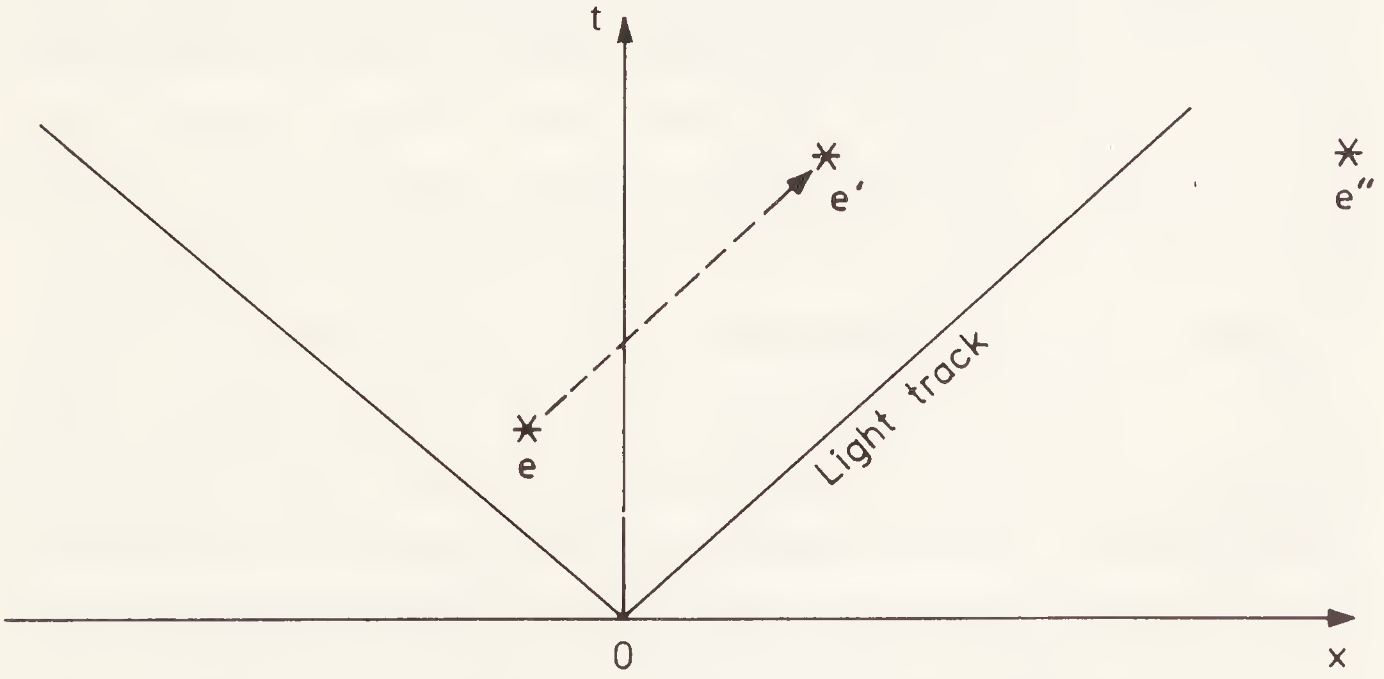

Fig. 6.9. Events e and e' are connectible, but e and e'' are not because there are no (known) superluminal signals.

fundamental property of spacetime. Yet note that (*a*) connectibility is definable as a ternary relation among physical entities, and (*b*) connectibility depends on there being things capable of moving. If superluminal entities (tachyons) were discovered we would cease to regard connectibility within just the light cone as a universal property of things and their changes

A third important instance of the attribution of physical properties to spacetime concerns the vacuum polarization postulated in quantum field theory. Actually this is not a property of spacetime but of the background field, e.g. of the electromagnetic field in its ground state, where it exists and fluctuates but has no quanta (photons).

We generalize the preceding considerations, in line with our relational view of spacetime, and state that the latter *has no properties*, and this because it is itself a property, namely the basic mesh of the sum total of changing things. It is things and their changes, as well as the patterns of either – i.e. the laws – that have spatiotemporal properties. For example a hydrogen atom in its ground state is spherically symmetric, and the development of an embryo is not time symmetric, or rather reversible – but these are properties of the things concerned not of spacetime.

An important spatiotemporal characteristic of a factual item is its absoluteness or the lack of it. Some facts, such as light emission, childbirth and industrial production, are absolute, i.e. independent of any reference frame. Others are not: for example a light detector, such as a photocell or a retina, tuned to respond to a certain wavelength band, will detect certain signals coming from a stationary source but will fail to detect the same radiation if the source moves either towards or away from the sensor. Light absorption depends then upon the reference frame. Needless to say a relative fact is as objective as an absolute one. The circumstance that the detector might belong to a living being, in particular a subjectivist philosopher, does not render the fact subjective.

Likewise while some laws are absolute others are relative to some frame. In particular all the basic laws are invariant under spatial (actually spatiotemporal) translations and rotations. That is, place and spatial orientation make no difference to the basic patterns. (Most laws are also reflection invariant, i.e. they do not distinguish between left and right, or East and West.) In other words, if a basic law obtains in a given region $m \subset M^4$ of spacetime, then it also holds in any other region $m' \subset M^4$. This principle of spatiotemporal invariance (or rather covariance) applies only to the basic laws: the derived laws need not have this property, since they may embody particular circumstances of a spatiotemporal character, such as initial conditions and boundary conditions. Another caution: the preceding principle does not entail that, if there are biological (or sociological) laws in a given region, then the same laws are also in force in any other region of spacetime, even if devoid of organisms and a fortiori of societies. The principle is satisfied vacuously by the regional laws that happen to obtain in a region but are not "exemplified" in another.

5.2. *Time Reversal and Process Reversibility*

The matter of invariance under time reversal deserves a special section because it is often misunderstood. Call π a net representing a linear chain of states of some thing, i.e. a nonbranching process (relative to some reference frame of course). Call $\tilde{\pi}$ the transpose of π, i.e. the same set of states in reverse order. For example, if $\pi = \langle s_1, s_2, s_3 \rangle$ then $\tilde{\pi} = \langle s_3, s_2, s_1 \rangle$. The given net and its transpose are related by the order reversing operator T such that $\tilde{\pi} = T\pi$. (Caution: given π and T, the transpose is uniquely determined. But in general T is not uniquely determined by π and π', i.e. the preceding equation does not define T uniquely. As it so often happens the inverse problem does not have a single solution.) The operator T is usually called the *time reversal* operator. This is a misnomer because T represents the inversion of the order of states not the reversal of time itself (see Figure 6.10). A better name would be that of *process reversal* operator.

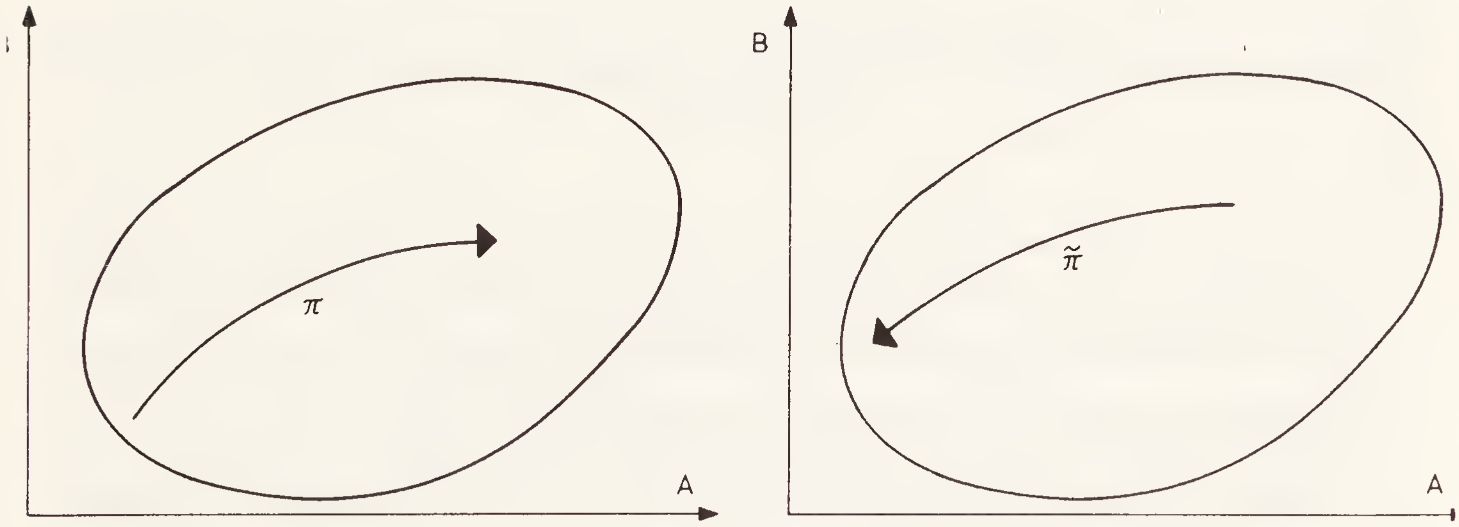

Fig. 6.10. A process π in the state space $S \subset A \times B$ of a thing and the transpose $\tilde{\pi} = T\pi$ of π. T maps the first onto the second.

The relation $\tilde{\pi} = T\pi$ between a process and its transpose can be interpreted in two different ways. A first interpretation is this: if we decide to count time intervals backwards, e.g. by using a clock whose pointers turn counter-clockwise, then we must invert the order of the states: the last state will come (temporally) before all the previous states, as shown in Figure 6.11. An alternative interpretation of the same mathematical operation of time (or rather state order) reversal is this. The transpose $\tilde{\pi}$ of π is not just a nonstandard representation of π but stands for a possible process going forward in time and traversing in reverse order the same stages as π – as when a film is projected backwards. However, this second interpretation of time reversal is legitimate only provided $\tilde{\pi}$ is lawful, which is not the case with every process. When a process happens to have a transpose going forward in time it is called a *reversible* process – otherwise it is said to be *irreversible*. (Recall Definition 5.21 in Ch. 5, Sec. 3.1.)

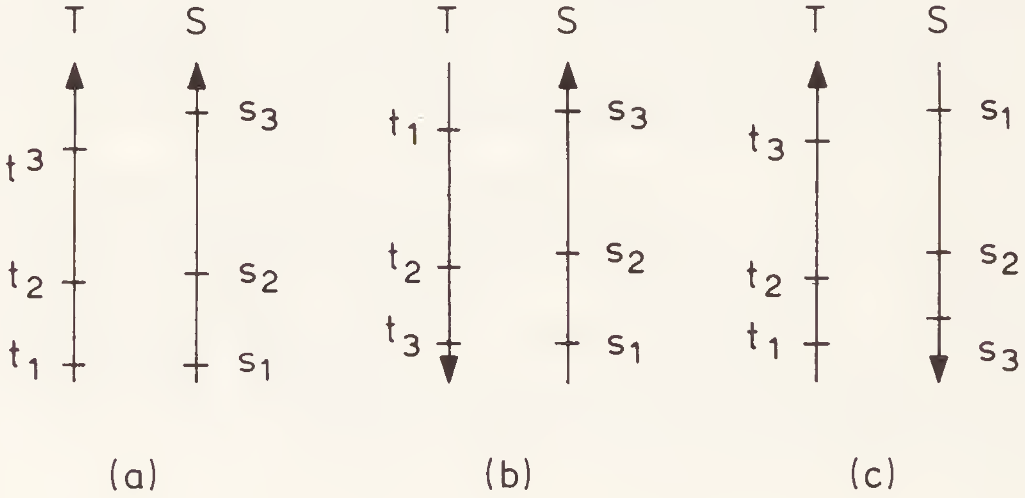

Fig. 6.11. (*a*) The standard instant-state correspondence. (*b*) The queer but possible representation of a process by its transpose. (*c*) The actual inversion of a process in case it is reversible.

If a process is reversible, the time coordinate values of its successive states afford a convenient if misleading representation. By Corollary 6.5 in Sec. 3.3, the metric duration function t_f is antisymmetric (odd) in the sense that, if s and s' belong to the same process, then $t_f(\langle s, s', g\rangle, u) = -t_f(\langle s', s, g^{-1}\rangle, u)$ for every frame f and every scale-cum-unit system u. Calling t the value $t_f(\langle s, s', g\rangle, u)$, as is usual in science, we discover the factual meaning of the inversion of the sign of t: it corresponds to an inversion of the order of appearance of the underlying states. That is, *time reversal represents process reversal*:

$$\textit{forward process } \langle s, s', g \rangle, \quad t_f(\langle s, s', g \rangle, u) = t$$

$$\textit{reverse process } \langle s', s, g^{-1} \rangle, \quad t_f(\langle s', s, g^{-1} \rangle, u) = -t.$$

Reversibility, a property of certain processes, must not be mistaken for the invariance of a basic law statement under time reversal, i.e. under the inversion of the sign of t (or, equivalently, under the T operation). Call $L(t)$ a law statement involving a time coordinate t. If $L(-t) = L(t)$, the law is said to be *T-invariant*, or invariant under time reversal. The basic electromagnetic laws (Maxwell's) are T-invariant, whereas the fundamental law of heat transfer (Fourier's) is not. The time inverse of a process described by a T-invariant law statement is just the reverse of the original (reversible) process – e.g. a motion with inverted velocities and spins. No "inversion of time" is involved even if the process can be described by exchanging t for $-t$ in the derived equations. The reverse or transpose of a reversible process goes forward in time just as much as the original process does. There is no *arrow of time* except as a misleading and overrated metaphor. The only "arrows" can be found in certain processes – namely the irreversible ones such as radioactive disintegration or ageing. Therefore the search for the origin of the arrow of time – in which many distinguished physicists have engaged – is as futile as the search for the philosopher's stone.

If a law statement fails to be T-invariant, i.e. if $L(-t) \neq L(t)$, then it concerns irreversible processes – provided the law is basic rather than derived. (E.g., whereas the equation of motion of a vibrating string is T-invariant, its elementary solution $u = a \sin(kx - \omega t)$, a derived law, is not.) The converse is false: some irreversible processes can be described with the help of T-invariant laws together with certain subsidiary conditions. For example the basic formulas of classical electromagnetism are T-invariant but, when conjoined with Sommerfeld's condition of outward radiation (exclusion of incoming waves), they describe the irreversible propagation of a retarded outgoing wave. In general a process or history is described jointly by a set of law statements and a set of constraints, initial conditions, boundary conditions, and possibly other subsidiary hypotheses representing particular circumstances of both the system and its environment. Thus radioactive processes are described by elementary quantum mechanics, which is T-invariant, together with the hypothesis that a nuclear potential barrier is semipermeable, in the sense that some nuclear particles can tunnel through it even if their energy is smaller than the height of the barrier. In sum the T-invariance of a bunch of law statements provides no indication as to the reversibility or otherwise of the process concerned: only the whole theory can supply such an indication (cf. Bunge, 1970b, 1972).

5.3. *Antecedence* (*"Causality"*) *Principle*

Contemporary physics asserts explicitly, in various forms and under the misnomer *causality condition* (or *relation*), an overriding metaphysical principle, namely clause (vii) of Postulate 6.1. This principle states that causes precede their effects or, equivalently, that the present is determined (whether uniquely or stochastically) by the past, never by the future – this relation being moreover frame invariant unlike the mere succession of states. We proceed to state this principle in terms of the property concept and shall distinguish two cases, the stochastic and the non-stochastic ones (Bunge, 1968c).

Let P_1 and P_2 be two time dependent properties of things of a certain kind K. As usual we assume that the properties are represented by functions and, more particularly, that both $F_1 \hat{=} P_1$ and $F_2 \hat{=} P_2$ are defined on $K^n \times \{f\} \times T$, where f is a reference frame, T the range of the metric duration function attached to f, and $n \geqslant 1$ a natural number. (Actually there may be more than one kind of thing, so K may have to be interpreted as a thing genus or else K may have to be split into a cartesian product.) As far as pure mathematics is concerned there are three possibilities as to the relations between the two properties:

(*a*) P_1 and P_2 are mutually independent;

(*b*) one of them depends upon the other – e.g. P_1 determines P_2;

(*c*) both P_1 and P_2 depend upon a third property, so that they are indirectly related to one another.

Here we are interested in case (*b*), i.e. that of one-sided dependence. Again, as far as pure mathematics is concerned, there are no limitations on the form of dependence. But it so happens that actually the dependence forms are restricted by a general principle according to which the value of F_2 at any given time is the outcome of the P_1-history of the thing prior to that time. In other words the dependence of any one property on another is *retarded* or *nonanticipatory*: there is no action by the future – hence no precognition, i.e. no information flow coming from future events. This fundamental ontological hypothesis can be formulated as follows:

POSTULATE 6.12 Let P_1 and P_2 be properties of a system composed of things of kind K and assume that P_1 determines P_2.

(i) If P_1 and P_2 are representable by ordinary functions F_1 and F_2 respectively, both defined on the domain $K^n \times \{f\} \times T$, then the instantaneous value $F_2(x, y, \ldots, z, f, t)$ of F_2 for $x, y, \ldots, z \in K$, relative to the frame f, is a functional G of the P_1-history of the thing up to the given instant:

$$F_2(x, y, \ldots, z, f, t) = \underset{u=-\infty}{\overset{u=t}{G}} [F_1(x, y, \ldots, z, f, u)];$$

(ii) if P_2 is representable by a random variable F_2 (whether or not F_1 is one), then the probability that, at time t, its values lie in a preassigned interval $[a, b]$ is a functional of the entire P_1-history of the thing up to the given instant:

$$Pr[F_2(x, y, \ldots, z, f, t) \in [a, b]] = \underset{u=-\infty}{\overset{u=t}{G}} [F_1(x, y, \ldots, z, f, u)]$$

Simpler forms of the preceding axiom are obtained by forgetting that all substantial properties are defined for things and are often relative to a reference frame. I.e., by calling the property-representing functions x and y respectively, the antecedence principle simplifies to

$$\left.\begin{matrix} y(t) \\ Pr[y(t) \in [a, b]] \end{matrix}\right\} = \underset{u=-\infty}{\overset{u=t}{G}} [x(u)].$$

Actually for every thing but the whole universe, the value of G will be nil between $-\infty$ and the instant t_0 of its coming into being.

About the simplest and most common functional dependence is this:

$$\left.\begin{matrix} F_2(x, y, \ldots, z, f, t) \\ Pr[F_2(x, y, \ldots, z, f, t) \in [a, b]] \end{matrix}\right\} =$$

$$= \int_{-\infty}^{t} K(t, u) \cdot F_1(x, y, \ldots, z, f, u)\, du.$$

The particular case of instantaneous dependence of P_2 upon P_1, or instantaneous action, is obtained by setting $K(t, u) = \delta(t-u)$, where δ is the Dirac delta.

The antecedence principle has interesting consequences. One of them is

THEOREM 6.6 There is no return to the past.

Proof If there were (timelike) loops in spacetime it would be possible to modify the past states of things from the future – contrary to Postulate 6.12.

In other words, time machines are impossible. If they were possible then we could land in the past and mend it so as to obtain a better present. But then we would get two different presents. One seems enough.

Note that "time travel" to the past has nothing to do with reversibility. Even a strictly reversible universe would be subject to the restriction that the past cannot be undone. So much so that the antecedence or "causality" principle is part and parcel of quantum field theory and other stochastic theories dealing with reversible processes. Nor does Theorem 6.6 have any bearing on the frame dependence of duration as exemplified by the travelling twin "paradox". The latter consists in using the expansion of duration with motion in order to land in the future of a subject who has not taken part in the trip. This consequence of special relativity is counterintuitive to anyone brought up in the tradition of absolute time; but of course it is natural in the context of the theory and moreover it has been experimentally confirmed with great accuracy. But it is of dubious ontological value except in liberating us from the absolute theories of time.

Finally a few remarks. First, the antecedence principle is sometimes stated in this form: "Whereas the future can be influenced the past cannot". Actually neither past nor future can be influenced at any given time because they do not exist at that time (relative to a given frame). 'Influencing the future' is short and misleading for "Altering the odds of the present possibilities". There is no direct action of past on future: rather than jumping across a stretch of time we must let things unfold themselves relative to each other – or, as ordinary language puts it, in the course of time.

A second remark is this: the name 'causality condition' for Postulate 6.12 is mistaken on several counts (Bunge, 1959, Ch. 3, Sec. 3.2.) For one thing the postulate applies not just to input-output relations, which sometimes are genuinely causal, but also to certain pairs of functions mirroring different traits of one and the same thing – hence to situations in which there are no input and output terminals.

Third observation: although there is no experience of anticipation – but only hallucinations of such – some theories do allow for it at their own risk. The only great theory which is partially unfaithful to the antecedence principle is classical electrodynamics, according to which an electron is accelerated by an incoming wave before the latter actually strikes it. But this is usually regarded as one of the various unsatisfactory features of the theory, not just because it is unsupported by observation but also because it contradicts the general principle of antecedence. (See Bunge, 1967b, p. 167.)

Fourth: goal-directed behavior is only in seeming contradiction to antecedence. Indeed if an organism seems to be guided by its own future states it is only because the organism is equipped to behave in such a way that it will exploit its present circumstances so as to maximize its chances of survival or increase its welfare. Even human teleology is present-guided not future-guided: an anticipation (e.g. programming) of future events is nothing but the formation, at the present time, of a mental picture of certain possible future events, in particular those we wish to bring about.

5.4. *Action by Contact*

As far as logic is concerned a thing may act upon a separate (but of course connectible) thing either directly (*action at a distance*) or through the intermediary of a third thing (*nearby action*). And in either case such an influence could be exerted instantaneously or it could take some time. (See Figure 6.12.)

Action at a distance was assumed in all of the classical atomic theories, while nearby action has been a component of the plenistic cosmologies of Aristotle, Descartes and their followers. Until the

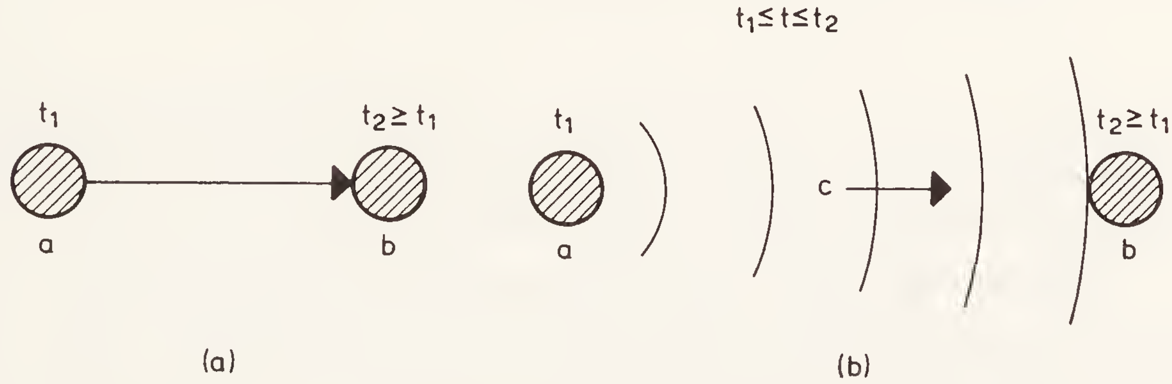

Fig. 6.12. (*a*) Thing *a* acts directly upon thing *b* (instantaneously or with some delay). (*b*) Thing *a* acts upon thing *b* through thing *c* (instantaneously or with some delay).

confirmation of the first successful field theory there was no compelling reason for preferring one of the alternatives to the other. Ever since then the hypothesis of nearby action has prevailed in every chapter of physics where interactions among different things are studied. True, corpuscularian metaphysics is still going strong among operationists who insist that we never measure anything but attributes of perceptible bodies such as the position of the hands of a clock. Here and there operationism raises its head and indicts the very concept of field, but only temporarily: it goes down every time because action-at-a-distance theories are definitely poorer than nearby action theories – in particular they cannot explain away processes which, like the propagation of an electromagnetic wave, are irreducibly plenistic. We bet then on nearby action. To formulate the principle we make use of the notion of place or bulk of a thing, introduced by Definition 6.6 in Sec. 2.4. The *principle of nearby action* reads then:

POSTULATE 6.13 If two things are at different places and one of them acts upon the other, then there is a third thing interposed between them. I.e.,

$$x, y \in \Theta \;\&\; \beta(x) \cap \beta(y) = \varnothing \;\&\; x \rhd y \Rightarrow$$
$$(\exists z)(z \in \Theta \;\&\; z \neq x \;\&\; z \neq y \;\&\; x|z|y).$$

A particularly appealing if specific version of this principle is the following. Let P_1 and P_2 be two substantial properties represented by functions F_1 and F_2 respectively defined on the space manifold M^3. Then for any point $x \in M^3$ there is a real valued function L on $M^3 \times M^3$ such that

$$F_2(x) = \int_{-\infty}^{\infty} dy\, L(x, y) F_1(y).$$

The principle of nearby action does not preclude the possibility that an action initiated in a thing remains confined to it. Such a possibility is denied by the strong version of the principle, which can be formulated thus: "Whatever happens at any given place is determined by what happens in its immediate vicinity and in turn influences every other thing". According to this principle no two things in the universe can be independent. We do not adopt it because there are cases of effective insulation and of spontaneous (uncaused) activity (Bunge, 1959).

5.5. *Spatiotemporal Contiguity*

The principles of antecedence and nearby action are logically independent: as suggested in the previous section one could assert the one while denying the other. But, since we have accepted both, we may as well merge them into a single principle, the more so since relativistic physics has taught us that spatial relations are enmeshed with temporal relations. A possible merger is the so called principle of *local causality*, which we prefer to call the *principle of spacetime contiguity*:

POSTULATE 6.14 Every action of one thing upon another satisfies both the antecedence and the nearby action conditions.

A possible but restricted formulation of this condition is as follows. If P_1 and P_2 are substantial properties of some thing (e.g. a field) representable by functions F_1 and F_2 respectively, defined on the spacetime manifold M^4, and if P_2 depends upon P_1, then relative to any frame f and for any quadruple $\langle x, t\rangle \in M^4$, there is a real-valued function N such that

$$F_2(x, t) = \int_{-\infty}^{t} dv \int_{-\infty}^{\infty} du\, N(x, u; t, v) F_1(u, v),$$

where

$$\langle u, v\rangle \in M_f^4$$

and $|x-u| \leq c|t-v|$, c being a positive real number. (To comply with special relativity c must be smaller than or equal to the velocity of light in vacuo. General relativity introduces certain modifications in the above formula, mainly the insertion of $g^{1/2}$ in the integrand, where g is the determinant of the metric tensor, and a slight liberation of the constraint on space and duration intervals, as c may now be a function defined on M^4, though one whose values will always be near the velocity of light in vacuo in the absence of gravitation.)

The previous principles, of nearby action and antecedence, are retrieved as special cases upon setting $N(x, u; t, v) = \delta(t-v) \cdot L(x, u)$ and $N(x, u; t, v) = \delta(x-u) \cdot K(t, v)$ respectively, where L and K are space dependent and time dependent functions respectively.

To realize that Postulate 6.14 underlies the whole of science suffice it to note that its denial would involve the following consequences. First, because the principle asserts the mutual independence of nonconnectible things, if it were false no thing could remain quasi-isolated from the rest of the universe even for a short while. Hence no thing could be known even approximately, and so the very concept of an individual thing would be idle. Far from being a system, the universe would be a block. Second, both the remote past and the remote future could pounce upon the present without notice and render it chaotic. This again would render knowledge utterly impossible and confusion would be even more dense and widespread than it is. Since we do succeed in knowing a thing or two we must infer that we are not at the mercy of things far removed in space and time. In particular, we may rest assured that events occurring in a distant space-like separated region of spacetime do not affect us.

True, it is occasionally claimed that Postulate 6.14 is at variance with quantum mechanics. But if this were true then the quantum theory would be incompatible with the special theory of relativity, which in turn embodies Postulate 6.14. And this conclusion is contradicted by the very existence of successful quantum relativistic theories such as Dirac's theory of the electron and quantum electrodynamics. Hence the results purporting to invalidate the so-called local causality – such as EPR inseparability and Bell's theorem – will have to be reinterpreted. In other words we do not have to give up ontological principles that are well entrenched in science just because they seem to be contradicted by an occasional and isolable fragment of scientific research. On the contrary, such strays have got to be reexamined in the light of scientific ontology. Thus when classical electrodynamics led to the conclusion that there are preaccelerations, hence events violating the antecedence principle (Postulate 6.12), most physicists doubted the physics rather than the metaphysics and made efforts to correct the former instead of the latter. (Recall Sec. 5.3.)

5.6. *The Causal Relation*

Finally let us elucidate the notion of causation and state the causal principle. We construe causation as a relation between events in different things – which of course may be parts of a bulkier thing. Furthermore we take it that causation subsumes antecedence and that, far from merely preceding the effect, the cause produces it (Bunge 1959). In sum, we make

DEFINITION 6.23 Let $e \in E(x)$ be an event in a thing x at time t and $e' \in E(x')$ another event in a thing $x' \neq x$ at time t', where the events as well as the times are taken relative to the same reference frame. Further, call $A(x, x')$ the total action or effect of x upon x' (Definition 5.31). Then we say that e is a *cause* of e' iff

(i) $t \leqslant t'$;

(ii) $e' \in A(x, x') \subseteq E(x')$.

A more precise condition than clause (ii) would be this: There is an energy transfer from x to x' during the interval $[t, t']$, and the quantity of energy transferred suffices for the occurrence of e'. But we do not need the extra precision.

The notion of causation allows us to formulate the strict *principle of causality*, namely as follows: "Every event is caused by some other event." More precisely: "Let x be a thing with event space $E(x)$. Then for every $e \in E(x)$ there is another thing $x' \neq x$, with event space $E(x')$ relative to the same reference frame, such that $e' \in E(x')$ causes e." But we shall not espouse this principle for, if we did, most of contemporary science would have to go (Bunge, 1959).

So much for the general principles involving the notions of space or time. Let us now approach matters of existence.

6. MATTERS OF EXISTENCE

6.1. *Existence in Space and Time*

It is usually assumed that, unlike ideas, physical things "exist in space and time". (For Aristotle only changing things exist in time: *Physics*, Bk. IV, Ch. 12. And for Kant ideas exist in time but not in space.) Moreover "existence in space and time" is sometimes taken to define the very concept of a physical object in contrast to that of a nonphysical object. In turn, what is meant by 'x exists in space and time' is that x occupies a region of space and endures throughout a time interval.

The statements we have just mentioned presuppose the autonomous existence of the spatiotemporal framework, which in turn would be a non-physical object. This is of course the absolute doctrine examined and rejected in Sec. 1.1. We do not accept the container view because our ontology does not assume any nonphysical entity – except of course as a fiction. In our view things do not float in a given spatiotemporal framework but hold spatiotemporal relations among each other – just as persons do not swim in a community but constitute it by holding connections with one another. Things "come" with their own (changing) spatiotemporal relations, and the latter are just relations (but not bonds) among things and their changes.

Consequently it makes as little sense, in our ontology, to say that a thing *exists in* spacetime, as to say that spacetime *exists in* a thing. The expressions 'x exists at a place y (or in a region y) relative to a frame z' and 'x exists at time t (or throughout time interval t) relative to a frame z' are elliptical. The location of a thing is always given by reference to another thing and the timing of a state or of an event is always referred to some other state or event – and in turn states are states of things, and events are changes of state of things. *No things, no nothing*, as the robust street corner philosopher put it. We can use those elliptical locutions because they save time, provided we remember what their purport is at the time of discussing foundations matters. In ontology and in the foundations of physics we have hardly any right to assume that spacetime preexists things, and that the spatiotemporal location of a thing or an event is in the nature of the part-whole relation, the part being the factual item and the whole spacetime. Only the bulk of a thing can be included in space, because that bulk is a set.

Finally, what about the *plenum* hypothesis held by Aristotle and his followers? (Cf. Lovejoy, 1936.) This hypothesis, that space is full of things, is favored by contemporary physics, in particular gravitation theory and quantum electrodynamics. In other words, there is no such thing as empty space or a perfect vacuum. (Particle void $\neq$ void.) We may then adopt this principle:

POSTULATE 6.15 There are things interposed between any two things located at different places. I.e.,

$$x, y \in \Theta \;\&\; \beta(x) \cap \beta(y) = \varnothing \Rightarrow$$
$$(\exists z)(z \in \Theta \;\&\; z \neq x \;\&\; z \neq y \;\&\; x|z|y).$$

Since this assumption entails Postulate 6.13, we could have gotten the latter as a theorem.

6.2. *Existence of Space and Time*

It is tempting to doubt the existence of space and time. After all, they are not things – not even imperceptible things – and they have no causal power. (It is sometimes said that, according to general relativity, spacetime guides the motion of things: that there are tracks in spacetime. But this is a mistake: what guides the motion of things is the gravitational field, which the theory represents as a departure of spacetime from flatness.)

As a matter of fact a number of philosophers and mystics have doubted the reality of space and many more have maintained that time is unreal. While the topoclasts have usually argued from the imperceptibility of space, the chronoclasts have often argued from the alleged immutability of a Reality behind appearances. In particular Kant held space and time to be phenomenal not real – which is the only reasonable view if the container doctrine is kept, not however on a relational doctrine of space and time (Lotze, 1887, Bk. II, Ch. I). And Russell held at one time that both space and time are fictitious because the *concepts* of space and time should be constructible out of "real entities", namely perceptual items. We cannot accept these phenomenalist views if only because they ignore the basic distinction made in contemporary physiological psychology between physical spacetime on the one hand and the various perceptual (e.g. visual and tactual) spaces and the perception of duration on the other.

In our view neither the topoclasts nor the chronoclasts are right. Although space and time are not things and have no being independent of things and their changes, they are no less real than any other substantial properties of real things. Indeed recall that a relation was called *real* if and only if it holds among real things – which is the case with spatiotemporal relations. (Cf. Definition 2.17 in Ch. 2, Sec. 5.1.) The *esse* of spatiotemporal relations consists not in their *percipi* but in their obtaining between real things and real events.

The role of space and time in science is not always well understood. Thus just because spatiotemporal concepts do not occur in the systematics of elementary particles, or because they play a subdued role in the black box theories of these entities – namely the scattering matrix and the dispersion relation theories – it has occasionally been claimed that they play no role at all (Chew, 1963). However, the fact that a dynamical theory of fundamental "particles" is not around the corner does not entail that we can dispense with space and time concepts. This is a case of sour grapes. It is no less glaring a mistake than that of assigning spacetime causal efficacy – which Aristotle did in his *Physics*. The locution 'x was knocked down because x was at place y' is just short for 'x was knocked down by some other thing z that happened to be at place y'. Likewise the phrase 'Time brought about the decline of x' is an ellipsis for 'Certain events brought about the decline of x'. Space and time are as harmless as they are unavoidable.

Another point that has not been well understood on occasion is the nature of coordinates. Because the general covariance requirement shows coordinate systems and coordinate values to be conventional or a priori, it is sometimes held that spacetime itself is not physically objective (e.g. Einstein, 1916). That coordinate values just label points in the four-manifold M^4 is true and even trivially so, as we saw in Sec. 4.2. But this does not entail that M^4 fails to represent objective relations among physical objects, as shown by the absolute character of certain invariants such as spatiotemporal distances (the values of the numerical partners of the qualitative spatiotemporal separation introduced by Definition 6.18). In fact they do not change under the substitution of coordinate systems; in particular they do not depend on the observer's point of view nor even upon his location and motion. Moreover the coefficients of the metric, though not covariant themselves (since they are the components of a tensor), are no less than the gravitational potentials and, as such, they occur centrally in the field equations of gravitation: they represent a feature of the thing called 'gravitational field'. If the metric were conventional (as Grünbaum (1973) has claimed), the laws of gravitation should be conventional as well. And if this were so we should be smart enough always to choose a metric that will prevent any nasty fall and even keep our enemies at bay.

In conclusion, space and time have no autonomous existence, hence no causal power either. But then no relation exists on its own, i.e. apart from its relata – as we know from Ch. 2. Although spatiotemporal relations are not entities, nor even couplings or connections on the same footing with mechanical or electrical or social bonds, they are real relations in the sense that they hold among real things. Spacetime is no more nor less than *the fundamental structure or basic framework of the world.*

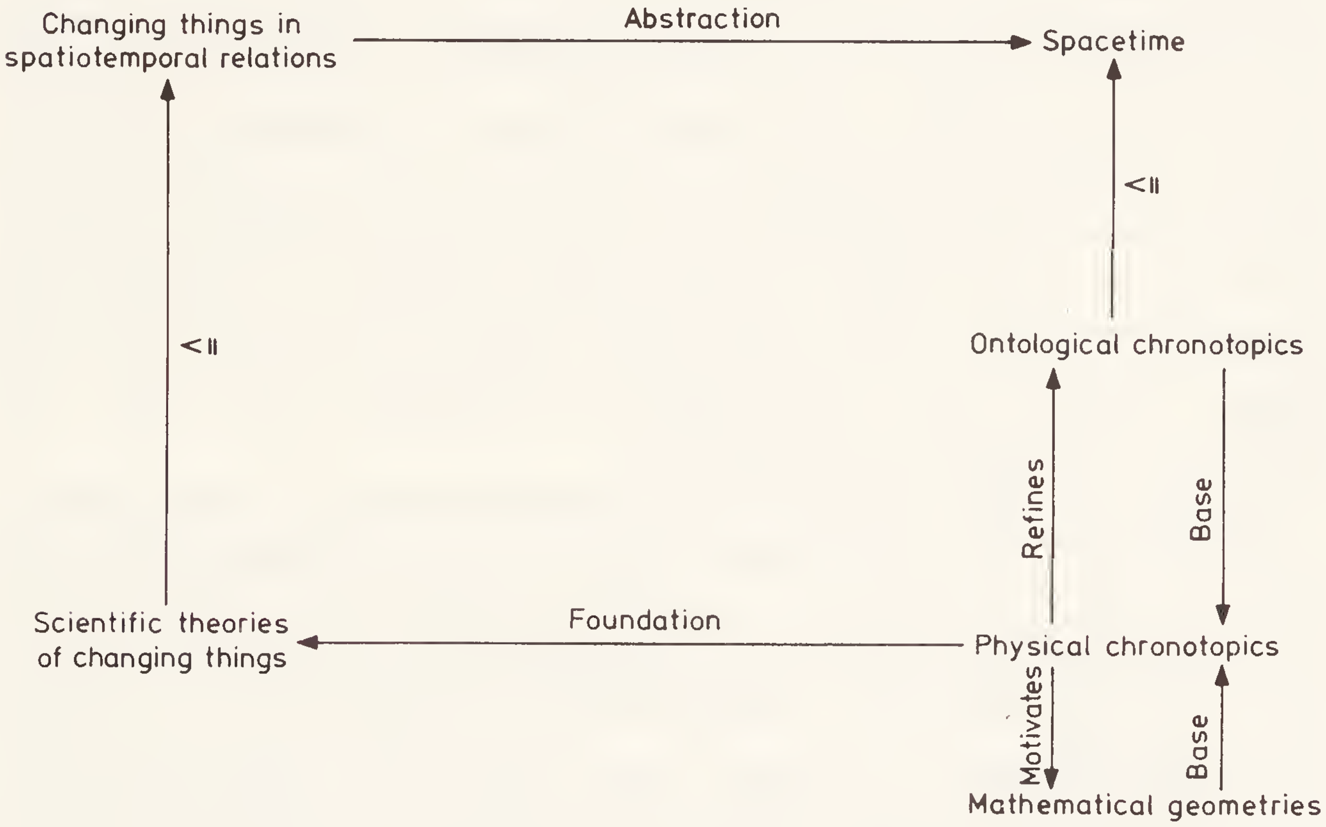
In sum: mathematical spaces are multiple and unreal – neither objective nor subjective; physical space(time) is one, real, and objective (or subject-independent); and phenomenal (or perceptual) spaces and times are multiple, real, and subjective (or subject-dependent).

7. CONCLUDING REMARKS

According to Cartesian mechanism all facts can and should be explained in terms of space and time only. This program, though wonderfully fruitful, has never been fully implemented in physics, let alone in other fields of research. Indeed some of the basic properties of matter, such as mass, charge, spin, and parity, are not explained in terms of spatiotemporal concepts. And even features that are dependent on spatiotemporal location, such as field strengths and cultural production, are not spatiotemporal themselves. In sum, things are not warts of spacetime. And spacetime, not being independent of things, is not illusory either. Reality is the aggregation of things holding spatiotemporal relations. Now, relations do not preexist their relata but hold among them. In particular spatiotemporal relations, such as "between" and "before", can be understood only in terms of the things, states, or events between which they hold. Hence we must try and understand spacetime in terms of changing things: this is what the present chapter is all about.

Once the spatiotemporal framework has been anchored to things we can invert the procedure and study things *in* spacetime – but this second, more detailed look, is taken by science not philosophy. (Likewise once we have formed the general concept of an event, belonging to ontology, we can start asking questions about events of special kinds.) In summary we have the situation depicted in Figure 6.13.

How do the various ontological theories of space and time fare in



Changing things in spatiotemporal relations

contemporary science, i.e. what support do they get from the latter? This is not easy to say because any physical theory containing spatiotemporal concepts can presumably be married either to an absolute or to a relational theory of spacetime. Such an ambiguity, clear as it is on analysis, is obscured by history. Thus just because Newton assumed that space and time are self-existent, and in particular independent of matter in motion, most philosophers believe that Newtonian mechanics and gravitation theory are soaked in the doctrine of the absolute character of space and time. This is mistaken: it is possible to reformulate classical mechanics assuming a relational (though not relativistic) theory of space and time (Noll, 1967). In other words, the equations of motion and the constitutive equations of classical mechanics are independent of the way space and time are understood. The same holds for all other non-relativistic theories, in particular quantum mechanics.

Even relativistic theories are rather insensitive to the absolute-relational issue. In this case too either one may attempt to build spacetime out of changing things, or one may take it for granted and build thereupon. One may even get carried away by the second procedure and conclude that, since the gravitational field equations possess solutions even in the absence of matter and radiation, general relativity actually uses an absolute concept of spacetime. But this would be just as mistaken as claiming that Newtonian mechanics is indissolubly married to an absolute doctrine of space and time. The solutions for the hollow universe are physically meaningless because, by definition, physics is concerned with physical objects. In sum, the fact that physics is compatible with a given ontological theory of space and time does not endorse the latter but only renders it epistemically possible. In particular, the compatibility of our own chronotopics with the science of the day, though necessary and encouraging, is insufficient. We must look elsewhere for additional confirmation.

We cannot verify conclusively our relational theory of spacetime – nor indeed any other chronotopics. However we can dispose of its rival, namely the absolute theory, in any of its possible versions. We can do it not with the help of crucial experiments but by a semantic analysis. Indeed, if one admits the methodological principle that a physical theory, by definition of 'physical', must contain only physically meaningful concepts, and if one accepts the definition of a physically meaningful concept as one that refers to physical items (cf. Vol. 1, Ch. 2 of this treatise), then the concepts of absolute or autonomous space and time must be discarded for not being physical. By this criterion only the class of relational theories of space and time remain. And the only criteria for choosing among the latter are (*a*) mathematical cogency, (*b*) closeness of fit with contemporary physics, and (*c*) clarifying power. We leave the reader the task of deciding whether our own theory of spacetime meets these criteria.

So much for extension and duration. We have now all we need to handle systems in general and in particular. But this will be a task for the 4th volume of this work, namely *A World of Systems*.

The present volume offers a new ontology. This system is materialist (though not reductionist) and dynamicist (though neither dialectical nor Whiteheadian). It is in tune with contemporary science and built with the help of some formal tools. It elucidates and systematizes, among others, the concepts of substance and property, thing and system, possibility and actuality, probability and law, state and event, and space and time. Many of the axioms and theorems of the system are found to be presupposed or else implied by contemporary scientific research. Therefore the work constitutes a bridge between the metaphysical tradition and contemporary philosophy of science. There are many examples and bibliographical references.

Dr Mario Bunge has been a professor of theoretical physics, and later on of philosophy, in his native Argentina and in the U.S.A. He has held visiting positions at the Universities of Pennsylvania, Texas, Temple, Delaware, Freiburg, and Aarhus, as well as at the E.T.H. in Zürich. He is currently professor of philosophy and head of the Foundations and Philosophy of Science Unit at McGill University. He has been awarded Guggenheim, Alexander von Humboldt and Ernesto Santamarina fellowships, as well as Killam grants. He has written a dozen books and edited seven volumes, one journal of philosophy and another of physics, and has founded three philosophical societies. His best known works are *Causality* (available in eight languages), *Scientific Research* (in two volumes), and *Foundations of Physics.* His latest publications are *Philosophy of Physics* and *Method, Model and Matter*. His most recent editorial jobs, *Problems in the Foundations of Physics*, *Exact Philosophy: Problems, Tools, Goals*, and *The Methodological Unity of Science.*

Audience: Philosophy teachers and graduate students, natural and social scientists, and systems scientists. This book can be used as a textbook for courses on metaphysics or on exact philosophy, and as supplementary reading for courses on philosophy of science, foundations of science, or systems theory.

GENERAL PREFACE TO THE *TREATISE*

This volume is part of a comprehensive *Treatise on Basic Philosophy*. The treatise encompasses what the author takes to be the nucleus of contemporary philosophy, namely semantics (theories of meaning and truth), epistemology (theories of knowledge), metaphysics (general theories of the world), and ethics (theories of value and of right action).

Social philosophy, political philosophy, legal philosophy, the philosophy of education, aesthetics, the philosophy of religion and other branches of philosophy have been excluded from the above *quadrivium* either because they have been absorbed by the sciences of man or because they may be regarded as applications of both fundamental philosophy and logic. Nor has logic been included in the *Treatise* although it is as much a part of philosophy as it is of mathematics. The reason for this exclusion is that logic has become a subject so technical that only mathematicians can hope to make original contributions to it. We have just borrowed whatever logic we use.

The philosophy expounded in the *Treatise* is systematic and, to some extent, also exact and scientific. That is, the philosophical theories formulated in these volumes are (*a*) formulated in certain exact (mathematical) languages and (*b*) hoped to be consistent with contemporary science.

Now a word of apology for attempting to build a system of basic philosophy. As we are supposed to live in the age of analysis, it may well be wondered whether there is any room left, except in the cemeteries of ideas, for philosophical syntheses. The author's opinion is that analysis, though necessary, is insufficient – except of course for destruction. The ultimate goal of theoretical research, be it in philosophy, science, or mathematics, is the construction of systems, i.e. theories. Moreover these theories should be articulated into systems rather than being disjoint, let alone mutually at odds.

Once we have got a system we may proceed to taking it apart. First the tree, then the sawdust. And having attained the sawdust stage we should move on to the next, namely the building of further systems. And this for three reasons: because the world itself is systemic, because no idea can

become fully clear unless it is embedded in some system or other, and because sawdust philosophy is rather boring.

The author dedicates this work to his philosophy teacher

Kanenas T. Pota

in gratitude for his advice: "Do your own thing. Your reward will be doing it, your punishment having done it".

MARIO BUNGE

PREFACE TO *ONTOLOGY II*

This volume continues and concludes the task begun in Part I, titled *The Furniture of the World* – namely the building of an exact and systematic ontology consistent with contemporary science. However, it can be read independently by anyone willing to take for granted the basic notions analyzed and systematized in the companion volume, namely those of substance, property, thing, possibility, change, space, and time.

The three main themes of this book are wholeness (or systemicity), variety, and change. These three notions are analyzed and systematized, and they occur in some of the main assumptions of our ontology. One of these hypotheses is that the universe is not a heap of things but a thing composed of interconnected things – i.e. a system. This supersystem is composed of subsystems of various kinds: physical, biological, social, etc. Only physical systems may be composed of things that are not themselves systems, such as elementary particles and field quanta. However, even nonsystems are components of some system or other, and every system but the universe is a subsystem of some system: there are no strays. Ours is, in sum, a world of interconnected systems. Moreover it is the only one.

Another postulate of this system of ontology is that concrete systems are not all alike except insofar as they are systems and therefore tractable with the help of a unifying systems-theoretic framework. There are different kinds of system and each is characterized by its own peculiar properties and laws. Surely we sometimes succeed in accounting for the emergence and the history of a system in terms of its composition, environment, and structure. Nevertheless, explaining need not be explaining away: explained systems are not heaps, explained emergence is no mere resultant, and explained novelty is not old. Systemicity, emergence, and qualitative novelty and variety are as genuine as they are capable of being explained. Far from being incompatible with reason, wholeness and emergence can be understood.

A third major thesis of this work is that no system, except for the world as a whole, lasts forever. Systems get assembled, change, and break down. If natural, systems emerge as a result of self-assembly processes – often from debris of former systems. Even modest accretion processes can ensue in systems possessing emergent properties. Order can thus emerge from randomness, systems from physical precursors, living systems from nonliving ones, and so on. (Entropy need not increase in open systems.)

All three theses are by now common knowledge or nearly so. Now they – jointly with many others – have become part and parcel of a science-oriented ontological system couched in a fairly exact language. Thus the novelty of this system resides sometimes in its components, and at other times in their organization.

This volume covers the following ground. Chapter 1 defines the notions of system and subsystem, and emergence and level, and it lays down a handful of laws supposed to be shared by systems of all kinds. Chapter 2 defines the notions of chemical system and biochemical system, regarding them as emergent relative to the physical level. Chapter 3 attempts to catch the elusive notion of life, and tackles the problems of biovalue, health, adaptation, and bioprogress. Chapter 4 is devoted to the mind-body problem from a point of view that combines the systemic approach with the psychobiological one. (Individual neurons cannot think; but certain systems of neurons, if connected in special plastic ways, can.) Chapter 5 defines the concept of a sociosystem and analyzes every society into four main subsystems – the kinship system, the economy, the culture, and the polity. Chapter 6 presents the world view that emerges from the preceding chapters – one which is naturalistic (but not physicalist), systemic (but not holistic), pluralistic (with respect to properties, not substances), and dynamicist. Finally, the two appendices review some mathematical models of systems and of change which, because of their generality, belong to ontology as well as to science. These appendices are helpful but not essential for the understanding of the text.

ACKNOWLEDGMENTS

I am grateful for the advice and criticism offered by Professors Lina Bettucci (Departamento de Biología, Universidad Autónoma Metropolitana, México), Ernesto M. Bravo (Instituto Superior de Medicina, La Habana), A. Brito da Cunha (Instituto de Biociências, Universidade de São Paulo), Sir Francis Crick (The Salk Institute), Bernardo Dubrovsky (Department of Psychiatry, McGill University), Máximo García-Sucre (Sección Física, Instituto Venezolano de Investigaciones Científicas), Bernd Küppers (Max-Planck-Institut für Biophysikalische Chemie, Göttingen), Rodolfo Llinás (Department of Physiology and Biophysics, New York University Medical Center), Roger Palfree (Department of Biology, McGill University), Rafael Pérez Pascual (Instituto de Física, Universidad Nacional Autónoma de México), Osvaldo A. Reig (Departamento de Estudios Ambientales, Universidad Simón Bolívar, Caracas), Daniel Seni (Institut d'Urbanisme, Université de Montréal), and René Zayan (Centre de psychologie expérimentale et comparée, Université de Louvain). I am also indebted to my former research assistant Robert Blohm for suggesting a number of corrections. My former students David Conter, Adolfo García de la Sienra, Gordon Graham, and John Hawthorne made several remarks for which I am grateful. I am thankful to Dr Ricardo Peralta Fabi for drawing all the diagrams in the book. Last, but not least, I thank Professors D. R. Axelrad and Walter Hitschfeld, as well as the Canada Council and the McGill Faculty of Graduate Studies and Research, for supporting my research.

MARIO BUNGE

SPECIAL SYMBOLS

$\varnothing$	the *empty set*
$a \in A$	individual a *belongs* to set A
$A \subset B$	set A is *included* in set B
$A \cup B$	the set of objects in A *or* in B
$A \cap B$	the set of objects in A *and* in B
$A - B$	the set of objects *in* A *but not in* B
$A \triangle B$	the set of objects in A *or* in B but *not in both*
$\langle a, b\rangle$	the *ordered pair* of a and b
$A \times B$	the *cartesian product* of A and B
$\lvert A\rvert$	the *cardinality* (numerosity) of A
$a \dotplus b$	the *association* of things a and $b = \mathit{sup}\ \{a, b\}$
$\mathscr{C}(x)$	the *composition* of system x
$\mathscr{E}(x)$	the *environment* of system x
$\mathscr{S}(x)$	the *structure* of system x
$f : A \to B$	*function* f maps set A into set B
$f(x)$	the *value* of function f at x
$\mathbb{F} = \langle F_1, F_2, \ldots, F_n, \ldots\rangle$	*state function* for some system
$h(x, \tau)$	the *history* of thing x during time interval τ
iff	*if and only if* (necessary and sufficient condition)
$\mathbb{L}(x)$	the *set of laws* of thing x
$\mathbb{N}$	the set of *natural numbers*
$x \sqsubset y$	thing x is a *part* of thing y
$x \prec y$	system x is a *subsystem* of system y
2^S	the *power set* (family of subsets) of set S
Pr	*probability* function
$\mathbb{R}$	the *real line*
$\mathbb{R}^+$	the set of *non-negative real numbers*
$S_{\mathrm{L}}(x)$	*lawful state space* of thing x
T	set of *time* instants

CHAPTER 1

SYSTEM

Every science studies systems of some kind, whether natural (physical, chemical, biological, or social) or artificial (technical). Moreover most sciences study nothing but systems. Thus biology studies biosystems, sociology sociosystems, and technology technosystems. Physics seems to be the only science that investigates not only systems, such as atoms and large scale fields, but also putatively simple or elementary things such as electrons and photons. Even so, physicists acknowledge that every such basic thing is a component of some system or other

Until recently every species of system was studied separately. About four decades ago a number of specialists joined efforts to launch various cross-disciplinary ventures, such as operations research and cybernetics. Their success suggested to some workers that a unified approach to problems in various fields was possible. They pointed out that (*a*) there are some concepts and structural principles that seem to hold for systems of many kinds, and (*b*) there are some modeling strategies – in particular the state space approach – that seem to work everywhere.

The discipline that purports to develop such a unified approach is often called 'general systems theory' (Bertalanffy, 1950, 1958; Boulding, 1956). Paradoxically enough, this is not a single theory but a whole set of theories – automata theory, linear systems theory, control theory, network theory, general Lagrangian dynamics, etc. – unified by a philosophical framework (Bunge, 1974c, 1977c). We shall call *systemics* this set of theories that focus on the structural characteristics of systems and can therefore cross the largely artificial barriers between disciplines.

Systemics has two related motivations, one cognitive and one practical. The cognitive or theoretical rationale of systemics is, of course, the wish to discover similarities among systems of all kinds despite their specific differences – e.g. between body temperature control systems and furnace thermostats. The practical motivation for systemics is the need to cope with the huge and many-sided systems characteristic of industrial societies – such as communications networks, factories, hospitals, and armies. This complexity, in particular the variety of components of such systems, violates the traditional borders among disciplines and calls for a cross-disciplinary approach.

Note the differences between the standard scientist, engineer or social scientist on the one hand, and the systems "specialist" (actually a generalist) on the other. Whereas the former do or apply some particular science, the systemics expert de-emphasizes the physics (chemistry, biology, or sociology) of his systems, focusing instead on their structure and behavior. Moreover he is interested particularly in duplicating or imitating (modeling or simulating) the behavior of any given system (e.g. a person) by one of a different kind (e.g. a pattern recognition automaton). This holds not only for the mathematician who takes systemics as an honorable pretext for playing with abstract structures but without any serious concern for practical problems in engineering or management: it also holds for the systemist intent on solving practical problems, such as modeling and simulating a grazing land system or a university.

The method employed by the system theorist is mathematical modeling and the experimental (or at least the computer) testing of system models. Both are of course part of the scientific method. What is peculiar to the way the systemics expert proceeds is that, far from incorporating any specific (e.g. chemical) laws into his model, he aims at building a black box, a grey box, or a kinematical model free from details concerning the materials composing the system, and noncommittal enough to cover some of the global aspects of the organization and behavior of the system on some of its levels. The scientific method is thus taken for granted: what is emphasized is the general or cross disciplinary approach in contrast to the specific or disciplinary one. In other words, the systemics expert is a jack of all trades – a quasi-philosopher if not a full blown one.

Systemics is not quite the same as *systems analysis*, a much advertised, ill defined, and sometimes controverted thing. Systems analysis too, when serious, uses the scientific method but, unlike systemics, it is not particularly interested in de-emphasizing the peculiarities of the components of the system concerned. What it does emphasize is that, because it studies many-sided and multi-level systems – such as ecosystems and transportation systems – it must adopt various points of view on different levels. For example, hospitals are not just buildings with medical equipment but social systems as well – whose components include medical personnel and patients – and moreover subsystems of a larger social system, namely a health-care system, which is in turn a subsystem of a society. The novelty of systems analysis resides less in its methods than in the objects it studies, namely complex man-artifact systems never before approached in a scientific manner. Unlike systemics, systems analysis is hardly interested in building extremely general models: it aims instead at drawing flow charts, network diagrams, and occasionally specific mathematical models accounting if possible not just for the structure and kinematics of the system but also for its dynamics, and thus enabling one to understand how it operates and malfunctions, hence how it can be repaired. (For a hilarious account of systems antics, see Gall (1977).)

Systemics, or general system theory, is a field of scientific and technological research and one of considerable interest to philosophy. Because of its generality it has a sizable overlap with ontology or metaphysics construed in the traditional, pre-Hegelian sense as well as in our own sense of scientific ontology (Bunge, 1973a, 1977a). Both sytemics experts and ontologists are interested in the properties common to all systems irrespective of their particular constitution, and both are intrigued by the peculiarities of extremely general theories, which are methodologically quite different from specific theories (Bunge, 1973a, 1977c).

The main differences between systemics and ontology seem to be these: (*a*) while systems theorists take certain concepts for granted – e.g., those of property, possibility, change, and time – ontologists take nothing for granted except logic and mathematics; (*b*) while systems theorists are often interested in the details of the couplings of the components of a system, ontologists seldom are; (*c*) while systems theorists focus their attention on input–output models of systems that are largely at the mercy of their environment, ontologists are interested in free systems as well (in which respect they do not differ from physicists); (*d*) while systems theorists are mainly interested in deterministic (or rather nonstochastic) models – partly because theirs are large scale things – ontologists are also interested in stochastic ones; and (*e*) while some systems theorists focus their attention on the search for analogies among systems of different kinds, and particularly on different levels, ontologists are primarily interested in analyzing and systematizing concepts referring to all kinds of system.

In this chapter we shall propose a number of definitions and principles concerning concrete systems in general. These ideas will be used in succeeding chapters, where certain system genera will be studied. Details on mathematical models of systems are found in the two appendices.

1. BASIC CONCEPTS

1.1. *Aggregate and System*

An *aggregate* or assemblage is a collection of items not held together by bonds, and therefore lacks integrity or unity. Aggregates can be either conceptual or concrete (material). A conceptual aggregate is a set. (But not every set is a conceptual aggregate: a set equipped with a structure is a conceptual system.) A concrete or material aggregate, on the other hand, is a compound thing, the components of which are not coupled, linked, connected, or bonded, such as a field constituted by two superposed fields, a celestial constellation, and a random sample of a biological population.

Because the components of an aggregate do not interact – or do not interact appreciably – the behavior of each is independent of the behavior of the others. Consequently the history of the aggregate is the union of the histories of its members. On the other hand the components of a concrete system are linked, whence the history of the whole differs from the union of the histories of its parts. We shall take the last statement to be an accurate version of the fuzzy slogan of holistic metaphysics, namely *The whole is greater than the sum of its parts.* But we shall go far beyond this characterization of wholeness or systemicity. To this end we shall make use of a few elementary mathematical concepts as well as of a number of common notions – such as those of thing, property, and time – that have been clarified in our companion volume (Bunge, 1977a).

A system, then, is a complex object, the components of which are interrelated rather than loose. If the components are conceptual, so is the system; if they are concrete or material, then they constitute a concrete or material system. A theory is a conceptual system, a school a concrete system of the social kind. These are the only system kingdoms we recognize: conceptual and concrete. We have no use for mixed systems, such as Popper's "world 3", allegedly composed of conceptual objects, such as theories, as well as concrete objects, such as books (Popper, 1968; Popper and Eccles, 1977). We do not because, in order to be able to speak of the association or combination of two items, we must specify the association bond or operation. And, while mathematical theories specify the way conceptual items combine, and ontological and scientific theories take care of the combination of concrete items, no known theory specifies the manner whereby conceptual items could combine with concrete ones – and no experience suggests that such hybrids exist.

Whatever its kingdom – conceptual or concrete – a system may be said to have a definite composition, a definite environment, and a definite structure. The composition of a system is the set of its components; the environment, the set of items with which it is connected; and the structure, the relations among its components as well as among these and the environment. For example, a theory is composed of propositions or statements; its environment is the body of knowledge to which it belongs (e.g. algebra or ecology); and its structure is the entailment or logical consequence relation. The merger of these three items is a propositional system, i.e. a system $\mathcal{T}$ composed of a set P of propositions, embedded in a certain conceptual body B, and glued together by the relation $\vdash$ of entailment: in short, $\mathcal{T} = \langle P, B, \vdash \rangle$. And the composition of a school is the union of its staff and pupils; the environment is the natural and social milieu, and the structure consists of the relations of teaching and learning, managed and being managed, and others. The environment must be included in the description of a system because the behavior of the latter depends critically on the nature of its milieu. But of course in the case of the universe the environment is empty, and so it is in the case of the important fiction known as the free particle (or field).

One way of characterizing the general concept of a system is this. Let T be a nonempty set. Then the ordered triple $\sigma = \langle C, E, S \rangle$ is (or represents) a *system over* T iff C and E are mutually disjoint subsets of T (i.e. $C \cap E = \varnothing$), and S is a nonempty set of relations on the union of C and E. The system is conceptual if T is a set of conceptual items, and concrete (or material) if $T \subseteq \Theta$ is a set of concrete entities, i.e. things. However, the preceding is not a definition proper, because it does not tell us what exactly is the membership of the coordinates C, E and S of the ordered triple. We must therefore define the notions of composition, environment, and structure of a thing.

1.2. *Concrete System: Definition*

Let us start by defining the composition of a system. A social system is a set of socially linked animals. The brains of such individuals are parts of the latter but do not qualify as members or components of a social system because they do not enter independently into social relations: only entire animals can hold social relations. In other words, the composition of a social system is not the collection of its parts but just the set of its atoms, i.e. those parts that are socially connectible. This particular notion of composition is that of atomic composition or A-composition for short. It will be defined thus: The *A-composition* (or *composition at the A level*) of a thing x is the set of parts of x that belong to A. In symbols: let $A \subseteq \Theta$ be a class of things and let x be a thing (i.e. $x \in \Theta$). Then the (absolute) *composition* of x is the set of its parts, i.e.

$$\mathscr{C}(x) = \{y \in \Theta \mid y \sqsubset x\},$$

where '$y \sqsubset x$' designates "y is a part of x". And the *A-composition* of x is the set of its A-parts:

$$\mathscr{C}_A(x) = \mathscr{C}(x) \cap A = \{y \in A \mid y \sqsubset x\}.$$

Let us introduce next the concept of link, connection, or coupling among the components of a thing. We must distinguish between a mere relation, such as that of being older, and a connection, such as that of exerting pressure. Unlike a mere relation, a connection makes some difference to its relata. That is, two things are connected just in case at least one of them acts upon the other – where the action need not consist in eventuating something but may consist in either cutting out or opening up certain possibilities.

In turn, we say that one thing *acts* upon another if it modifies the latter's behavior line, or trajectory, or history. The acting of thing a on thing b is symbolized

$$a \rhd b.$$

If a thing acts upon another, and the latter does not react back, the former is called the *agent* and the latter the *patient*. If neither action nor reaction are nil, the things are said to *interact*. Finally, two things are *connected* (or *coupled*, or *linked*, or *bonded*) if at least one of them acts on the other. The *bondage* of a set $A \subseteq \Theta$ of things is the set $\mathbb{B}_A$ of bonds (or couplings or links or connections) among them. So, the total set of relations among the components of a complex entity may be decomposed into its bondage $\mathbb{B}_A$ and the set $\bar{\mathbb{B}}_A$ of nonbonding relations.

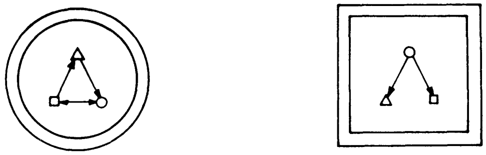
We can now introduce the notion of the *A-environment* of a thing x with A-composition $\mathscr{C}_A(x)$. It will be defined as the set of all things, other than those in $\mathscr{C}_A(x)$, that act on or are acted upon the latter:

$$\mathscr{E}_A(x) = \{y \in \Theta \mid \neg(y \in \mathscr{C}_A(x)) \;\&\; (\exists z)(z \sqsubset x \;\&\; (y \rhd z \vee z \rhd y))\}.$$

Finally the *structure* of a thing will be defined as the set of all the relations among the thing's components as well as among these and the things in the thing's environment.

We now have all we need to define the notion of a concrete system:

DEFINITION 1.1 An object is a *concrete system* iff it is composed of at least two different connected things.



(a) (b)

Fig. 1.1. Two systems with the same composition but different structures and environments.

Example A molecule, a coral reef, a family and a factory are systems. On the other hand a set of states of a thing and a collection of events, even if ordered, are not concrete systems. Symbol: Σ.

And now the three characteristics of any system:

DEFINITION 1.2 Let $\sigma \in \Sigma$ be a concrete system and $A \subset \Theta$ a class of things. Then

(i) the *A-composition* of σ at a given time t is the set of its A-parts at t:

$$\mathscr{C}_A(\sigma, t) = \{x \in A \mid x \sqsubset \sigma\};$$

(ii) the *A-environment* of σ at time t is the set of all things of kind A, not components of σ, that act or are acted on by components of σ at t:

$$\mathscr{E}_A(\sigma, t) = \{x \in A \mid x \notin \mathscr{C}_A(\sigma, t) \;\&\; (\exists y)(y \in \mathscr{C}_A(\sigma, t) \;\&\; (x \rhd y \vee y \rhd x));$$

(iii) the *A-structure* (or *organization*) of σ at time t is the set of relations, in particular bonds, among the components of σ, and among them and the things in the environment of σ, at t:

$$\mathscr{S}_A(\sigma, t) = \{R_i \in \mathbb{B}_A(\sigma, t) \cup \bar{\mathbb{B}}_A(\sigma, t) \mid \mathbb{B}_A(\sigma, t) \neq \emptyset \;\&\; 1 \leq i \leq n,\}$$

where $\mathbb{B}_A(\sigma, t)$ is the set of bonding relations, and $\bar{\mathbb{B}}_A(\sigma, t)$ that of non-bonding relations, defined on $\mathscr{C}_A(\sigma, t) \cup \mathscr{E}_A(\sigma, t)$.

Example The simplest possible system is one composed of two connected things, a and b, in an environment lumped into a single thing c. That is, $\mathscr{C}(\sigma) = \{a, b\}$, $\mathscr{E}(\sigma) = \{c\}$. This system can have either of the following internal structureses: $a \rhd b$, $b \rhd a$, or $a \bowtie b$: see Figure 1.2. (These are the conceivable internal structures. But some of them may not be nomologically possible, let alone technically feasible or even desirable.) As for

Fig. 1.2. A two component system with three possible internal structures.

the external structures, they can be any of these or their unions: $\{a \rhd c\}$, $\{b \rhd c\}$, $\{c \rhd a\}$, $\{c \rhd b\}$.

An exhaustive knowledge of a system would comprise the following items: (*a*) the composition, the environment and the structure of the system; (*b*) the history of the system (particularly if this is a biosystem or a sociosystem), and (*c*) the laws of the system. Such complete knowledge is seldom attainable, particularly with reference to complex systems. But in order to be able to speak of systems at all we should know at least their composition, their environment and their structure. Thus we can say that the model constituted by the ordered triple

$$s_A(\sigma, t) = \langle \mathscr{C}_A(\sigma, t), \mathscr{E}_A(\sigma, t), \mathscr{S}_A(\sigma, t)\rangle$$

is the *minimal model* of system σ at time t. Obviously, this qualitative model will not suffice for quantitative purposes, such as predicting the rate of formation or breakdown of a system. We shall therefore supplement the above minimal model with a quantitative model to be introduced in Sec. 2.2. However, before doing so we shall use the minimal model to clarify a number of issues that are often obscure in the literature on systems.

1.3. *More of the Same*

Before continuing our study of systems and their models we must make sure that the concept of a concrete system is not idle – i.e. that some things are systems while others are not. That some things are not systems follows from the assumption that there are basic or elementary things, i.e. things without parts (Vol. 3, Postulate 1.4). And that other things are systems follows from the ontological hypothesis that every thing – except the universe as a whole – acts on, and is acted upon by, other things (Vol. 3, Postulate 5.10). In sum, we have proved the nontrivial

THEOREM 1.1 (i) There are concrete systems. (ii) Every thing is a component of at least one system.

Surely the identification and modeling of a concrete system may be an extremely difficult task. Thus it is not always clear what the composition, hence also the environment, of a system is, particularly if it is strongly coupled to other systems – as is the case with the economic and the political systems of a society. However, this is a scientific problem not an ontological one.

Note that actions and the corresponding connections have been defined for things not for properties. The latter can be *interdependent* but not *interacting*. That is, the common phrase 'Properties P and Q interact' should be understood either as "Properties P and Q (of a given thing) are interdependent", or "Things with property P interact with things with property Q".

Connections can be permanent or temporary, static or dynamic. In the latter case they are often called *flows* – of energy, as in heat transfer, of matter, as in migrations, or of fields, as in a television network. If a physical flow happens to carry information, the connection is called *informational* and the entire system an 'information system'. However, the physical/informational distinction is one of emphasis, not a dichotomy, for every information flow rides on some energy flow. (See Appendix A, Sec. 1.4.)

Our definition of the environment of a system as the set of all things coupled with components of the system makes it clear that it is the *immediate* environment, not the *total* one – i.e. the set of all the things that are not parts of the system. Except in extragalactic astronomy and in cosmology, we are interested not in the transactions of a system with the rest of the universe but only in that portion of the world that exerts a significant influence on the thing of interest. This immediate environment or *milieu* is the cell in the case of chromosomes, the rest of the organism in the case on an organ, the ecosystem in the case of an organism, the solar system in the case of a biosphere, and so on. In other words, the immediate environment of a thing is the composition of its next supersystem. (More in Sec. 1.4.)

A system that neither acts on nor is acted upon by any other thing is said to be closed. In other words, we make

DEFINITION 1.3 Let σ be a system with environment $\mathscr{E}(\sigma, t)$. Then σ is *closed* at t iff $\mathscr{E}(\sigma, t) = \emptyset$ – otherwise σ is *open*.

Since every thing but the universe interacts with some other things, we infer

COROLLARY 1.1 The universe is the only system closed at all times.

This holds whether or not the universe turns out to be spatially infinite, for the universe may be defined as that thing which has a void environment (i.e. which is self-contained).

So much for the concept of total closure. We need also the notion of partial closure, or closure relative to a given property, since a system may be open in some respects and closed in others. (Thus all systems are gravitationally open, but some are electrically closed, others are closed to the exchange of matter, still others to cultural influences, and so on.) We make then

DEFINITION 1.4 Let P be a property of a system σ in an environment $\mathscr{E}(\sigma, t)$. Then σ is *open with respect to P at t* iff P is related, at t, to at least one property of things in $\mathscr{E}(\sigma, t)$ – otherwise σ is *closed* in the respect P.

Comparing this definition with the previous one we realize that a system is closed iff it is closed in every respect.

Finally some comments on the concept of structure. Our use of it is common in mathematics and in the social sciences. Thus a famous anthropologist: for the biochemist an organism "is a complexly integrated system of complex molecules. The system of relations by which these units are related is the organic structure. As the terms are here used the organism is *not* itself a structure; it is a collection of units (cells or molecules) arranged in a structure, i.e. in a set of relations; the organism *has* a structure" (Ratcliffe-Brown, 1935). Biologists use 'structure' sometimes in the above sense and at other times as a synonym for 'anatomic component'. In the latter case they run the risk of talking about the structure of a structure.

It is sometimes useful to distinguish a system's internal structure from its external one. The former is the subset of the total structure formed by the relations (in particular connections) among the system components. And the external structure is of course the complement of the internal structure to the total structure. Though distinct, the internal and the external structure are interdependent. Thus the internal structure of a molecule, far from being a permanent and intrinsic property of the molecule, depends critically upon its external structure – i.e. the interactions between the molecule and its milieu (e.g. the solvent).

Another distinction worth making is that between total structure and spatial structure, or set of spatial relations among the parts of a thing. (Spatial structure or configuration should not be mistaken for shape. The great majority of systems in the universe, i.e. the hydrogen and helium atoms, are shapeless. Nor do social systems have a shape although they have a spatial configuration since they are made up of living beings that stand in definite spatial relations to one another.) Every system has both a system structure (or bondage) and a spatial structure (or configuration). On the other hand aggregates or assemblages have spatial structures but no system structures.

For ease of reference we collect some of the above elucidations in

DEFINITION 1.5 Let σ be a concrete system with A-structure $\mathscr{S}_A(\sigma, t)$ at time t. Then

(i) the *internal A-structure* of σ at t is the subset of $\mathscr{S}_A(\sigma, t)$ composed of the relations among the A-parts of σ at t;

(ii) the *configuration* (or *spatial structure*) of σ at t is the subset of $\mathscr{S}_A(\sigma, t)$ composed of the spatial relations among the A-parts of σ at t.

1.4. *Subsystem*

A system component may or may not be a system itself. If it is we call it a 'subsystem'. More explicitly, we make

DEFINITION 1.6 Let σ be a system with composition $\mathscr{C}(\sigma, t)$, environment $\mathscr{E}(\sigma, t)$ and structure $\mathscr{S}(\sigma, t)$ at time t. Then a thing x is a *subsystem* of σ at t, or $x \prec \sigma$, iff

(i) x is a system at time t, and

(ii) $\mathscr{C}(x, t) \subseteq \mathscr{C}(\sigma, t)$ & $\mathscr{E}(x, t) \supseteq \mathscr{E}(\sigma, t)$ & $\mathscr{S}(x, t) \subseteq \mathscr{S}(\sigma, t)$.

By definition, the subsystem relation $\prec$ is an order relation, i.e. it is reflexive, asymmetric, and transitive. So, in particular, if $\sigma_1 \prec \sigma_2$ and $\sigma_2 \prec \sigma_3$, then $\sigma_1 \prec \sigma_3$. We shall make use of this property when defining the notion of a system of nested systems (Definition 1.7).

Example 1 Factories, hospitals and schools constitute subsystems of any modern society. On the other hand the persons composing them are not themselves social systems: they are biosystems. *Example 2* A foetus is a subsystem of its mother; it becomes a system in its own right after birth: before that it does not fall under any of the laws, natural or social, that hold for independent systems.

Systems of different kinds have different compositions or different structures. (A difference in composition induces a structural difference but not conversely, as shown by the existence of isomers, i.e. systems with the same composition but different structures.) However, all systems of the same genus seem to have the same overall structure or "general plan" –

pardon the anthropomorphism. For example, all atoms consist of nuclei surrounded by electrons, all solids are atomic or ionic lattices inhabited by wandering electrons, and even the overall structure of the skeleton and organs is the same for all vertebrates. (However, the precise characterization of the notion of overall structure is an open problem.)

Structures are often said to come superposed or nested like systems of Chinese boxes. Thus a polypeptide is said to have two structures, one primary or basic (the linear sequence of amino acids), the other secondary and consisting in the configuration of the entire coil. The helical configuration of the DNA molecule is an example of a secondary structure. In turn the secondary structure may determine a tertiary structure, e.g. the folding of the whole double strand into a regular configuration. See Figure 1.3.

In our view there is no such thing as a hierarchy of structures. (Etymologically 'hierarchy' means a set of sacred components ordered by a power or domination relation.) What we do have here is a system of nested systems, i.e. a collection of systems each of which is a subsystem of a larger system (or supersystem). And what molecular biologists call 'primary structure' is the structure of the innermost or core system, the secondary structure is the structure of the next supersystem, and so on. This notion is elucidated by

DEFINITION 1.7. Let σ be a system and call Σ the totality of systems, and

$$N_\sigma = \{\sigma_i \in \Sigma \mid \sigma \prec \sigma_i \,\&\, 1 \leq i \leq n\}$$

a collection of supersystems of σ partially ordered by the subsystem relation $\prec$. Then

(i) N_σ is a system of *nested* systems with core σ;

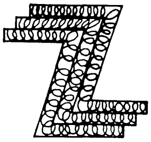


Fig. 1.3. An imaginary system of Chinese boxes or hierarchy of systems. The primary structure, i.e. the amino acid sequence, is not shown. The secondary structure is the helix, the tertiary the Z shape. And the quaternary structure is the way the individual Z's are assembled together, i.e. the double staircase.

(ii) the *primary structure* of σ is the structure of σ itself; the *secondary structure* of σ is the structure of the smallest supersystem of σ in N_σ, i.e. σ_1; in general, the *n-ary structure* of σ is the structure of σ_{n-1}.

1.5. *Level*

Talk of levels of organization (or complexity, integration, or evolution) and of a hierarchy of such has been rampant in science, particularly in biology, for the last half century or so. Unfortunately there is no consensus on the significance of the terms 'level' and 'hierarchy', which are used in a variety of ways and seldom if ever defined (Bunge, 1959b, 1959c). This fuzziness must be blamed not only on scientists but also on philosophers – on the inexact philosophers who despise clarity and on the exact ones who are not aware of the philosophical problems raised by scientific research. Let us attempt to remedy this situation by clarifying one concept of level, and the corresponding one of hierarchy, that are widely used in contemporary science.

The intuitive idea is simple: the things at any given level are composed of things belonging to preceding levels. Thus biospheres are composed of ecosystems, which are composed of populations, which are composed of organisms, which are composed of organs, which are composed of cells, which are composed of organelles, which are composed of molecules, which are composed of atoms, which are composed of so-called elementary particles. One way of exactifying this notion is by means of

DEFINITION 1.8 Let $L = \{L_i \mid 1 \leq i \leq n\}$ be a family of n nonempty sets of concrete things. Then

(i) one level *precedes* another iff all the things in the latter are composed of things in (some or all of) the latter. I.e. for any L_i and L_j in L,

$$L_i < L_j =_{df} (\forall x)[x \in L_j \Rightarrow (\exists y)\,(y \in L_i \;\&\; y \in \mathscr{C}(x))];$$

(ii) a thing *belongs to a given level* iff it is composed of things in (some or all of) the precedings levels. I.e. for any $L_i \in L$:

For any x in L_i: $x \in L_i =_{df} \mathscr{C}(x) \subset \bigcup_{k=1}^{i-1} L_k$;

(iii) $\mathscr{L} = \langle L, < \rangle$ is a *level structure.*

Note the following points. First, a level is not a thing but a set and therefore a concept, though not an idle one. Hence levels cannot act upon one another. In particular the higher levels cannot command or even obey the lower ones. All talk of interlevel action is elliptical or metaphorical, not literal. Second, the relation between levels is neither the part–whole relation nor the set inclusion relation but a *sui generis* relation definable in terms of the former. Third, there is nothing obscure about the notion of level precedence as long as one sticks to the above definition instead of construing '$L_i < L_j$' as "the L_i's are inferior to the L_j's" or in similar guise. Fourth, it is mistaken to call a level structure $\mathscr{L} = \langle L, < \rangle$ a *hierarchy*, because the level order $<$ is not a dominance relation (Bunge, 1973a). Fifth, our concept is so far static: we are not assuming anything about the origin or mode of composition of systems in terms of evolution.

1.6. *Systems Association*

Whether or not two things form a system, they can be assumed to associate (or add physically) to form a third thing. Thus thing a and thing b, no matter how distant and indifferent, may be assumed to form thing $c = a \dotplus b$. In other words, the set of things is closed under the operation $\dotplus$ of *association*, physical addition, or juxtaposition (Vol. 3, Ch. 1, Sec. 1).

Not so with systems: two systems may or may not associate to form a third. Thus two molecules may not combine to form a system, and two social systems may not merge to form a third. In general the physical addition or association of two things will be a thing but not a system: *systemicity is not conserved.* The environment, the structure and perhaps even the composition of the resulting thing are different from the mere union of the partial compositions, environments, and structures. See Figure 1.4. In short, the set of all systems has no algebraic structure – not even the rather modest one of a semigroup. But, of course, since systems are things, they do comply with the algebra of things. In particular they associate to form further things.

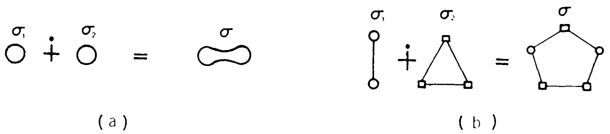

Fig. 1.4. (*a*) Before fusion, $\mathscr{E}(\sigma_1) = \{\sigma_2\}$, $\mathscr{E}(\sigma_2) = \{\sigma_1\}$. After fusion, $\mathscr{E}(\sigma_1 + \sigma_2) = \varnothing$. (*b*) Before merger, $\mathscr{S}(\sigma_1) = \{\text{Linear link}\}$ and $\mathscr{S}(\sigma_2) = \{\text{Triangular link}\}$. After merger, $\mathscr{S}(\sigma_1 + \sigma_2) = \{\text{Pentagonal link}\}$.

1.7. *Other Kinds of System: Property and Functional*

We are interested not only in concrete systems but also in property systems, or sets of interrelated properties, as well as in functional systems, or sets of coupled processes. For example, most of the properties of a thing that is either simple (basic) or a system hang together, i.e. a change in one of them is accompanied by changes in others. As a consequence most of the changes occurring in either a simple thing or a system are coupled, so that if one of them starts or stops, others change. (The cautious prefix 'most' is intended to exclude superficial properties, such as position and color, which can often change considerably, within bounds, without dragging changes in other properties.) Although every thing other than an aggregate or conglomerate has properties and undergoes processes that constitute systems, property systems and functional systems are particularly conspicuous among organisms. In particular the mental abilities of an animal form a system.

We shall use the following conventions:

DEFINITION 1.9 Let $p(x)$ be the set of properties of a thing x, and $\pi(x)$ the set of processes occurring in x. Then

(i) the subset $p_0(x) \subset p(x)$ is a *property system* of x iff every property in $p_0(x)$ is lawfully related to at least one other property in $p_0(x)$;

(ii) the subset $\pi_0(x) \subset \pi(x)$ is a *functional system* of x iff every process in $\pi_0(x)$ is lawfully related to at least one other process in $\pi_0(x)$.

Because in a system all properties and processes are lawfully interrelated we conclude that, for every x, x is a concrete system iff $p(x)$ is a property system or $\pi(x)$ a functional system.

1.8. *Concluding Remarks*

The literature on systems is vast, rapidly growing, and somewhat bewildering. (Cf. Klir and Rogers, 1977.) However, the field is still immature and its reputation is jeopardized by a fringe of charlatans. Suffice it to mention three indicators of immaturity.

Firstly, the very definition of the concept of a system is still in doubt, so that many a paper starts by spending time defining or redefining the concept. Yet, so much effort spent on definitions has yielded only three which are as popular as they are incorrect. According to the first definition, a system is a set of interrelated elements – which is fine for conceptual systems but not for concrete ones since sets, no matter how structured, are sets, hence concepts not things. The second definition equates a system with a black box equipped with inputs and outputs, which is fine in a few cases but useless when the internal structure of the system is relevant. And the third widely used definition is a generalization of the preceding, namely this: a system is a binary relation – again a conceptual object.

Secondly, some writers claim that everything imaginable is a system, and that a general theory of systems should deal with every possible thing (without thereby becoming part of philosophy) and every possible problem, theoretical or practical, concerning the behavior of systems of all kinds. Some have even asserted that such a theory should cover not only concrete systems but also conceptual ones, so that it would be a thoroughly unified science of everything.

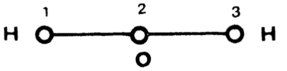
Thirdly, some enthusiasts of general theories of systems have seen in these a vindication of holistic philosophies, hence a condemnation of the analytic method characteristic of science. However, most of those who approve of general systems theories for their alleged holistic virtues either misuse the term 'holistic' to designate "systemic", or are interested in instant wisdom rather than painstaking scientific or philosophical research.

Such confusions and wild claims, which linger because of insufficient foundational research in the field of systemics, have elicited some entirely negative reactions to it (e.g. Berlinski, 1976). While there is some legitimacy in such reactions, there is no denying that systemics abounds in good theories – such as automata theory and general lagrangian dynamics – serviceable in a number of fields, and that it provides an inspiring framework for posing problems and building models. Rather than throw out the baby together with the bath water we ought to change the latter once in a while.

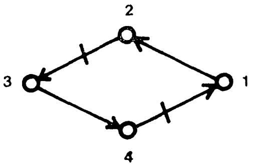
2. SYSTEM REPRESENTATIONS

2.1. *Coupling Graphs and Matrices*

We shall presently review two standard and equivalent ways of representing a system with a denumerable composition, be it a molecule or an industrial plant. They are the graph and the matrix representations. (See Klir and Valach (1967).) The following examples show how to proceed.

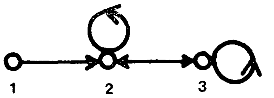


$$\sigma_1 = \begin{Vmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{Vmatrix}$$



$$\sigma_2 = \begin{Vmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \\ -1 & 0 & 0 & 0 \end{Vmatrix}$$

The arrows indicate excitation, the crossed arrows inhibition.



$$\sigma_3 = \begin{Vmatrix} 0 & 1 & 0 \\ 0 & 1 & 1 \\ 0 & 1 & 1 \end{Vmatrix}$$

The loops indicate self action or feedback.

We generalize the foregoing into the following semantic assumptions. Let σ be a system with m components and n different kinds of connection among them (e.g. mechanical, chemical, informational, social, etc.). Then σ is representable by

(i) a set of n directed graphs over the composition of σ, one for each kind of connection, with a total of m nodes (vertices), in such a way that (*a*) the nodes represent the components and (*b*) the edges represent the connections; or

(ii) a set of n $m \times m$ matrices ${}^pM$, where $1 \leq p \leq n$, such that (*a*) the matrix element ${}^pM_{rs}$ of the pth matrix represents the strength of the action of component r, in the pth respect, upon component s, and (*b*) the matrix element ${}^pM_{rr}$ stands for the action of kind p of the rth component on itself (feedback).

The off-diagonal elements ${}^pM_{rs}$, with $r \neq s$, represent connections other than self connections. There are $m^2 - m = m(m - 1)$ such elements per matrix, and a total of $nm(m - 1)$ per system with n different kinds of connection. This number is called the *coupling capacity* of the system.

So far we have represented the composition and the internal structure of a system while neglecting its environment, hence its external structure. An open system, i.e. one connected with its environment, can be represented as follows. Instead of building an $m \times m$ matrix for an m component system, as directed by the previous semantic postulate, we form an $(m + 1) \times (m + 1)$ matrix for each kind of connection, letting 0 stand for the environment *en bloc*. Any system component r for which $M_{0r} \neq 0$ is an input or receiver component, whereas s is an output or donor component of the system if $M_{s0} \neq 0$. For example, a two component open system with a single kind of connection can be represented by the matrix

$$M = \begin{Vmatrix} 0 & M_{01} & M_{02} \\ M_{10} & M_{11} & M_{12} \\ M_{20} & M_{21} & M_{22} \end{Vmatrix}.$$

The elements M_{01} and M_{02} are the inputs (to the first and second components respectively) and the entries M_{10} and M_{20} the outputs (of the first and second components respectively). The other entries represent the internal (or internuncial) connections among the system's components.

We generalize the preceding into the following semantic assumption. Let σ be a system with m components and n different kinds of connections among them. Moreover, let the environment of σ be construed as a single entity labelled 0. Then σ is representable by n $(m + 1) \times (m + 1)$ matrices ${}^pM$, where $1 \leq p \leq n$, such that

(i) the *internal connectivity* of σ in the pth respect is representable by the matrix obtained from ${}^pM$ by striking off the M_{r0} and M_{0s} elements;

(ii) the *input* to σ in the respect p is represented by the row of input entries of ${}^pM$, i.e.

$${}^p\mathscr{I}(\sigma) = \left\| {}^pM_{01} \quad {}^pM_{02} \ldots {}^pM_{0m} \right\|;$$

(iii) the *output* of σ in the respect p is represented by the column of output entries of ${}^pM$, i.e.

$${}^p\mathscr{O}(\sigma) = \left\| {}^pM_{10} \quad {}^pM_{20} \ldots {}^pM_{m0} \right\|^t,$$

where t designates the transposition operation (conversion of row matrix into column matrix);

(iv) the *behavior* (or *observable performance*) of σ in the respect p is the ordered pair

$${}^p\beta(\sigma) = \langle {}^p\mathscr{I}(\sigma), {}^p\mathscr{O}(\sigma) \rangle;$$

(v) the (total) *behavior* of σ is the set of its partial behaviors:

$$\beta(\sigma) = \{{}^p\beta(\sigma) \mid 1 \leq p \leq n\}.$$

Example In the simplest case, of a two component system interacting with its environment in a single way, we have

$$\mathscr{I}(\sigma) = \|M_{01} \quad M_{02}\|, \qquad \mathscr{O}(\sigma) = \begin{Vmatrix} M_{10} \\ M_{20} \end{Vmatrix}.$$

In the absence of any data or hypotheses concerning the internal structure (i.e. the full coupling matrix) of such a system, we must restrict our attention to its behavior. The best we can do is to guess that the latter is linear, i.e. that there exists a matrix T transforming inputs into outputs: $\mathscr{O} = T\,\mathscr{I}^t$, where $\mathscr{I}^t$ is the transpose of $\mathscr{I}$. We set then

$$T = \begin{Vmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{Vmatrix}$$

with unknown T_{ij}'s and perform the indicated operations:

$$T\,\mathscr{I}^t = \begin{Vmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{Vmatrix} \cdot \begin{Vmatrix} M_{01} \\ M_{02} \end{Vmatrix} = \begin{Vmatrix} T_{11}M_{01} + T_{12}M_{02} \\ T_{21}M_{01} + T_{22}M_{02} \end{Vmatrix} = \begin{Vmatrix} M_{10} \\ M_{20} \end{Vmatrix},$$

thus obtaining the algebraic system

$$\begin{aligned} T_{11}M_{01} + T_{12}M_{02} &= M_{10} \\ T_{21}M_{01} + T_{22}M_{22} &= M_{20}. \end{aligned}$$

This system of equations has no unique solution when only the behavior of the concrete system (i.e. the M_{0i}'s and the M_{j0}'s) are given, for in this case there are only two conditions (equations) for four unknowns (the T_{ij}'s). Even hitting upon a solution by trial and error won't advance us a single step in the process of finding out the structure of the system, i.e. the complete coupling matrix M. The only procedure that could bring success is to guess and try out alternative assumptions about the system's structure and check whether they do yield the observed (or conjectured) behavior. That is, the way to theoretical knowedge is not from behavior to inferred structure but from hypothesized structure to behavior. This shows that behaviorism, phenomenalism, and inductivism are incapable, not just unwilling, to explain behavior.

Obviously neither the graph nor the matrix representation of a system suffices for all purposes. It represents only the composition, structure, and environment of a system with neglect of its dynamics. A more complete representation can only be obtained by setting up a full fledged dynamical theory incorporating and expanding the information contained in the graph or the matrix representation. We turn next to the common core of such dynamical representations, namely the state space representation. (See the Appendices for a number of particular, yet also cross-disciplinary, mathematical models of systems.)

2.2. *The State Space Representation*

Every system of a given kind K has a finite number n of general properties, such as age, number of components, connectivity among them, inputs, and outputs. And each such general property is representable by a function $F_i\colon A \to V_i$, where $1 \leq i \leq n$. Collecting all such property-representing functions into a single ordered n-tuple or list

$$\mathbb{F} = \langle F_1, F_2, \ldots, F_n \rangle : A \longrightarrow V_1 \times V_2 \times \ldots \times V_n,$$

we form the *state function* of systems of the given kind. Just as $\mathbb{F}$ represents the totality of general properties of the K's, so each value $\mathbb{F}(a) = \langle F_1(a), F_2(a), \ldots, F_n(a) \rangle$ represents the totality of individual properties of a particular system, such as its age and composition at a given time.

The domain A of the state function $\mathbb{F}$ of systems of kind K is the cartesian product of certain sets, such as K, the family 2^E of sets of environmental items with which the members of K are coupled, the set F of reference frames, the set T of time instants, and so on. (2^E is the power set of the set E of environmental things, so the environment e of a particular system is a member of that family, i.e. $e \in 2^E$.) And the codomain V_i of the ith component F_i of the state function is usually taken to be some subset of the real line $\mathbb{R}$. (If a property is represented by a complex valued function each component of the latter counts as a component of $\mathbb{F}$.) In short,

$$\mathbb{F} : K \times 2^E \times F \times T \times \cdots \longrightarrow \mathbb{R}^n.$$

The value $\mathbb{F}(k, e, f, t, \ldots) = \langle a, b, \ldots, n \rangle \in \mathbb{R}^n$ of the state function of system $k \in K$ interacting with environmental items $e \in 2^E$, relative to reference frame $f \in F$ at time $t \in T$, is the *state* of k at t. The collection of all such possible states, which is a subset of $\mathbb{R}^n$, is the (conceivable) *state space* of systems of kind K, or $S(K)$ for short. However, since the components of $\mathbb{F}$ are lawfully interrelated, and thus mutually restricted, not every n-tuple of real numbers represents a really (or nomologically) possible state of a system. I.e. the *lawful state space* of systems of kind K, or $S_L(K)$ for short, is a proper subset of the conceivable state space $S(K)$.

In short, every really possible state of a K is a point in some region $S_{\mathbb{L}}(K)$ of the cartesian space $\mathbb{R}^n$. See Figure 1.5.

Example 1 In the elementary kinetic theory of gases, the state function is the triple consisting of the pressure, volume, and temperature functions. The corresponding state space is a cube contained in $(\mathbb{R}^+)^3$. *Example 2* In Hamiltonian dynamics the state (or phase) vector is $\langle q(k, f, t), p(k, f, t)\rangle$, where q is the canonical coordinate and p the corresponding momentum – neither of which need be mechanical properties. *Example 3* In chemical kinetics the instantaneous state of a chemical system is described by the values of the partial concentrations of reactants and reaction products. Therefore the state space of the system is a hypercube contained in $(\mathbb{R}^+)^n$, where n is the number of system components (reactants, catalyzers, and products). If there is diffusion, further axes must be added to the state space, in particular temperature and position coordinates. *Example 4* In the genetics of populations three commonly used state variables are the size of a population, the probability (incorrectly called "frequency') of some particular gene or gene constellation, and the latter's adaptive value. Hence for a system composed of two interacting populations, A and B, the state space is the region of $\mathbb{R}^6$ spanned by the sextuples $\langle N_A(t), N_B(t), P_A(t), P_B(t), v_A(t), v_B(t)\rangle$ in the course of time.

The concept of state space can be used to clarify that of system. The state space of an aggregate or conglomerate of non-interacting things is uniquely determined by the partial states spaces. Moreover, since the

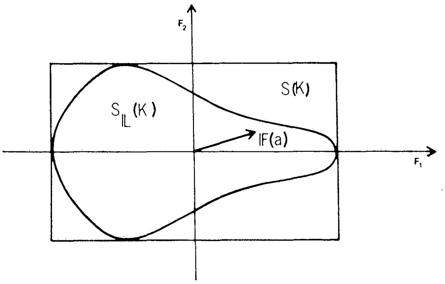


Fig. 1.5. The lawful state space $S_{\mathbb{L}}(K)$ of systems of kind K is a subset of the cartesian product of the ranges of the components of the state function. Only two such components, F_1 and F_2, are depicted here. $\mathbb{F}(a) = \langle F_1(a), F_2(a)\rangle$ is a (really) possible state of a particular system of the given kind. As time 'goes by', the tip of $\mathbb{F}(a)$ moves about within $S_{\mathbb{L}}(K)$.

contributions of the latter are all on the same footing, we may take the total state space to equal the union of the partial state spaces. In particular, let $S_{\mathbb{L}}(K)$ and $S_{\mathbb{L}}(M)$ be the lawful states spaces of things of kinds K and M respectively. Then the state space of the association $k + m$ of two non-interacting things of kinds K and M respectively, relative to the same reference frame, is $S_{\mathbb{L}}(K) \cup S_{\mathbb{L}}(M)$. Not so in the case of a system: here the state of every component is determined, at least partly, by the states other system components are in, so that the total state space is no longer the union of the partial state spaces. Thus in Example 4 above the state space of the two component system must be constructed *ab initio* rather than on the sole basis of the state spaces for the individual biopopulations. In sum, a thing is an *aggregate* if and only if its state space equals the union of the state spaces of its components – otherwise it is a (concrete) *system.* (Cf. Bunge, 1977a, 1977b.)

Every event occurs in or to some concrete thing and it consists in a change of state of the thing – the change being merely quantitative, as in the case of motion, or qualitative as well, as in the case of the coming into being or the metamorphosis of a thing. A light flash, the dissociation of a molecule, a storm, the growth of a bud, the learning of a trick, and the fall of a government are events – or rather processes, for they are complex and therefore analyzable into further events. Being changes in the states of things, events and processes are representable as trajectories in the state spaces of changing things. (An unchanging thing, if there were one, would have a state space consisting of a single point.) Different trajectories in a state space may have the same end points. That is, there are cases in which one and the same net change can be effected along alternative routes. See Figure 1.6.

The functions g and g' occurring in Figure 1.6 are not supposed to be arbitrary: they must be lawful if we are to allow only lawful events and discard lawless ones, i.e. miracles. In other words, the g occurring in the event representation $e = \langle s, s', g\rangle$ must be compatible with the laws of the system(s) concerned. Equivalently: a *lawful event or process* occurring in a system of kind K, with end points s and s', is representable by a triple $\langle s, s', g\rangle$, where $g : S_{\mathbb{L}}(K) \rightarrow S_{\mathbb{L}}(K)$ is compatible with the laws of the K's. If we disregard the intermediate states between the end points of the processes, we are left with arrows or ordered pairs $\langle s, s'\rangle \in S_{\mathbb{L}}(K) \times S_{\mathbb{L}}(K)$. The collection of all such pairs of states, i.e. the set of all net events (for a given g) constitutes the *event space* of the K's (for g). Symbol:

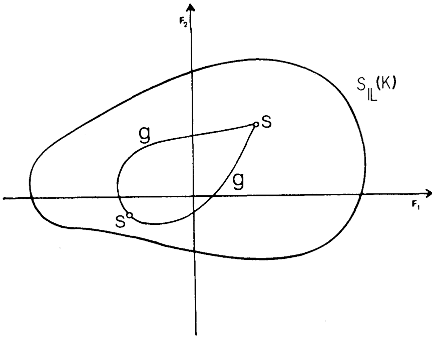

Fig. 1.6. Two different processes resulting in the same net change. The net change from state s to state s' can be represented as the ordered pair (or arrow) $\langle s, s' \rangle$. Since the change along curve g may be distinct from the change along curve $g' \neq g$, we must represent the full events (or processes) by $\langle s, s', g \rangle$ and $\langle s, s', g' \rangle$ respectively.

$E_{\mathbb{L}}(K) \subseteq S_{\mathbb{L}}(K) \times S_{\mathbb{L}}(K)$. In general the inclusion is proper: not all state transitions are lawful.

Since we shall make ample use of the state space representation in this work, we may as well compress the preceding into the following semantic assumption. For each kind K of system possessing n properties there is a property-representing function $\mathbb{F}: A \to V_1 \times V_2 \times \ldots \times V_n$ with n components, called a *state function* for systems of the kind. Furthermore

(i) the *totality of general properties* of systems of kind K is representable by the set of all the components (or coordinates) of $\mathbb{F}$, i.e. $p(K) = \{F_i \mid 1 \leq i \leq n\}$;

(ii) every *particular property* of a system of kind K is representable by a value of a component of $\mathbb{F}$, i.e. by $F_i(a)$ for $a \in A$ and some $1 \leq i \leq n$;

(iii) the *state* of systems of kind K at $a \in A$ is representable by the value of $\mathbb{F}$ at a, i.e. $s = \mathbb{F}(a) = \langle F_1(a), F_2(a), \ldots, F_n(a) \rangle$;

(iv) the collection of all such states of things of kind K, i.e. the range of $\mathbb{F}$, is the *lawful state space* of the K's, or $S_{\mathbb{L}}(K)$ for short;

(v) every *event* occurring in a system of kind K is representable by an ordered triple $\langle s, s', g \rangle$, where $s, s' \in S_{\mathbb{L}}(K)$ and g is a lawful map of $S_{\mathbb{L}}(K)$ into itself;

(vi) the collection of all really possible (lawful) events occurring in systems of kind K is the *event space* of K, or $E_{\mathbb{L}}(K)$ for short;

(vii) for a system in a given environment, and relative to a given reference frame, the state function takes often the form of a time-dependent function $\mathbb{F}: T \to \mathbb{R}^n$, where $T \subseteq \mathbb{R}$ is the set of instants relative to the given frame;

(viii) If $\mathbb{F}: T \to \mathbb{R}^n$, then the totality of *processes* occurring in a system x of kind K during the time interval $\tau \subseteq T$ is representable by the set of states x is in during τ:

$$\pi(x, \tau) = \{\mathbb{F}(t) \mid t \in \tau\};$$

(ix) the *history* of a system x of kind K representable by a state function $\mathbb{F} : T \to \mathbb{R}^n$, during the interval $\tau \subseteq T$, is representable by the trajectory

$$h(x) = \{\langle t, \mathbb{F}(t)\rangle \mid t \in \tau\};$$

(x) the *total action* (or *effect*) of a thing x on a thing y equals the difference between the forced trajectory and the free trajectory of the patient y:

$$A(x, y) = h(y \mid x) \cap \overline{h(y)}.$$

A detailed treatment of these concepts is given elsewhere (Vol. 3, Ch. 5). We shall presently use them to advance a handful of general principles concerning systems.

3. BASIC ASSUMPTIONS

3.1. *Structural Matters*

So far we have made only a few definitions and semantic assumptions but no substantive hypotheses on the nature of systems. (Theorem 1.1 on the existence of systems and the nonexistence of stray things, as well as Corollary 1.1 on the openness of systems, followed from our definition of a concrete system in conjunction with certain general postulates, about the nature of things, laid down in Volume 3.) We shall presently wager a handful of basic assumptions concerning systems of all kinds, the first being certain postulates of a structural kind. Since these assumptions will concern the transactions of a system with its environment, we may as well define the concepts of input and of output in more general terms than we did in Sec. 2.1. We start then with

DEFINITION 1.10 Let σ be a system with an (immediate) environment $\mathscr{E}(\sigma)$. Then

(i) the totality of *inputs* of σ is the set of all the environmental actions on σ:

$$U(\sigma) = \bigcup_{x \in \mathscr{E}(\sigma)} A(x, \sigma);$$

(ii) the totality of *outputs* of σ is the set of all the actions of the system on its environment:

$$V(\sigma) = \bigcup_{y \in \mathscr{E}(\sigma)} A(\sigma, y);$$

(iii) the *activity of the environment* of σ is

$$E(\sigma) = \bigcup_{x, y \in \mathscr{E}(\sigma)} A(x, y) \cup U(\sigma) \cup V(\sigma).$$

Our first hypothesis is that all systems receive inputs and are selective, i.e. accept only a (small) subset of the totality of environmental actions impinging on them. More precisely, we lay down

POSTULATE 1.1. Let σ be a system with total input $U(\sigma)$. Then
(i) $U(\sigma) \neq \emptyset$;
(ii) $U(\sigma) \subset E(\sigma)$ or, equivalently, the (in-selection) function

$$\mu: U(\sigma) \longrightarrow E(\sigma)$$

is the inclusion (or embedding) map of $U(\sigma)$ into $E(\sigma)$.

Example Talking to plants is ineffectual – except insofar as it nourishes them with water and carbon dioxyde.

A second, equally pervasive, feature of concrete systems is that they react on their environment, i.e. that their output is never nil. (The so-called machines without output, studied in automata theory, are of course fictions.) Moreover, in every system there is spontaneous activity, i.e. not elicited by any inputs. Thus we make

POSTULATE 1.2. Let $V(\sigma)$ be the total output of a system σ. Then
(i) $V(\sigma) \neq \emptyset$;
(ii) the (out-selection) function

$$\nu: V(\sigma) \longrightarrow E(\sigma)$$

assigns each system output an environmental action but not conversely.

Example In every neuron there is spontaneous activity that is superposed on the activity elicited by afferent stimulation.

The previous hypotheses are typical metaphysical principles in as much as they can be confirmed but not refuted, for they hinge on an item that is only partially knowable, namely the set E of environmental actions. Any evidence unfavorable to our postulates may be blamed on our ignorance of most of E.

The in-selection function μ and the out-selection function ν are joined in

DEFINITION 1.11 The function f that composes with the out-selection function ν of a system to yield its in-selection function μ, i.e. such that $\mu = f \circ \nu$, is called the *transfer* (or *transducer*) function f: $U(\sigma) \rightarrow V(\sigma)$ of σ:

$$\begin{tikzcd}
U(\sigma) \arrow[r, "\mu"] \arrow[dr, "f"'] & E(\sigma) \\
& V(\sigma) \arrow[u, "\nu"']
\end{tikzcd}$$

Example The retina transforms (or maps or codes) light stimuli into nervous signals.

We close this subsection with a batch of general principles that will be stated in an informal way:

POSTULATE 1.3 Let σ be an arbitrary system other than the universe. Then

(i) every input to σ is an output of some other system (i.e. there are no inputs out of the blue);

(ii) σ receives inputs of several kinds (i.e. at some time or other every one of the components of the state function of σ is bound to be affected by environmental changes);

(iii) for every action upon σ there is a threshold below which σ does not respond;

(iv) the total input of σ has a nonvanishing random component;

(v) there is a delay, however small, between every input and the corresponding output if any.

So much for our general structural assumptions. Let us now look at systems from an evolutionary perspective.

3.2. *Assembly and Emergence*

Any process whereby a system is formed out of is components is called 'assembly'; if the process is spontaenous, it is called 'self-assembly'. An assembly process can occur either in a single step or, more likely, in a number of steps: see Figure 1.7. We can express the idea formally with the help of the concept of bondage, or set of bonds among the components of a system, introduced in Sec. 1.2. Indeed we make

DEFINITION 1.12 Let x be a concrete thing composed initially of uncoupled parts (possibly systems themselves), i.e. such that $\mathbb{B}(x, t) = \varnothing$. Then

(i) *x assembles into y* at time $t' > t$ iff y is a system with the same composition as x but a nonempty bondage, i.e.

$$\mathscr{C}(y, t') = \mathscr{C}(x, t) \,\&\, \mathbb{B}(y, t') \neq \varnothing;$$

(ii) the assembly process is one of *self-assembly* iff the aggregate x turns by itself [i.e. naturally rather than artificially] into the system y;

(iii) the self-assembly process is one of *self-organization* iff the resulting system is composed of subsystems that were not in existence prior to the onset of the process.

Assembly processes can be natural or artificial, and those of the latter kind in turn experimental (or laboratory) or industrial. Artificial assembly processes are of course man-guided. However, there are degrees of control. It is one thing to assemble a machine from its parts and another to assemble a molecule from its precursors. In most cases the latter process

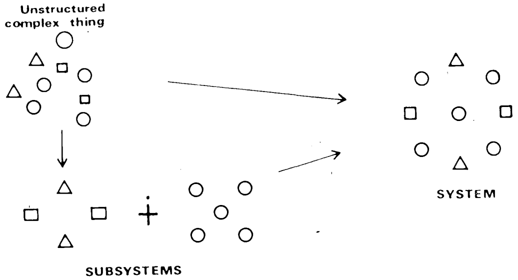

Fig. 1.7. Assembly of a system out of previously unconnected units, either directly or step-wise.

proceeds on its own – i.e. by virtue of its inner dynamics – once suitable reactants and physical conditions have been supplied. For example, proteins and even ribosome units will self-assemble *in vitro* in a matter of minutes if suitable precursors and physical conditions are provided. In this case man only lends a hand to nature, by reproducing conditions that have or could have occurred spontaneously.

All chemical and biochemical syntheses are of course assembly processes and moreover processes accompanied by the emergence of new properties. However, self-assembly occurs on all levels in a variety of manners. Perhaps the most conspicuous of all self-assembly process is the aggregation or clumping of atoms and cosmic dust brought about by gravitation. This is how planets and other celestial bodies are believed to have formed. Moreover, far from always leading to disorganized lumps, gravitational attraction can give rise to complex clustering on all astronomical scales, in particular star clusters, galaxies, and galaxy clusters. (See, e.g. de Vaucouleurs, (1970).) Similar examples of self-assembly by condensation of units of the same kind are the formation of molecular complexes (such as the haemocyanine polymolecule), of polymers such as the polypeptides and of crystals out of solutions. (See Calvin (1969); Eigen (1971); Lehninger (1975).) Needless to say, self-assembly, and in particular self-organization, occurs also on the social level: witness the formation of families, bands, communities, and social organizations of various kinds. In sum self-assembly and self-organization are not exclusive to life. What is peculiar to biotic self-organization is that it happens to ensue in living systems rather than in biochemical systems or in systems of some other kind. (In other words, it is an emergence mechanism leading to a new level of organization.) We shall assume that all systems short of the entire world have formed by assembly:

POSTULATE 1.4 All systems, except the universe, originate by assembly.

Remark 1 Natural systems originate by self-assembly, and artificial systems by artificial or man-made assembly. *Remark 2* An exception is made for the universe because (*a*) in naturalistic cosmologies the universe has neither an origin nor an end, and (*b*) in religious cosmologies it makes no sense to say that the universe originates by assembly, as this presupposes the prior existence of its components. *Remark 3* Surely a system may be formed by the breakdown of some supersystem. However, this is no counterexample to our postulate, which requires only that the original supersystem was the result of some assembly process. *Remark 4* Our axiom is far from obvious and it could not have been formulated before systems-theoretic thinking became pervasive, if only because the general concept of a system had not been elucidated until recently. *Remark 5* Our axiom is of particular relevance to the problem of the origin of biomolecules and biosystems. Until recently both were assumed either to have been created by divine *fiat* or to have existed from all eternity. Darwin's *Origin of Species* appeared only in 1859, and scientific research into the evolution of molecules started only one century later.

The components of a self-assembled system are called its *precursors*, an apt name suggesting that the system had not always been around but emerged from pre-existing things. Interestingly enough, (*a*) the precursors of a system are not blended but keep their individuality to some extent, and yet (*b*) they give rise to a thing possessing emergent properties. For example, the two hydrogen atoms that combine into a hydrogen molecule are distinct components of the latter, yet the spectrum of the molecule is radically different from that of its components. The first characteristic is formalized by saying that the composition of the self-assembled system equals the set of parts of its ancestors – i.e. the set of its precursors. And the notion of emergence can be elucidated as follows.

Call x a thing and $t \in T$ an instant of time, and introduce a function p that assigns the ordered couple $\langle x, t\rangle$ the set $p(x, t)$ of all the properties of x at t. That is, p is a function $p\colon \Theta \times T \to 2^{\mathbb{P}}$, where Θ is the set of all things, T the set of all instants, and $2^{\mathbb{P}}$ the family of subsets of the set $\mathbb{P}$ of all general properties of things. A change in thing x can be viewed as a certain change of state of x. Since x is held fixed throughout that change of state, we can use the simpler function

$$p_x\colon T \to 2^{\mathbb{P}} \quad \text{such that } p_x(t) = p(x, t).$$

In short, $p_x(t)$ is the collection of properties of thing x at time t. (For details on p_x, see Vol. 3, Ch. 2.)

Now let t and t' be two distinct instants, such that t precedes t'. The corresponding values of p_x are of course $p_x(t)$ and $p_x(t')$. If these two sets of properties of x are the same, then the thing has not changed qualitatively. If they are different, then the thing has gained or lost some properties. If the latter is the case, the newly gained properties will be said to be *emergent* relative to the given thing, even though they may be possessed by other things as well. In sum, we make

DEFINITION 1.13 Let x be a thing with properties $p_x(t)$ at time t, and properties $p_x(t')$ at a later time $t' > t$. Then

(i) the *total qualitative novelty* occurring in x during the interval $[t, t']$ is the symmetric difference

$$n_x(t, t') = p_x(t) \triangle \bigcup_{t<\tau\leq t'} p_x(\tau);$$

(ii) the *emergent properties* that appear in x during the interval $[t, t']$ are those in

$$e_x(t, t') = \bigcup_{t<\tau\leq t'} p_x(\tau) - p_x(t).$$

Example 1 Every nuclear and every chemical reaction results in the emergence of things endowed with emergent properties. *Example 2* The breakdown (dismantling) of a system, and the substitution of some of its components, are emergence processes.

We make bold and generalize:

POSTULATE 1.5 Every assembly process is accompanied by the emergence of some properties and the loss of others. I.e. let the parts of a thing x self-assemble into a system during the interval $[t, t']$. Then the system lacks some of the properties of its precursors – i.e. $p_x(t) - p_x(t') \neq \varnothing$–but on the other hand it possesses some new properties – i.e. $p_x(t') - p_x(t) \neq \varnothing$.

Thus far we have been concerned with qualitative novelty in a particular thing regardless of whether the given emergent properties are possessed by any other things. We now elucidate the concept of emergence for the first time, or absolute emergence:

DEFINITION 1.14 The *absolutely emergent properties* (or firsts) appearing in a thing x during the lapse $[t, t']$ are those in

$$e_x^a(t, t') = e_x(t, t') - \bigcup_{y\in\Theta} \bigcup_{\tau\in T} p_y(\tau) \quad \text{with } y \neq x \quad \text{and} \quad \tau \leq t'.$$

3.3. *Selection*

New systems are being formed all the time, but not all of them are viable in the environment in which they emerge. In fact many are unfit, hence ephemeral, and this either because they are internally unstable or because they cannot cope with environmental aggression. In the latter case we have to do with selection. In other words, the environment selects the fittest systems, be they molecules or men. We can formulate this idea with more precision in the following way.

We assume that every environment performs a selective or filtering action on any population of systems of some kind. This selective action consists in the shrinking of the original population S to some subset A of S, namely the collection of viable or adapted members of S. A permissive environment is such that A is almost as big as the original S, whereas a harsh environment will reduce A to a very small, possibly empty, subset A of S. We condense these ideas into a definition and a postulate.

DEFINITION 1.15 Let S be a set of systems of a given kind K, assembled during some time interval in a given environment $E = \mathcal{E}(\sigma)$ common to all $\sigma \in S$. Further, call $i_E\colon S \to A_E$ the inclusion function from S into A_E, where $A_E \subseteq S$. (I.e. $i_E(x) = x$ for any x in A_E.) Then

(i) the environment E exerts the *selectivw action*

$$i_E\colon S \longrightarrow A_E$$

on the population S iff, during the next time interval, only the members of A_E remain in S;

(ii) A_E is the set of systems of kind K *selected by* (or *adapted to*) the environment E, and $\overline{A_E} = S - A_E$ the collection of systems of the same kind *eliminated by* (or *ill adapted to*) E, during the given time interval;

(iii) the *selection pressure* exerted by E on S is the number

$$p(S, E) = \frac{|\overline{A_E}|}{|S|} = 1 - \frac{|A_E|}{|S|},$$

where '$|X|$' designates the numerosity of the set X.

Clearly, the p values range between 0 (maximal fitness) and 1 (maximal unfitness).

Our promised hypothesis reads thus:

POSTULATE 1.6 All systems are subject to environmental selection (or to a nonvanishing selection presssure). I.e. for every set S of any kind K and every environment E common to the members of S, there is a selective action function $i_E\colon S \to A_E$ with $A_E \subset S$.

An immediate consequence of this axiom together with Postulate 1.4 is

COROLLARY 1.2 All self-assembled systems are subject to environmental selection (or to a nonvanishing selection pressure).

Different environments may exert different selective pressures on one and the same system population. (This is why for every S we have as many inclusion maps i_E as possible environments of the S's.) For example, two different habitats, or two different seasons in the same habitat, may exert different selective actions upon one and the same population of organisms. And such actions compose in accordance with

THEOREM 1.2 Let E and E' be two different consecutive environments of members of a population S of systems of some kind, and let i_E and $i_{E'}$ be their respective selective actions (during the corresponding consecutive periods). Then the resulting selective action is the composition of the two partial selective actions, i.e.

$$i_{EE'} = i_{E'} \circ i_E,$$

and the corresponding selection pressure equals

$$p(S, EE') = p(S, E) \cdot p(A_E, E') = \left(1 - \frac{|A_E|}{|S|}\right) \cdot \left(1 - \frac{|A_{E'}|}{|A_E|}\right).$$

It should be obvious that the selective actions of two environments do not commute in general. So much so that, if the first environment is totally hostile, there is nothing left for the second to select from. The last environment always has the last word. See Figure 1.8.

It is often maintained that the environment is not creative, for all it is capable of is weeding out the maladapted. This is false. Firstly, the environment of every system includes further systems, some of which are capable of acquiring new properties. Secondly, every new system is as-

$$\begin{tikzcd}
S \arrow[r, "i_E"] \arrow[dr, "i_{EE'}"'] & A_E \arrow[d, "i_{E'}"] \\
& A_{E'}
\end{tikzcd}$$

(a)

$$\begin{tikzcd}
S \arrow[r, "i_{E'}"] \arrow[dr, "i_{E'E}"'] & A_{E'} \arrow[d, "i_E"] \\
& A_E
\end{tikzcd}$$

(b)

Fig. 1.8. The selective action of E followed by E' (diagram (*a*)) differs from the resulting selective action in the reverse order (diagram (*b*)).

sembled from units supplied by the environment: the latter provides the opportunity for self-assembly, hence for emergence. In sum, the environment of any system is creative – only, it is selective and exclusive rather than permissive.

3.4. *Evolution*

Self-assembly may result in evolution – and this at the molecular, the organismic, the populational, and other levels. Let us then examine the general concept of evolution. To this end let us begin by elucidating the general concept of descent:

DEFINITION 1.16 Let S be a collection of systems of some kind. Then for any x and y in S,

(i) x is an *immediate ancestor* of y (or y *descends immediately* from x) iff x and y belong to the same species and x or a part of x is a precursor in the assembly of y;

(ii) x is a *mediate ancestor* of y (or y *descends mediately* from x) iff there is a z in S such that x is an immediate ancestor of z, and z an immediate ancestor of y;

(iii) x is an *ancestor of* y (or y *descends* from x) iff x is either an immediate or a mediate ancestor of y. Symbol: $x < y$;

(iv) the *ancestry* of x is the collection of ancestors of x:

$$A(x) = \{y \in S \mid y < x\};$$

(v) the *progeny* of x is the collection of things of which x is an ancestor:

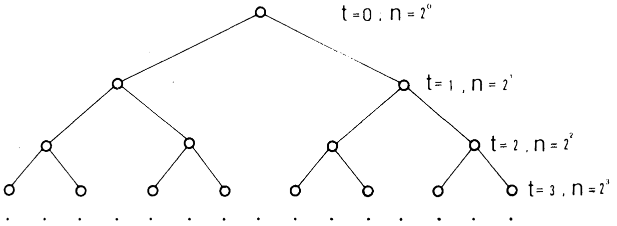
$$P(x) = \{y \in S \mid x < y\};$$

(vi) the *lineage* of x is the union of the ancestry and the progeny of x:

$$L(x) = \{y \in S \mid y < x \quad \text{or} \quad x < y\}.$$

Clearly, the ancestry relation $<$ is a strict partial order. The graph of $<$ is then directed with single edges and no loops.

Example 1 Hydrocarbons descend from C and H, polymers from the respective monomers, ribosomes from RNA molecules and proteins, animals from their parents, etc. *Example 2* The progeny of a bacterium reproducing by binary division looks like this:



$t = 0, \quad n = 2^0$

$t = 1, \quad n = 2^1$

$t = 2, \quad n = 2^2$

$t = 3, \quad n = 2^3$

While in many cases the members of the lineage of a system belong to the same species, sometimes they do not. When they don't, the lineage constitutes an evolutionary line. More precisely, we make

DEFINITION 1.17 Let $L(x)$ be the lineage of a system x of kind K. Then $L(x)$ is an *evolutionary lineage* iff at least one ancestor or one descendant of x belongs to a kind K' different from K.

The notions of descent, lineage and evolutionary lineage carry over to collections of systems:

DEFINITION 1.18 Let S be a family of collections of systems: $S = \{S_i$ is a collection of systems $| \; 1 \leq i \leq n\}$. Then for all S_j and S_k in S,

(i) S_k *descends* from S_j iff every member of S_k descends from some members of S_j: $S_j \prec S_k$;

(ii) the *lineage* of S_j is the family of collections descending from S_j or from which S_j descends:

$$\Lambda(S_j) = \{X \in S \mid X \prec S_j \quad \text{or} \quad S_j \prec X\};$$

(iii) $\Lambda(S_j)$ is an *evolutionary lineage* iff at least one of the ancestors or the descendants of S is included in a species different from that which includes S_j.

Recall now that, according to Postulate 1.4, every system is formed by assembly. Since a system and its precursors belong to different species, it follows that assembly ensues in speciation, i.e. the formation of new species. In other words, we have

THEOREM 1.3 Every concrete system belongs to some evolutionary lineage.

In closing this subsection let us emphasize that the preceding hypotheses are assumed to hold for systems of all kinds – physical, chemical, biological, or social. The peculiarities of systems of these system genera will be studied in succeeding chapters.

4. SYSTEMICITY

4.1. *Integration, Cohesion, Coordination*

Whatever is a system is also a whole but not conversely: an aggregate of independent components is a whole but not an integrated or unitary one. (Compare a living being with its ashes.) Now, systemicity or integration comes in degrees: some systems are more tightly knit than others. The degree of integration depends on the connections or links among a system's components relative to the disintegrating actions of the environment. If the inner couplings are "positive" (or "attractive") and strong, the degree of integration is high; if the links are still positive but weak, the degree of integration is low; and if the links are "negative" (or "repulsive"), there is no systemicity or integration at all. Finally, if some of the links are "positive" while others are "negative", the degree of integration depends on which of them are overriding. For example, a stable atomic nucleus is held together by nuclear forces that overcome the electrical repulsions; and a stable human community is held together by participation in enterprises of common interest, the value of which is greater than that of rivalry or competition – until of course the latter gets the upper hand.

In the case of physical, chemical, and perhaps also biological systems, what measures their degree of integration is their binding energy or, what comes to the same, their dissociation energy. This is the minimal energy required to dissociate the system into its components. It is zero for an aggregate. But such a measure is not universal: it fails to apply to systems where information links play at least as important an integrating role as forces proper – as is the case with social systems. In short, there is no universal measure of the degree of integration or cohesion of a system. However, we can assume the methodological postulate that a measure can be set up for each system genus, or even for each class of models, regardless of the nature of the components of the systems represented by such models.

Example Two things, labeled 1 and 2, form a *linear system* if the components of the state function $\mathbb{F} = \langle F_1, F_2 \rangle$ of the latter satisfy the rate equations

$$\dot{F}_1 = a_{11}F_1 + a_{12}F_2, \qquad \dot{F}_2 = a_{21}F_1 + a_{22}F_2,$$

where the a_{ij} are in general complex numbers. The *degree of integration* or *cohesion* of the system can then be defined as

$$w = \frac{|a_{12}|}{|a_{11} + a_{12}|} + \frac{|a_{21}|}{|a_{21} + a_{22}|}.$$

If the a_{ij} are not constant but time dependent, w itself will depend on time. In general, $w: T \to [0, 1]$.

If $a_{12} = a_{21} = 0$, the components do not form a system; in every other case they do. In particular, if component 1 controls component 2, then $a_{12} = 0$ and $a_{21} \neq 0$, whence $0 < w \leq 1$. And if there is symmetric interaction, $a_{12} = a_{21} \neq 0$. Finally, if all the a_{ij} equal unity, $w = 1$, i.e. the system is maximally cohesive.

Assume then that it is possible to define in each case a measure $w: T \to [0, 1]$ of the degree of integration of systems of any given kind. Then by charting the course of w values we can follow the history of the system from buildup to breakdown through its stable stage if any. In other words, we can introduce

DEFINITION 1.19 Let σ be a system with degree of cohesion or integration $w(t)$ at time t. Then σ is *stable* during the time interval τ iff $w(t)$ is constant for all $t \in \tau$ or at most fluctuates within bounds around a constant value. Otherwise σ is *unstable* and, in particular,

(i) *builds up* (*integrates* or *assembles*) iff its degree of integration increases in time;

(ii) *breaks down* (*disintegrates* or *dismantles*) iff its degree of integration decreases in time.

The degree of integration or cohesion of a system is related to its size or number of components as well as to the nature of the latter. A system with an extremely large number of components may be unstable and ultimately break up into a number of subsystems: there is always some upper limit to the size of a system – a limit to growth. See Figure 1.9. We summarize this empirical generalization into

POSTULATE 1.7 For every kind of system there is an optimal size, i.e. a number of components that maximizes the degree of integration (cohesion) of the system in the given environment. That number is called the *critical size*.

An immediate consequence of this assumption is that, for every kind of system, there is (*a*) a *threshold size*, i.e. a number of components below

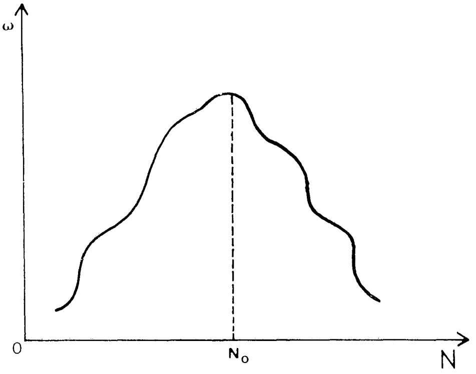


Fig. 1.9. Degree of integration (cohesion) per number of components vs. total number of components. N_0 = optimal or critical size.

which the aggregate does not form a system, and (*b*) a *maximum size*, i.e. a number above which the system breaks down.

Remark 1 Unlike most other axioms of our theory, Postulate 1.7 is empirically testable. For one thing it might well be that for systems of certain kinds there is more than a single critical size. If this were the case we would have to make a small adjustment in Postulate 1.7. *Remark 2* Accretion by gravitational pull would seem to refute our postulate. It does not, for the same process increases the density of matter and radiation energy, and this eventually sets up nuclear reactions that may lead to either explosion or collapse.

The preceding axiom concerns the overall integrity or cohesion or a system without regard for the integration of its subsystems. If a system does have subsystems, not just components, then the cohesion of the subsystems competes with that of the overall system. *Example 1* A molecule with all of its valences saturated is stable, hence it coheres poorly with similar molecules, e.g. its fellow components in a polymer. In general, the greater the complexity of a molecule the lower its overall binding energy. *Example 2* A large human family has weaker interactions with the rest of society, per family member, than a small family: the members of a large family spend a larger amount of energy interacting among themselves than with their social environment. Hence while they fare well in cases of disaster they may not make good citizens.

We compress these observations into

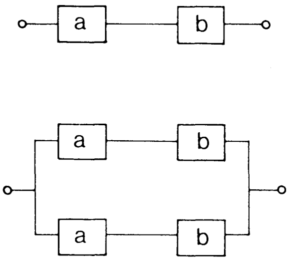
POSTULATE 1.8 The more cohesive each subsystem the less cohesive the total system.

A problem for the systems designer, be he an engineer or an applied social scientist, is to hit on a structure that will maximize overall integrity. He cannot maximize the cohesion of each subsystem because then it becomes self-sufficient instead of serving the whole. And he cannot minimize the partial integrities because then the subsystems would become unstable (unreliable). A compromise solution is to choose medium cohesion subsystems and to have more than one perform a given function or role. Such design enhances the reliability of the system regardless of its nature. See Figure 1.10.

Finally, another concept relevant to that of systemicity is the notion of coordination, which must be distinguished from that of integration. If integration fails the system undergoes *structural breakdown.* On the other hand coordination concerns the relation among either components or functions resulting in functional maintenance. If coordination fails the system undergoes *functional breakdown.* There can be integration without coordination but not conversely. A complex machine out of kilter is integrated but not coordinated. On the other hand organisms are coordinated and *a fortiori* integrated as long as they live. A possible characterization of the concept of coordination is given by

DEFINITION 1.19 If x and y are either in the composition or in the structure of a system, then x and y are said to be *coordinated* iff they contribute jointly to the integrity of the system.

Coordination does not exclude inhibition. Quite on the contrary: when



Reliability $= R = P(a) \cdot P(b)$
Probability of failure $= 1 - R$.

Probability of failure of one branch $= 1 - R$.
Probability of failure of both branches $=$
$(1 - R)^2 \leq 1 - R$
Reliability of system $= 1 - (1 - R)^2 = 2R - R^2$
$\cong 2R$ for small R.

Fig. 1.10. Increasing overall reliability (or degree of integration), by increasing redundancy, i.e. the number of subsystems performing the same function. $P(a)$ is the probability that component a will perform its regular function(s).

coordination is a result of control it includes feedback, which, when negative, is a kind of inhibition. Indeed without such a control excitation might destroy the system. But of course there can be coordination without the intervention of a control system. For example the corpus callosum bridges the two brain hemispheres in vertebrates and thus renders their coordination possible but is not a control system itself. On the other hand the entire central nervous system, which is a controller, coordinates all the subsystems that make up the vertebrate organism.

So much for the concept of wholeness. We now turn to the three main philosophical doctrines concerning wholes.

4.2. *Holism, Atomism, Systemism*

There are three possible doctrines concerning wholes: holism, atomism, and systemism. Holism is the ontological view that stresses the integrity of systems at the expense of their components and the mutual actions among them. It is characterized by the following theses.

H1 The whole precedes its parts. At first blush this thesis looks true. Thus before going for a hair cut we must have grown some hair. But of course the hair grew gradually, not all of a sudden: it became a whole in the course of a process of multiplication of parts (cells). Before making a general pronouncement concerning which precedes which we should examine the actual process in question. A system precedes its components only during a breakdown process; it succeeds them during the synthesis or formation process. In any case the existence of a system may not be obvious: it may call for an explanation in terms of both the mutual actions of parts and environment. No such explanation will be sought if the whole is taken for granted and regarded as the ultimate ground for the existence of its parts.

H2 The whole acts on its parts. For example, it will be said that the needs of the organism (or the society) as a whole dictate the functioning of its parts. But of course there would be no whole were it not for the coordination of its parts. There is no action of the whole on ist parts; rather, there are actions of some components upon others. Thus the vibration modes of any single particle in an elastic body are influenced by the motion of the other particles; likewise the behavior of any person is partially determined by that of his fellow society members. In all these cases we have not the whole acting on its parts but some or even all of the remaining components of the system acting on the given component, or the behavior of the latter being partly determined by the place it occupies in the system, in particular by its function or role.

H3 The whole is more than the sum of its parts. As it stands the thesis is hardly intelligible. It becomes intelligible if by 'sum' one means the juxtaposition (physical sum or association $+$) that we met in Sec. 1.6, and if by 'more' one means that the whole, provided it is a system, has emergent properties that its components lack (cf. Sec. 3.2). Reformulated in this way, i.e. in a nonholistic fashion, H3 acquires a definite sense – but it proves to be only partially true. Indeed, although every system is a whole, not every totality is a system; thus the mere aggregation of things need not result in an integrated whole or system (cf. Sec. 4.1.). What make a whole into a system are precisely the actions exerted by some of its parts upon others. But the holist does not care for the disclosure of such couplings, i.e. the system structure: he despises analysis.

H4 Wholes emerge under the action of agents that transcend both the actions among the components and the environmental influences. For example, morphogenesis is guided by an entelechy, or *élan vital*, or morphogenetic field external to the components. In sum, the formation of totalities transcends their components and is traceable to inscrutable entities. Thus far the holistic account of the formation of wholes. Needless to say, science has no use for such secret hence incontrollable principles of organization. Instead, science acts on a principle of immanence, not transcendence, namely this: Only the components, the way they come together, and the environment determine what kind of thing a totality shall be. (Hence our representing a system by the ordered triple: composition-environment-structure.)

H5 Totalities cannot be explained by analysis: they are irrational. This thesis is trivially true if by 'analysis' is meant only decomposition into parts, since then only the composition of a system but not its structure is revealed. If the latter is left out then of course it becomes impossible to account for the systemic or gestalt properties of a totality. But the physicist does not claim that water is just an aggregate of H_2O molecules, and the sociologist does not assert that society is just a collection of persons. In either case the links among the components (hydrogen bonds, work relations, or what not) must be disclosed or hypothesized to understand the formation, cohesion, and eventual breakdown of a totality. Such an analysis is the conceptual basis for any effective synthesis or upward building, as well as for the effective analysis or disintegration of a system.

H6 The whole is better than any of its parts. This value judgment has been brandished as an ideological hatchet aimed at suppressing the rights of individuals and groups in the name of the good of the whole or higher system, in particular the economico-political establishment, regardless of whether the latter does in fact work for the common good. We shall waste no time on this fig leaf.

Holism, in a nutshell, is antianalytic and therefore antiscientific. In effect, it has been responsible for the backwardness of the nonphysical sciences. And it has contributed precious little to serious systemics precisely because (*a*) it has not engaged in a study of the links that hold any system together, and (*b*) rather than constructing conceptual systems (theories) to account for concrete systems, it has spent itself in attacking the analytical or atomistic approach and praising totality as such. Whatever truth there is in holism – namely that there are totalities, that they have properties of their own, and that they should be treated as wholes – is contained in systemism, or the philosophy underpinning systemics or the general theory of systems (cf. Bunge, 1977d).

In opposing holism we do not espouse its opposite, namely atomism – the thesis that the whole is somehow contained in its parts, so that the study of the latter should suffice for understanding the former. Certain wholes, to wit systems, do have collective or systemic properties not possessed by their components, and this is why they must be studied as systems. Consider the celebrated though ill understood example of a so-called contingent identity, namely Water = H_2O. This is no identity at all for, whereas the LHS is short for 'water body' (e.g. a lake), the RHS describes a property of its molecular components. (No identity is possible between a thing and a property.) What is true, of course, is that the molecular composition of water is a set of H_2O molecules, but this is no identity statement. (In other words, the correct statement is this: For any water body w, $\mathcal{C}(w) \subset$ The set of H_2O molecules.) Moreover, specifying the composition of a system does not suffice to characterize it as a system: we must add a description of the system structure. And it so happens that water, as a system composed of myriads of H_2O molecules, has properties that none of its components has – e.g. transparency, a high dielectric power (hence a high dissolving power), freezing at 0°C, and so on and so forth. Some such properties must be included in any realistic model of water.

The ontological differences between a body of water and a H_2O molecule are such that, to account for the behavior of the former, we need not only all the knowledge we have about the individual H_2O molecule but also a host of hypotheses and data concerning the structure of water (i.e. the relative configuration of H_2O molecules in the lattice) as well as hypotheses and data about the dynamics of water bodies – hypotheses and data which vary of course according to whether water is in the gaseous, liquid, or solid phase. In sum, to describe, explain or predict the properties of water we use both microlaws and macrolaws.

Atomism, an ontological doctrine, is usually, though not necessarily, allied with *reductionism*, the epistemological doctrine according to which the study of a system is reducible to the study of its components. (The converse is false: one can be an epistemological reductionist, yet acknowledge wholes, emergence, and levels.) The reductionist will claim of course that we may use macrolaws and, in general, laws of systems, as a convenience, though in principle we should be able to get along with microlaws (or laws of components) alone, since the former are reducible to (deducible from) the latter. This thesis contains a grain of truth but is not the whole truth. No theory T_2 of water as a body follows solely from a microphysical theory T_1 of the H_2O molecule – not even by our adjoining what some philosophers call the bridge laws relating macrophysical concepts (e.g. pressure) to microphysical ones (e.g. molecular impact). Much more than this must added to the primary or reducing theory T_1 in order to obtain the secondary or reduced theory, namely hypotheses concerning the interactions among the system components.

The extreme case of reduction is that of straightforward deduction from a given set of premises, or *strong reduction*. Examples: reduction of particle mechanics to continuum mechanics, and of ray optics to wave optics. (The converse reductions are impossible.) These are rather exceptional cases. In general we must resort to a more complex strategy, namely *weak reduction*, or deduction from a primary theory in conjuction with a set of conjectures and data congenial with but alien to the former. The structure of this inference is:

$$T_1 \cup \text{Subsidiary hypotheses and data concerning interactions among components} \vdash T_2.$$

The subsidiary hypotheses constitute a model of the composition and structure of the system. Since this model, though couched in the language of T_1, is not included in T_1, we are in the presence not of straight (or strong) but of partial (or weak) reduction. (Cf. Bunge, 1977f.)

Note that we are not stating that the properties of water, or of any other macrosystem, are mysterious. On the contrary, they can be explained at least in outline. For example, the exceptionally high boiling point and evaporation heat of water are explainable in terms of the hydrogen bonds linking together all the H_2O molecules in a water body, bonds which are in turn explained by the composition and the structure of the H_2O molecule. But the point is that the intermolecular hydrogen bonds do not occur in the study of the individual H_2O molecule. In other words, although water is composed of H_2O molecules it does not reduce to H_2O – *pace* the efforts of enlightened philosophers to crush the holistic monster (e.g. Kemeny and Oppenheim, 1956; Oppenheim and Putnam, 1958, Putnam, 1969).

In short, atomism is almost as false as holism, the difference lying in that, whereas the former stimulates research, the latter blocks it. Each of these views has a grain of truth that the systemic view preserves and expands.

5. CONCLUDING REMARKS

The idea of a system, as distinct from a loose aggregate, is very old. Yet it has only recently been elucidated and exploited systematically. The mere suggestion that the thing we happen to be looking at, manipulating, or investigating might be a system rather than an unstructured object or a mere heap, will guide our study and handling of it. Indeed, if we suspect that a certain thing is a system then we shall endeavor to identify its composition, its environment, and its structure.

The order in which the three coordinates of the system concept appear is natural rather than accidental. Indeed, listing a system's components must precede any question regarding its environment and its structure; and identification of the environment comes before display of the structure, because the latter is the collection of relations among the components and among these and environmental items. True, when coming across certain systems, such as a plant, a watch, or a galaxy, we often begin our search with the totality and its environment, ending up by disclosing its composition and its structure. But when investigating a forest, a social system, and *a fortiori* a social supersystem such as a nation, we first meet its components (or atomic parts) in their milieu and try to figure out the structure of the whole by studying the behavior of the individual components. In either case, i.e. whatever our mode of perception may be, the conceptual analysis of a system must proceed in the way indicated – identification of composition, environment, and structure – if only for mathematical reasons.

Indeed it makes no sense to hypothesize any relations without knowing what the relata (system components and environmental units) may be. Therefore the holistic claim that atomistic analysis or the part method is incapable of grasping totalities, is groundless. On the contrary, holism is incapable of accounting for any totalities precisely because it refuses to disclose the components that are held together in the system: no components, no bonds among them. This is not to condone the antithesis of holism, namely atomism, and its usual epistemological partner, reductionism, according to which wholes – in particular, systems – are artifacts, emergents are identical with resultants, and levels are just convenient methodological categories.

The world view that emerges from this chapter is systemic: it holds that the universe is a system composed of subsystems. More precisely, the universe is the supersystem of all other systems. The world is thus neither a solid block nor a heap of disconnected items. It is held together by a number of links, from intermolecular bonds to gravitation to information. The world is material but not just a lump of physical entities: it is composed of systems of a number of qualitatively different kinds. Although all systems are physical not all of them are just physical. The universe is enormously variegated: its components can be grouped into a number of levels, such as the physical, the chemical, the biological, and the social levels. Moreover the world is restless and all of its changes are patterned (lawful). The world is, in sum, a coherent or integrated system of systems, and one that is varied, changeable, and regular.

CHAPTER 2

CHEMISM

All concrete systems are physical entities, in that they possess energy – a measure of changeability (Vol. 3, Postulate 5.3). However, some concrete systems are more than just physical entities, in the sense that the categories of physics are insufficient to account for them. For example, some are social systems. And although some of the concepts of physics – in particular the notion of energy – are necessary to account for any society, most are unnecessary. On the other hand social science requires new concepts, such as those of artifact, social group, justice, and culture. The peculiar concepts of social science are supposed to represent emergent properties of a society, i.e. properties that are not possessed by its components. Likewise the study of the components of any society, i.e. social animals, calls for a number of distinctly biological categories, such as reproduction, sex, and death. And if the animals happen to have a highly evolved nervous system, we shall need still other categories, such as the concepts of altruism and planning, which are usually regarded as psychological. Finally, organisms are composed of chemical systems, which are physical entities of a very special kind, namely composed of atoms and molecules engaged in chemical reactions.

Thus the totality of concrete entities may be grouped into five genera: the set of physical things (e.g. atoms and fields), the set of chemical systems (e.g. protein-synthesizing units), the set of biosystems (organisms and their organs), the set of sociosystems (societies and their subsystems and supersystems), and the set of artificial things. (The set of psychosystems, or animals endowed with mental abilities, is assumed to be a subset of that of biosystems.) The first three genera precede the other two in the sense that they supply the components of the higher order things or take part in some other way in their assembly. Since the lower a genus the more populous it is, we may depict the structure of reality as a pyramid: see Figure 2.1. This suggests the plan of this volume. (More on this structure in Ch. 6.)

In this chapter we shall hardly touch on physical systems: first, because they are the best understood of all; second, because we have actually dealt with them in Vol. 3. We shall focus instead on certain key chemical categories of crucial importance in the study of life, such as those of che-

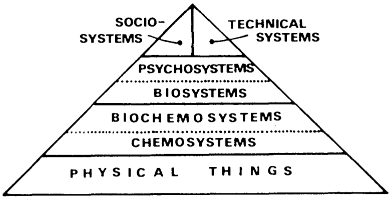


Fig. 2.1. The five main genera of things constituting the furniture of the world.

mical reaction and chemosystem, protein and nucleic acid. These categories are certainly more specific (less universal) than those of thing, property, system, and others we have encountered so far. On the other hand our chemical categories are far more universal than some of those that have dominated ontology for centuries, such as those of mind and purpose.

1. CHEMICAL SYSTEM

1.1. *Atom*

Since we shall make ample use of the concept of a chemical system, we must characterize it, the more so since no definition of it in systems theoretic terms seems to be available. And, since a chemical system is one whose components are reacting chemicals, we must start by characterizing the notions of a chemical and of a reaction.

The components of a chemical system are chemical atoms or molecules. A detailed characterization of things of these kinds calls for a number of specific scientific concepts. Luckily atoms have an essential or root property from which many another depends, namely atomic number. And molecules have an essential property of their own, namely atomic composition. These two properties will suffice for our limited purposes.

Our starting point is then the notion of chemical atom of a kind, or elementary chemical species, or element for short. There are 100 odd elements, among them hydrogen (H), carbon (C), nitrogen (N), and oxygen (O), the atomic numbers of which are 1, 6, 7, and 8 respectively. Every member of such a natural kind or species is a material system formed by at least two things of different genera, namely a system of nucleons (protons or neutrons), and an aggregate of electrons. In turn the nucleons are probably composed of subunits (quarks?), and the atoms can join forming molecules. See Figure 2.2. (This diagram suggests that molecules and their

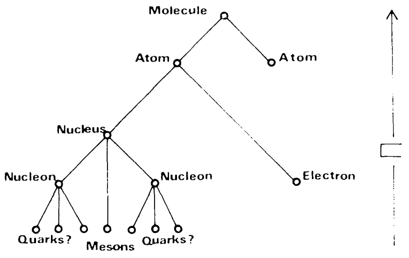

Fig. 2.2. A molecule is composed of two or more atoms. Each of these is in turn composed of a nucleus and one or more electrons. The number of protons in the nucleus equals the atomic number of the atom. Nucleons are possibly held together in the nucleus by meson fields. In turn every nucleon (proton or neutron) is presumably composed of smaller units (quarks?). Altogether six different kinds of thing are involved in a molecule.

components constitute a *sup* semilattice the order of which is that of the part-whole relation $\sqsubset$. Thus if a_1 and a_2 are two atoms forming a molecule m, then $sup\ \{a_1, a_2\} = m$. However, we shall not pursue this point here.)

In short, we steal from physics and chemistry

POSTULATE 2.1 Let A be a nonempty subset of the collection of all concrete things (or entities), and $\mathbb{N}_0$ the set formed by the first N positive integers. There exists a many to one relation (function) $Z : A \to \mathbb{N}_0$ of A onto $\mathbb{N}_0$(i.e. a surjection) that assigns each thing in A a natural number in $\mathbb{N}_0$, representing a property of the thing.

A is of course the set of atoms and Z the atomic number. The atoms with the same Z value are Z-equivalent:

If x and y are in A, then $x \sim_Z y =_{df} Z(x) = Z(y)$. The quotient of A by $\sim_Z$, or $A/\sim_Z$, is the family of classes of atoms with the same Z value. (We do not need to make the finer distinction among the isotopes of an element.) In other words, we can make

DEFINITION 2.1 Let A be the domain of the function $Z: A \to \mathbb{N}_0$. Then

(i) if x is in A, x is an *atom*;

(ii) the property represented by the function Z is called the *atomic number*, and the value $Z(a)$ of Z at $a \in A$, the *atomic number* of a;

(iii) the nth set

$$^{n}A = \{x \in A \mid Z(x) = n\}, \quad \text{for } 1 \leq n \leq N,$$

is the nth *atomic kind* or *chemical element*;

(iv) the partition

$$\mathscr{A} = A/\sim_Z = \{{}^nA \subset A \mid 1 \leq n \leq N\}$$

is the *family of atomic kinds* or *chemical elements*.

Since by definition $\mathscr{A}$ is the partition of A induced by $\sim_Z$,

$$A = \bigcup_{n=1}^{N} {}^nA, \quad \text{and} \quad {}^mA \cap {}^nA = \varnothing \quad \text{for } m \neq n.$$

In other words, the totality of atoms is the disjoint union of all the atomic kinds. The latter are those displayed in the periodic table. It is not known whether the number of atoms of each atomic kind is finite.

So much for the (atomic) components of a molecule.

1.2. *Molecule*

A molecule is a system composed of atoms – or, if preferred, of nuclei and electrons. Molecules range from hydrogen or H_2 (molecular weight $= 2$) to deoxyribonucleic acids or DNA (molecular weight up to 1 billion). There are about 4 million known species of molecules, 96 percent of which contain carbon. The combinations of atoms to form molecules are brought about by either ionic bonds or covalent bonds. In turn molecules stick together by virtue of hydrogen bonds or van der Waals forces (e.g., hydrophobic forces). All of these bonds are ultimately electric forces and they are studied by quantum chemistry, an application of quantum mechanics.

In ontology we take such bonds for granted and let chemists inquire into their nature. (Remember the fate of Hegel's alleged refutation of Berzelius' brilliant hypothesis that chemical bonds are electrical: cf. Hegel (1830), Sec. 330). The metaphysician accepts gratefully what the chemist is willing to teach him about the spontaneous formation (self-assembly) of molecules out of atoms, or of other molecules, as well as about the breakdown or dissociation of such systems as a result of their interaction with their environment (in particular thermal motion). The philosopher's task is not to compete with the chemist but to try and discover the structure and peculiarities of chemical processes *vis à vis* other kinds of process. If in the course of his work he comes up with results helping to clarify the foundations of chemistry, so much the better.

The statement that all molecules are composed of atoms can be exactified in a number of ways. We shall proceed as follows. Consider for example the first atomic species or

$$^1A = \mathrm{H} = \text{The set of all hydrogen atoms} = \{x \in \Theta \mid Z(x) = 1\}.$$

Since we disregard the individual differences among the hydrogen atoms, to concentrate on their shared atomic number, we may regard the species H as formed by an unspecified number of copies of a single individual. Assume now that each hydrogen atom can combine with any number of other H atoms forming hydrogen molecules – possible ones like the diatomic ones, and impossible ones like the icosiatomic ones. Since we are disregarding idiosyncrasies and concentrate on atomic composition, we can speak of the m-fold concatenation of an unspecified hydrogen atom x with itself, or $x \cdot x \cdot \ldots \cdot x = x^m$, as representing the combination of m hydrogen atoms. In this form we fashion

$$^1A^* = \mathrm{H}^* = \text{The set of finite concatenations of hydrogen atoms.}$$

Imagine now that the same construction is carried out for every atomic species, so that we have

$$^nA^* = \text{The set of finite concatenations of atoms of kind } {}^nA.$$

This set is the union of the following sets:

$$\begin{aligned} {}^nA_1 &= \{z \in \Theta \mid z \in {}^nA\} \\ {}^nA_2 &= \{z \in \Theta \mid z = x^2 \;\&\; x \in {}^nA\}, \\ &\ldots\ldots\ldots\ldots\ldots\ldots \\ {}^nA_m &= \{z \in \Theta \mid z = x^m \;\&\; x \in {}^nA\}. \end{aligned}$$

In other words, the set of all conceivable ^nA compounds is

$$^nA^* = \bigcup_m {}^nA_m = \{z \in \Theta \mid z = x^m \;\&\; x \in {}^nA \;\&\; 1 \leq m < \infty\}.$$

But of course not all conceivable compounds are really possible, i.e. lawful. (For the definition of real possibility in terms of lawfulness, see Vol. 3, Ch.4, Sec. 2,3.) The really possible compounds from ^nA are a proper subset of $^nA^*$, i.e.

$$^nA^{**} = \{z \in \Theta \mid z = x^m \;\&\; x \in {}^nA \;\&\; 1 \leq m < \infty \;\&\; z \text{ is lawful}\}.$$

(Do not think just of the stable compounds satisfying the valence requirements but also of all the transient molecules and free radicals.) These are all the homogeneous compounds, i.e. the molecules composed of atoms of a single atomic species. A heterogenous compound, such as the member of the chemical species CH_4, or methane, is a member of the set

$${}^1A_4{}^6A_1 = \{z \in \Theta \mid z = x^4y \;\&\; x \in {}^1A \;\&\; y \in {}^6A\}.$$

The totality of heterogeneous compounds is

$$A^* = \{z \in \Theta \mid z = x_1^{m_1} x_2^{m_2} \ldots x_N^{m_N} \;\&\; x_i \in {}^iA \;\&\; 1 \leq i \leq N \;\&\; 0 \leq m_i < \infty\}.$$

This is the set of all conceivable molecules, in turn a superset of the set of all really possible molecules.

The structure of A^* is obviously that of a semigroup under the binary operation $\cdot$ of combination or concatenation. More exactly, the structure $\langle A^*, \cdot\rangle$ is the *free semigroup generated by the set A* of atoms, and this because every element of A^* is either a member of A or a string of members of A. Now, as noted before, A^* contains not only the really possible molecules but also the unlawful ones. If we shrink A^* to the subset A^{**} of really possible molecules, we face the difficulty that A^{**} is not closed under the operation $\cdot$ of combination or concatenation (i.e. it does not contain all the concatenates). Equivalently: $\cdot$ is a *partial* operation on A^{**}, i.e. one not defined for every pair of members of A^{**}. We shall therefore say that the system $\mathscr{A}^{**} = \langle A^{**}, \cdot\rangle$ is a *partial* semigroup *embedded* in the free semigroup $\mathscr{A}^* = \langle A^*, \cdot\rangle$ generated by A. In other words, we make

POSTULATE 2.2 Let $\mathscr{A}^* = \langle A^*, \cdot\rangle$ be the free semigroup generated by the set A of all atoms of all kinds (Postulate 2.1), and call

$$A^{**} = \{z \in \Theta \mid z = x_1^{m_1} x_2^{m_2} \ldots x_N^{m_N} \;\&\; x_i \in {}^iA \;\&\; 1 \leq i \leq N \;\&\; 0 \leq m_i < \infty \;\&\; z \text{ is lawful}\}.$$

Then

(i) the partial semigroup $\mathscr{A}^{**} = \langle A^{**}, \cdot \rangle$ is embedded in $\mathscr{A}^*$;

(ii) for any two things x and y in A^{**}, if xy is in A^{**}, then xy represents the combination of x with y (or the xy compound).

Note that we are not postulating that $\mathscr{A}^{**}$ is a commutative semigroup. Hence the isomers xyz and yxz will be distinct molecules.

The previous axiom supports the following conventions that will come in handy in the sequel.

DEFINITION 2.2 Let $\mathscr{A}^{**}$ be the set defined in Postulate 2.2 Then

(i) the set of *compounds* is the complement of A^{**} to A, i.e.

$$M = A^{**} - A = A^{**} \cap \bar{A};$$

(ii) any subset of M, of the form

$$M_j = \{z \in \Theta \mid z = x_1^{m_1} x_2^{m_2} \dots x_N^{m_N} \ \& \ x_i \in {}^iA \ \& \ 1 \leq i \leq N\},$$

with fixed values of the m_i for $0 \leq m_i < \infty$, is a *molecular species*;

(iii) every member of a molecular species is a *molecule.*

(Note the strategy of first defining a set and then naming its members.)

DEFINITION 2.3 The *composition* of a molecule is the set of its constituents. I.e. let

$$\mathscr{C}^{**} : A^{**} \longrightarrow 2^{A^{**}}$$

be the function from the set of atoms and molecules to its power set, such that, if $z = x_1^{m_1} x_2^{m_2} \dots x_N^{m_N} \in A^{**}$, where $x_i \in {}^iA$ and $0 \leq i < \infty$,

$$\mathscr{C}^{**}(z) = \{x_1^{m_1}, x_2^{m_2}, \dots, x_N^{m_N}\}.$$

Then $\mathscr{C}^{**}(z)$ is the *composition* of the molecule z.

Example The composition of glucose, or $C_6H_{12}O_6$, is given by:

If $z \in C_6H_{12}O_6$, then $\mathscr{C}^{**}(z) = \{6$ carbons, 12 hydrogens, 6 oxygens$\}$.

The next definition requires a generalization, to an arbitrary set T of things, of the notion of physical addition (or association) occurring in the formula '$a + b = c$.' For an arbitrary set T of things, the association or addition of its members is the thing $[T] = \sup T =$ least upper bound of T. (Clearly, for any x in T, $x \sqsubset [T]$.)

DEFINITION 2.4 Let x be a thing. Then

(i) x is a *chemical* iff x is either a member of A^{**} (i.e. an atom or a molecule) or the aggregation of a finite set of atoms or molecules – i.e. if there is a $T \subset A^{**}$ such that $x = \sup T = [T]$;

(ii) x is a *compound* iff x is either a molecule or the aggregation of a finite set of molecules, i.e. $x \in M = A^{**} - A$ or $x = [T]$, with $T \subset M$;

(iii) x is a *polymer* iff x is either a string of molecules of a single molecular species, or the aggregation of a finite set of strings of different molecular species.

Polymers are of particular interest to us because all biomolecules are polymers. In particular, the DNA molecules are extremely long chain polymers.

Finally we make

DEFINITION 2.5 Let A^{**} be the totality of compounds and $l: A^{**} \to \mathbb{N}$ a function assigning each atom or molecule a natural number. Then the *length* of a member z of A^{**} equals the number of atoms in z. More precisely,

$$\text{If } z = x_1^{m_1} \cdot x_2^{m_2} \ldots x_N^{m_N} \in A^{**}, \quad \text{then } l(z) = m_1 + m_2 + \cdots + m_N.$$

This concept of length applies to molecules of all shapes, not just the linear ones. Thus the length of the planar molecule CH_4 is, according to our definition, equal to 5.

So much for structural matters. (For somewhat different treatments see Rosen (1959) and Chiaraviglio (1965).) Let us now turn to chemical processes.

1.3. *Chemical System*

We shall characterize a chemical system as a system whose components are chemicals varying in number (or in concentration) for being engaged in reactions. To render this idea more precise we shall avail ourselves of the state representation of systems explained in Ch. 1, Sec. 2.2. Consider a concrete system represented by a time-dependent state function $\mathbb{F} = \langle F_1, F_2, \ldots, F_n \rangle$, each component (coordinate) of which represents a property of the system. The state function spans the total lawful state space of the system. Now single out those components of $\mathbb{F}$ that represent the numbers (or else the concentrations) of the chemicals in the system. The resulting state function, and the accompanying state subspace, deserve names of their own:

DEFINITION 2.6 Let T be the time span (relative to a given reference frame) and let

$$\mathbb{F} = \langle F_1, F_2, \ldots, F_n \rangle : T \longrightarrow \mathbb{R}^n$$

be a state function for an arbitrary system σ of a certain kind, satisfying the laws in a set $\mathbb{L}$. Further, let the first $m < n$ coordinates of $\mathbb{F}$ (at a given time) equal the number of components of each kind of chemical in the system (at that time). Then

(i) the function

$\mathbb{F}_c = \langle F_1, F_2, \ldots, F_m \rangle$, with $F_i(t)$ = Number of atoms or molecules of kind $K_i \subset A^{**}$ in σ at time $t \in T$, is called the *composition state function* of σ;

(ii) the value of the composition state function at time $t \in T$, i.e. $\mathbb{F}_c(t)$, is called the *instantaneous composition* of σ;

(iii) the set of all possible instantaneous compositions of σ, i.e.

$$S_c(\sigma) = \{\mathbb{F}_c(t) \in \mathbb{R}^n \mid t \in T \ \& \ \mathbb{F}_c \text{ satisfies } \mathbb{L}\},$$

is called the *composition state space* of σ.

Example The composition state function of a system where water is formed out of hydrogen and oxygen, according to the reaction $2H_2 + O_2 \rightarrow 2H_2O$, has

$$\text{the } \textit{initial value } \mathbb{F}_c(t_i) = \langle 2, 1, 0 \rangle$$

and (on completion of the reaction)

$$\text{the } \textit{final value } \mathbb{F}_c(t_f) = \langle 0, 0, 2 \rangle,$$

where the integers are the numbers of molecules of the chemicals in the system. If we wish to represent the entire process from start to end, rather than only the initial and the final states, we can use the partial concentrations, to obtain

$$\mathbb{F}_c = \langle C_{H_2}, C_{O_2}, C_{H_2O} \rangle,$$

where each coordinate of the triple is a function from T to $\mathbb{R}$. A condition for being able to use these functions is that the system be rather bulky, as is tacitly assumed in chemical kinetics.

Finally we can make

DEFINITION 2.7 Let σ be a concrete system with an n component state function $\mathbb{F}$ (in a given representation). Then σ is a *chemical system*, or *chemical reactor*, during the period $\tau \subseteq T$, iff

(i) the first m coordinates of $\mathbb{F}$, where $0 < m < n$, form the composition state function $\mathbb{F}_c$ of σ (i.e., σ is composed, among other things, of chemicals: $\mathscr{C}(\sigma) \cap A^{**} \neq \varnothing$);

(ii) the instantaneous value of the ith component F_i of $\mathbb{F}_c$, for $1 \leq i \leq m$, equals the number of atoms or molecules (or else the concentration) of ith chemical natural kind or species included in A^{**} at the time concerned;

(iii) the chemical composition of σ (i.e. the value of $\mathbb{F}_c$) changes in the course of τ, and this change is not just a transport from or to environment of σ.

According to this definition there can be talk of a chemical system only where and while chemical reactions are in progress. Thus a dead battery is no longer a chemical system. Before the reactions start, and after they have reached completion, the system is a physical one and only potentially a chemical system. (A chemical system is then an essentially dynamical system that can be at most in a state of dynamical equilibrium, or steady state, which is the one at which every reaction proceeds at the same pace as its converse, so that there is no net variation of the composition of the system.) This suggests

DEFINITION 2.8 A concrete system σ is a *physical system* during the period τ iff the composition state function of σ is constant (e.g. zero) throughout τ or, if it changes, it does so by transport from or to the environment of σ.

In sum a chemical system is a system whose chemical composition changes in the course of time, however slowly, and does so not just by importation or exportation of chemicals, but by virtue of processes involving its components. These processes are of course the chemical reactions. Let us look into these.

1.4. *Chemical Reaction*

Every really possible (lawful) process in a chemical system is representable as a curve in the total state space of the system. Each m-tuple of initial concentrations of the chemicals in the system corresponds to a distinct trajectory of the tip of the state vector $\mathbb{F}$. ($\mathbb{F}$ is not really a vector, for its product with an arbitrary real number may lie outside the bounds set by the laws.) And the bundle of all such possible trajectories, for all variations of initial conditions and all systems of the same kind, represents the totality $\mathbb{L}$ of laws "at work" in chemical systems. Since a system is a chemical system only as long as there are chemical transformations going on in it, the set $\mathbb{L}$ includes every one of the laws concerning such transformations, in particular the reaction formulas and the corresponding kinetic equations. But, of course, $\mathbb{L}$ includes also every other law satisfied (possessed) by the chemical system of the given kind. See Figure 2.3.

We spell out the foregoing in

DEFINITION 2.9 Let $\mathbb{F}$ be a state function for a concrete system σ of kind K, and let $S_{\mathbb{L}}(K)$ be the corresponding lawful state space. Then

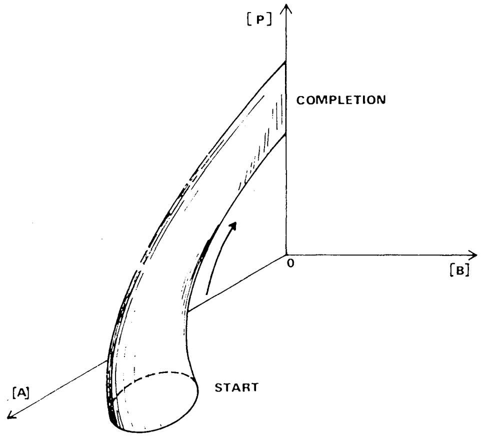

Fig. 2.3. Composition state space of a chemical system in which only reactions of the form $A + B \rightharpoonup P$ occur. $[X]$ designates the concentration of X. Each line within the conoid, from beginning to end, represents one possible complete reaction compatible with the reaction schema as well as with the formula for the rate of formation of P from A and B.

(i) the full trajectory of the state point $\mathbb{F}(t)$ in $S_{\mathbb{L}}(K)$ is called the total *history* of σ during $\tau \subseteq T$:

$$h(\sigma, \tau) = \{\langle t, \mathbb{F}(t)\rangle \mid t \in \tau\};$$

(ii) the set of *laws* of concrete systems of kind K is the family of all the histories of all the systems in K over all periods:

$$\mathbb{L} = \{h(\sigma, \tau) \mid \sigma \in K \,\&\, \tau \in 2^T\},$$

where 2^T is the family of all time periods included in T.

We are interested in certain segments of the history of an arbitrary chemical system called 'chemical reactions'. Equivalently: we shall pay particular attention to the chemical law statements (formulas) that focus on chemical transformations, especially those that disregard all the concomitant physical processes. Consider for example the substitution schema

$$r = \ulcorner A + B \rightharpoonup C + D\urcorner,$$

usually interpreted as "One unit of species A reacts with another of species B to produce one unit of species C and another of species D". (The interpretation of the more general reaction schema $mA + nB \rightharpoonup pC + qD$ is obvious.) This statement says nothing about the reaction mechanism or about the environmental conditions for it. (The latter are taken care of in the antecedent of the conditional statement of which r is the consequent. The entire conditional is then of the form: "If the pressure, temperature, etc., are such and such, then r".) Nor does the statement inform us about the pace of the chemical process: it just tells us what there is in the beginning and at the end of the transformation. I.e. it speaks only of net events. (Moreover r is ambigous; it uses class symbols, such as 'A' and 'B', to refer to members of such classes.) In any case, this is how the above reaction schema can be translated into the state space language: the system is initially in the composition state

$$\mathbb{F}_c(t_i) = \langle C_A, C_B, 0, 0\rangle$$

and finally in the composition state

$$\mathbb{F}_c(t_f) = \langle 0, 0, C_C, C_D\rangle$$

so that the size of the net change is

$$r = \mathbb{F}_c(t_i) - \mathbb{F}_c(t_f) = \langle C_A, C_B, -C_C, -C_D\rangle.$$

Example The overall photosynthesis reaction (which has a great many intermediate steps) is

$$6CO_2 + 6H_2O \rightharpoonup C_6H_{12}O_6 + 6O_2.$$

Setting

$$\mathbb{F}_c = \langle C_{CO_2}, C_{H_2O}, C_{C_6H_{12}O_6}, C_{O_2}\rangle,$$

we get

$$r = \langle 6, 6, 0, 0\rangle - \langle 0, 0, 1, 6\rangle = \langle 6, 6, -1, -6\rangle.$$

And the converse reaction, which (barring differences in intermediate steps) is that of respiration, is of course

$$-r = \langle -6, -6, 1, 6\rangle,$$

a systems theoretic rewrite of

$$C_6H_{12}O_6 + 6O_2 \rightharpoonup 6CO_2 + 6H_2O.$$

We compress the foregoing into the following semantic assumption. Let $\mathbb{F}_c$ be a composition state function for a chemical system σ between the initial time t_i and the final time t_f (relative to a certain reference frame). Then

(i) the *overall* or *net reaction* in σ between t_i and t_f is representable by the difference between the initial and final values of $\mathbb{F}_c$:

$$r = \mathbb{F}_c(t_i) - \mathbb{F}_c(t_f);$$

(ii) while the positive components of r represent the *reactants*, the negative ones represent the *reaction products*;

(iii) the *inverse* (or *converse*) of a reaction r is the reaction $-r$;

(iv) the *null reaction* is $\mathbb{O} = \langle 0, 0, \ldots, 0 \rangle$.

As we know from elementary chemistry, reactions can add to form further reactions: see Figure 2.4. For example, the enzymatic reaction sequence (or pathway) represented by the system of reaction schemata

$$\begin{aligned} &A + C \rightharpoonup AC \\ &AC + B \rightharpoonup ACB \\ &ACB \rightharpoonup AB + C \end{aligned}$$

adds up to the overall reaction

$$A + B \rightharpoonup AB.$$

In our state space representation we form the composition state function

$$\mathbb{F}_c = \langle C_A, C_B, C_C, C_{AB}, C_{AC}, C_{ACB} \rangle,$$

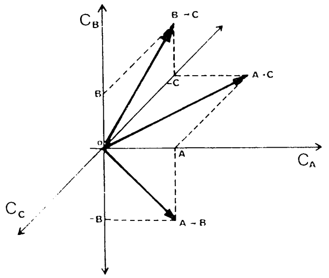

Fig. 2.4. The reactions A ⇀ B and B ⇀ C add up to the overall reaction A ⇀ C. Each reaction is represented by an arrow in the cartesian three-space of the concentrations (or the numbers of atoms or molecules).

so that the three successive reactions are

$$\begin{aligned} r_1 &= \langle 1, 0, 1, 0, 0, 0\rangle - \langle 0, 0, 0, 0, 1, 0\rangle = \langle 1, 0, 1, 0, -1, 0\rangle \\ r_2 &= \langle 0, 1, 0, 0, 1, 0\rangle - \langle 0, 0, 0, 0, 0, 1\rangle = \langle 0, 1, 0, 0, 1, -1\rangle \\ r_3 &= \langle 0, 0, 0, 0, 0, 1\rangle - \langle 0, 0, 1, 1, 0, 0\rangle = \langle 0, 0, -1, -1, 0, 1\rangle. \end{aligned}$$

The overall reaction is formed by adding the coordinates term by term:

$$r = r_1 + r_2 + r_3 = \langle 1, 1, 0, -1, 0, 0\rangle,$$

which, in effect, represents ⌜A + B ⇀ AB⌝. That is, the catalyzer C and the intermediate products cancel out, so that only the consumed reactants and the newly formed chemicals occur in the overall reaction. If the net result had been a return to the initial state of the system, we would have had the null overall reaction.

We summarize the preceding into

DEFINITION 2.10 Let the *m*-tuples

$$r_1 = \langle a_1, b_1, \ldots, m_1\rangle, \qquad r_2 = \langle a_2, b_2, \ldots, m_2\rangle$$

represent each one reaction in a given chemical system. Then the *sum* of the two reactions in the same system is the third reaction represented by

$$r = r_1 + r_2 = \langle a_1 + a_2, b_1 + b_2, \ldots, m_1 + m_2\rangle.$$

Since in principle every reaction has an inverse, any two reactions in a chemical system can add up to form a third, and the null reaction adds to any reaction leaving it unchanged, we have (Aris, 1965)

THEOREM 2.1 Let R be the set of all chemical reactions that can occur in a given chemical system, $+$ the binary operation of reaction addition, $-$ the unary operation of reaction inversion, and $\mathbb{O}$ the null reaction. Then the structure $\mathscr{R} = \langle R, +, -, \mathbb{O}\rangle$ is a group.

Now, whereas some reactions are concurrent, others are successive. The notion of reaction succession is obvious:

DEFINITION 2.11 Let $\langle R, +, -, \mathbb{O}\rangle$ be the group of possible reactions in a chemical system, and call

$$r_i = \mathbb{F}_c(t_i) - \mathbb{F}_c(t_f), \qquad r_j = \mathbb{F}_c(t_i') - \mathbb{F}_c(t_f')$$

two members of R. Then r_i *precedes* r_j in time iff r_j sets on after r_i. I.e.

$$r_i < r_j =_{df} t_i' \geq t_f.$$

This concept forms part of a notion of particular interest to the chemistry of living systems, namely that of pathway. A pathway is a set of reactions such that the product of one occurs as the reactant in the next. More precisely, we make

DEFINITION 2.12 Let $\langle R, +, -, \mathbb{O} \rangle$ be the group of possible reactions in a chemical system, and call

$$R_n = \langle r_i \in R \mid i \in \mathbb{N} \rangle$$

a list of n members of R. Then R_n is a *pathway* or *reaction sequence* iff, for any value of i occurring in R_n,

(i) r_i precedes r_{i+1} in time, i.e. $r_i < r_{i+1}$, and

(ii) some reaction products of r_i are reactants of r_{i+1}.

In closing this subsection, it will be fair to warn the reader that there are alternative ways of representing chemical compounds and chemical reactions, in particular those proposed by Aris (1965); Sellers (1967, 1970, 1971); Krohn, Langer and Rhodes (1967); and Feinberg (1972). All these alternative representations accept the usual chemical notation, which conflates individual chemicals (e.g. molecules) with their species, writing for example 'H_2O' for both the water molecule and the chemical species water. Another ambiguity of the usual chemical notation is that, when "reading" (interpreting) a reaction schema such as $\ulcorner A + B \rightharpoonup C + D \urcorner$, we are asked to interpret the first '+' as symbolizing the combination of the reactants, and the second '+' as the mixture of the reaction products. For these reasons the standard chemical notation is a paradigm of double talk – of Platonism and materialism. Therefore we had to go our own, even if mathematically less sophisticated, way.

1.5. *Chemical Control*

Every system is controlled by its environment; in particular, the milieu of a chemical system is a variable source and sink of chemicals and energy. If the environment is "fit", the chemical system will come into being and subsist for a while. On the other hand a "hostile" environment, e.g. one that supplies either too little or too much energy, or else one that is not wet enough, or far too oxydating (like Mars), will preclude certain reactions or even all of them. Therefore the existence of a chemical system is a sufficient condition for that of a "congenial" environment, i.e. one compatible with the reactions going on in the system.

Certain chemical systems have internal controls in addition to the external or environmental ones. That is, some of either the reactants or the reaction products of a chemical system contribute to controlling the pace of the reactions, often to the point of starting them or bringing them to a halt. In some cases a reaction is accelerated by the action of a catalyzer (e.g. an enzymatic protein). In particular the reaction product itself may catalyze the reaction (*autocatalysis*). In other cases the reaction product, as it builds up, inhibits the further progress of the reaction until the latter stops even if the supply of reactants is not exhausted (*product inhibition*). Or the catalyzer itself may at some point be broken down by some other enzyme – as is the case with a protein when no longer "needed". And a number of processes of these various kinds may occur sequentially (in particular cyclically) or even at the same time in the same system, e.g. a living cell (cf. Eigen, 1971; Lehninger, 1975).

We are particularly interested in chemical systems equipped with controls, because the living cells and its organelles are of that kind. Hence we define explicitly:

DEFINITION 2.13 A chemical system with composition state function $\mathbb{F}_c = \langle F_1, F_2, \ldots, F_m \rangle$(in some representation) is *self-controlled* iff some of the components of $\mathbb{F}_c$ depend exclusively upon other components of it (rather than on any components of the total $\mathbb{F}$ representing properties of the environment of the system).

Consider for example an enzymatic reaction in an aqueous solution – the standard biochemical process. Let E denote an enzyme acting upon a substrate S to form an intermediate compound ES (or enzyme-substrate complex), which eventually dissociates into a product P with liberation of E. Moreover suppose that this is a product inhibition reaction, i.e. one in which the product gets in the way of the reaction because it binds with the enzyme, thus inhibiting the latter from acting upon the substrate. In conventional chemical notation, we have

$$\begin{array}{ccccccc} \mathrm{E} + \mathrm{S} & \underset{k'_1}{\overset{k_1}{\rightleftharpoons}} & \mathrm{ES} & \underset{k'_2}{\overset{k_2}{\rightleftharpoons}} & \mathrm{EP} & \underset{k'_3}{\overset{k_3}{\rightleftharpoons}} & \mathrm{E} + \mathrm{P} \\ t_1 & & t_2 & & t_3 & & t_4 \end{array}$$

where the last two reaction constants are comparable, i.e. $k_3 \approx k'_3$. We leave the reader the task of representing the six reactions in our state space

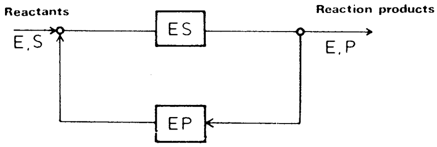

Fig. 2.5. A self-controlled chemical system of the negative feedback type. The reaction product P combines with the catalyzer E forming the 'ntermediate compound EP and thus slows down the left-to-right reactions.

notation. At this point we are only interested in emphasizing that the composition of our system is variable and that it is a self-controlled system and moreover one that is self-accelerated during certain periods and self-decelerated during others. The system can be diagrammed like an ordinary controlled system: see Figure 2.5.

Control systems of this kind fall under the general theory of control. However, chemical self-controlled systems do not accord with the now popular paradigms of control systems, namely the balancing wheel, the thermostat, and the self-controlled missile. Indeed in the latter cases the control is effected by a detachable subsystem. Moreover the whole system has fixed components and its behavior is usually assumed to be linear. Being detachable from the controlled system, a controlling system of this kind can be studied separately, not only as a component of the total self-controlled system. On the other hand if either the enzyme or the reaction product were removed from our chemical system represented by Figure 2.5, the system would cease to be chemical: it would become a physical system. Second, by definition of a chemical system, its composition is not constant but varies in the course of time. Thirdly, most of the chemical kinetics equations – in particular the ones for the formation rate of ES from the reactants – are nonlinear. These three peculiarities of chemical self-controlled systems seem to have prevented most scientists and engineers from recognizing them as systems, hence from using the systems theoretic approach to chemical problems.

2. BIOCHEMICAL SYSTEM

2.1. *Biomolecule*

We shall call *biomolecule* any macromolecule that, like a protein or a nucleic acid, is essential to some typically biological process such as cell division, morphogenesis, or development. And we shall call *biochemical* any system, natural or artificial, where biomolecules are formed or broken down. There are myriads of kinds of processes of this type, and some of them culminate in the formation of subsystems of live cells, such as ribosomes: see Figure 2.6.

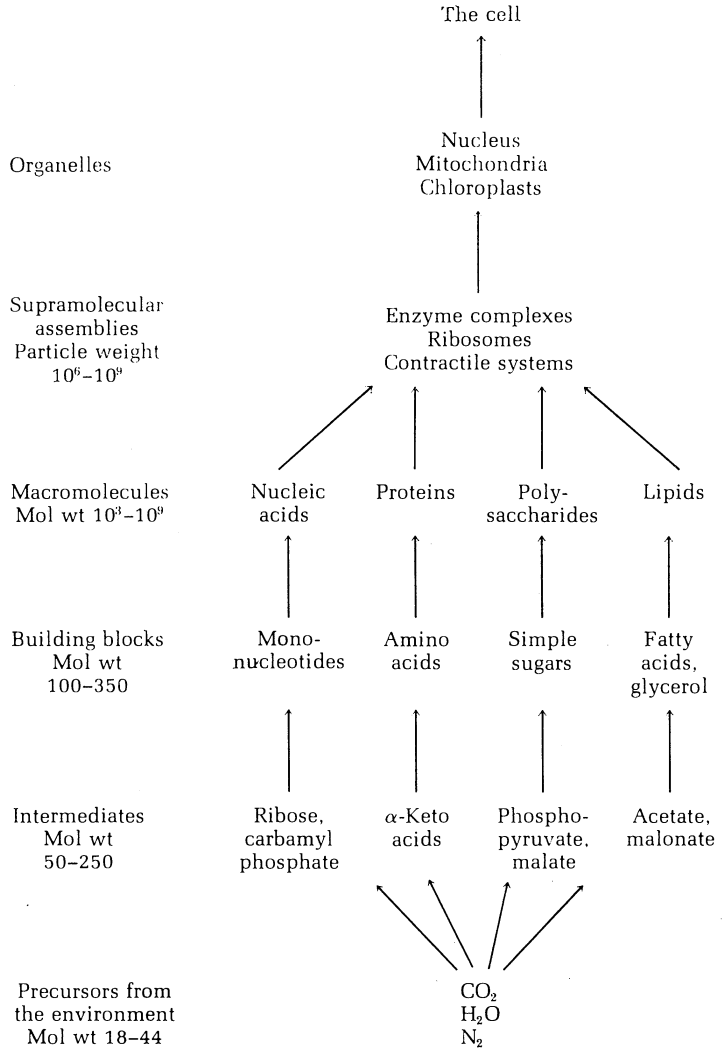
The key biomolecules are the proteins and the nucleic acids: as Szent–György used to say, while the former carry on the business of life the latter are the guardians of life. Both are polymers (Definition 2.4(iii)). Whereas the building blocks (monomers) of the latter are nucleotides of mainly 8 different kinds, proteins are formed by amino acids, of which 20 species are commonly found in bioproteins. The biomolecules are then macromolecules, and they are constituted by so many units that they can attain remarkable sizes and weights. Because they are so large they are quite sensitive to environmental disturbances. Hence their stability requires fairly constant physical environmental conditions. To a first approximation some such molecules can be modeled as very long chains that can fold-in forming closely packed particles. (Cf. Vol'kenshtein, 1970; Lehninger, 1975; Watson, 1976.)

We shall borrow from biochemistry the notions of nucleotide and of amino acid. We shall also borrow the postulate that, whereas the nucleic acids are formed from eight nucleotide species, proteins involve 20 kinds of amino acids. (We shall disregard proteins other than those occurring in living beings.) More precisely, we incorporate the following biochemical axiom in our ontology:

POSTULATE 2.3. The family M of molecular species contains eight species of mononucleotides and 20 species of amino acids.

Each of the members of the mononucleotide family is composed of phosphoric acid, a sugar, and a nitrogenous base. There are two genera of nucleotides: the ribonucleotides and the deoxyribonucleotides. These genera differ by the kind of sugar: the former contain ribose whereas the latter contain deoxyribose. (A RNA molecule is a polymer of blocks of the ribo type, and a DNA molecule is a string of units of the deoxyribo kind.) In turn, there are four species of ribonucleotides and another four of deoxyribonucleotides.

The nitrogenous bases of greatest biological interest are adenine (A), guanine (G), cytosine (C), uracil (U) and thymine (T). The first four combine with ribose and phosphoric acid to form ribonucleotides or constituents of RNA:



The cell
Organelles
Nucleus
Mitochondria
Chloroplasts
Supramolecular assemblies
Particle weight
10^6–10^9
Enzyme complexes
Ribosomes
Contractile systems
Macromolecules
Mol wt 10^3–10^9
Nucleic acids
Proteins
Poly-saccharides
Lipids
Building blocks
Mol wt
100–350
Mono-nucleotides
Amino acids
Simple sugars
Fatty acids, glycerol
Intermediates
Mol wt
50–250
Ribose, carbamyl phosphate
α-Keto acids
Phospho-pyruvate, malate
Acetate, malonate
Precursors from the environment
Mol wt 18–44
CO_2
H_2O
N_2

Fig. 2.6. Build-up processes that start with simple molecules in the environment and end up in living cells. 'Mol wt' is short for 'molecular weight'. From Lehninger (1975).

$$a = \text{AMP}, \qquad g = \text{GMP}, \qquad c = \text{CMP}, \qquad u = \text{UMP}.$$

('AMP' is short for 'Adenosine 5′-phosphoric acid'. Similarly with the other three.) On the other hand the nitrogenous bases A, G, C and T combine with deoxyribose and phosphoric acid to form deoxyribonucleotides or constituents of DNA:

$$a' = \text{dAMP}, \qquad g' = \text{dGMP}, \qquad c' = \text{dCMP}, \qquad t' = \text{dTMP}.$$

In short, there are two sets of units (monomers) from which the polynucleotides or nucleic acids are formed:

Ribonucleotides $R = a \bigcup g \bigcup c \bigcup u$
Deoxyribonucleotides $D = a' \bigcup g' \bigcup c' \bigcup t'$.

We proceed to characterize the nucleic acids and in the first place the members of the DNA family. We start with the building blocks in the set $D = a' \bigcup g' \bigcup c' \bigcup t'$ and form the set of all possible strings or sequences of members of D, with the sole restriction that the composition of each compound be equal to the union of the compositions of its constitutents or precursors. I.e. if x and y are in D and combine to form $z = xy$, then $\mathscr{C}_A(z) = \mathscr{C}_A(x) \bigcup \mathscr{C}_A(y)$, where '$\mathscr{C}_A(u)$' stands for the atomic composition of u. (Cf. Chap. 1, Sec.1.2.) The new set D^* formed from members of D contains all the conceivable combinations, with repetitions and permutations, of deoxyribonucleotides. In particular D^* contains all the polynucleotides forming the DNA molecules as well as monotonous strings such as $x^n = xxx...x$ with $x \in a'$. We shall restrict our attention to those molecules that contain all four nucleotides, i.e. members of a', g', c', and t'.

Call D_4^* the subset of D^* formed by the strings containing *all four* deoxyribonucleotides in all conceivable numbers and locations, such as $wxyz$, $zxwyx$, $yywxxyzzz$, where $w \in a'$, $x \in g'$, $y \in c'$, and $z \in t'$. The set D_4^* contains all the components of all the DNA molecules we need to consider – both the actual and the merely possible ones. The structure of D_4^* is that of a semigroup. More precisely, $\mathscr{D}_4 = \langle D_4^*, \cdot \rangle$ is a subsemigroup of the free semigroup $\mathscr{D} = \langle D^*, \cdot \rangle$ generated by D.

DNA molecules are double strands of things of kind D_4^*. These double strands are coupled in such a way that every *A* base in one of the strands is paired off to a *T* base in the other, and likewise every *C* base is paired off to a *G* base in the other. Hence we make

POSTULATE 2.4 Let $\mathscr{D} = \langle D^*, \cdot \rangle$ be the free semigroup generated by the set $D = a' \cup g' \cup c' \cup t'$ of deoxyribonucleotides under the operation $\cdot$ of chemical combination, subject to the condition that, for any x and y in D^*, if $z = xy$, then $\mathscr{C}_D(z) = \mathscr{C}_D(x) \cup \mathscr{C}_D(y)$. Further, call $\mathscr{D}_4 = \langle D_4^*, \cdot \rangle$ the subsemigroup formed by those sequences that contain molecules of all four kinds in D. There are systems composed of two chains of molecules in D_4^*, whose structure includes the bijection $p : D \to D$ such that for any $x_A \in a'$, $x_G \in g'$, $x_C \in c'$, and $x_T \in t'$,

$$p(x_A) = x_T,\ p(x_C) = x_G,\ p(x_G) = x_C,\ p(x_T) = x_A.$$

DEFINITION 2.14 The systems characterized by Postulate 2.4 are called *DNA molecules.*

Remark We are assuming that an arbitrary string of molecules satisfying Postulate 2.4 is not just a formal string but a chemically possible compound. The justification for this hypothesis is that there are no known restrictions on the stringing of nucleotides nor, for that matter, on carbon (or even boron) compounds in general. In short, using the notation of Sec. 1.2, $D_4^{**} = D_4^*$.

We proceed similarly with the RNA molecules, which are constituted by mononucleotides of the species a, g, c, and u:

POSTULATE 2.5 Let $\mathscr{R} = \langle R^*, \cdot \rangle$ be the free semigroup generated by the set $R = a \cup g \cup c \cup u$ of ribonucleotides, and call $\mathscr{R}_4 = \langle R_4^*, \cdot \rangle$ the subsemigroup formed by those sequences that contain molecules of all four kinds in R. Every member of R_4 is a possible *RNA molecule.*

The union of all kinds of DNA and RNA molecules is the totality of *nucleic acids*:

$$N = D_4^* \cup R_4^*.$$

The case of proteins is similar. Here the building blocks are the amino acids or rather some of them, such as glycine or NH_2CH_2COOH. More precisely, the *protein amino acids* form the genus

$$AA = \text{Ala} \cup \text{Arg} \cup \text{Asn} \cup \text{Asp} \cup \text{Cys} \cup \text{Gln} \cup \text{Glu} \cup \text{Gly} \cup \text{His} \cup \text{Ile} \cup \text{Leu} \cup \text{Lys} \cup \text{Met} \cup \text{Phe} \cup \text{Pro} \cup \text{Ser} \cup \text{Thr} \cup \text{Trp} \cup \text{Tyr} \cup \text{Val}.$$

This set has the semigroup property under the operation $\cdot$ of chemical combination. Also: the structure $\mathcal{AA} = \langle AA^*, \cdot \rangle$, where AA^* is the set of all possible strings or sequences of members of AA, is the *free semigroup generated by* AA. The members of this group are called *polypeptides* and the longer among them *proteins.* More often than not a protein contains at least one member of every species included in AA. However, there are important exceptions to this rule. Therefore we cannot restrict our attention to the subsemigroup formed by those sequences of amino acids that contain representatives of all 20 kinds of protein amino acids.

We summarize the foregoing in

POSTULATE 2.6 Let $\mathcal{AA} = \langle AA^*, \cdot \rangle$ be the semigroup generated by the set AA of protein amino acids. Every member of AA^* is a possible *polypeptide.*

DEFINITION 2.15 A *protein* is a polypeptide composed of at least 100 amino acids. Symbol for the set of proteins: $\mathcal{P}$.

It is estimated that there are at least 10,000 kinds of proteins in the cells of contemporary organisms. Roughly half of them are enzymes, i.e. reaction controllers.

Postulates 2.3 to 2.6 entail

COROLLARY 2.1 (i) Differences among kinds of DNA molecules consist in differences in composition or in the order (sequence) of the deoxyribonucleotides (members of D);

(ii) differences among kinds of RNA molecules consist in differences in composition or in the order (sequence) of the ribonucleotides (members of R);

(iii) differences among kinds of protein molecules consist in differences in composition or in the order (sequence) of the 20 protein amino acids (members of AA).

Molecules with the same composition but a different structure – in particular polymers differing only in the relative position of the component monomers along the chain – are called *isomers.* A polymer constituted by n distinct monomers has $1.2. \ldots n$ isomers.

So much for the composition and structure of nucleic acids and proteins. Let us now turn to their formation and breakdown.

2.2. *DNA Replication, and RNA and Protein Synthesis*

Not only are the nucleic acids the stuff of heredity: they are assumed to control whatever goes on in the cell, from protein synthesis to cell division. We must therefore take a closer look at them, particularly at their mode of emergence and the way they control the synthesis of proteins. However, we are forced to simplify, even to the point of disregarding the differences among the three kinds of RNA (ribosomal RNA, mRNA and tRNA).

The typical DNA molecule is composed by two polynucleotide chains that twist about each other forming what has become the most popular microsystem – the double helix. This has the well known property of self-duplication. This process involves the gradual detachment of the two strands, each of which serves as a mold or template for the formation of a complementary strand out of the molecules that pullulate in the rich cellular background. The attachment of these molecules is activated by enzymes. The overall process is captured by

POSTULATE 2.7 The duplication of a DNA molecule is a process whereby the molecule joins with molecules from its D-environment E to form two DNA molecules. In other words, the structure of a DNA molecule contains a function

$$\rho\colon D_4^* \times 2^E \longrightarrow D_4^* \times D_4^*$$

such that $\rho(d, e) = \langle d', d''\rangle$, with $d, d', d'' \in D_4^*$, $e \in 2^E$, and $\mathscr{C}_D(d)$, $\mathscr{C}_D(d')$, $\mathscr{C}_D(d'') \in 2^E$.

As mentioned above, DNA molecules control their own reproduction, i.e. are their own templates. But they are not the only molecular systems acting as templates: RNA molecules template for the synthesis of proteins. We must therefore elucidate the notion of a template. See Figure 2.7.

DEFINITION 2.16 Let $\tau \in T$ be a concrete system of kind T and let E be a set of things in the environment of τ. Assume that τ pre-exists a second system σ of kind Σ. Further, call i_T the identity function on T, and $\mathscr{C}_A\colon \Sigma \to 2^E$ the atomic composition function that assigns each (assembled) system σ its atomic composition $\mathscr{C}_A(\sigma) = e \in 2^E$. Then f is a *molding function* for σ, and τ a *template* for σ (or a *σ-template*) iff

(i) $f = i_T \times \mathscr{C}_A\colon T \times \Sigma \to T \times 2^E$ such that

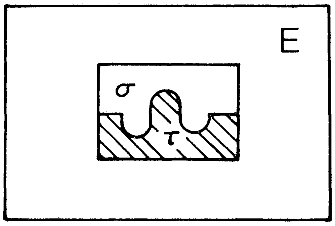


Fig. 2.7. System τ is a σ-template, i.e. τ provides a sort of mold for the assembly (e.g. synthesis) of σ out of environmental entities.

$$f(\tau, \sigma) = \langle \tau, e \rangle \quad \text{for } \tau \in T, \sigma \in \Sigma, \mathscr{C}_A(\sigma) = e \in 2^E;$$

(ii) the boundaries of τ and σ match in shape.

Molecular templates are, of course, molecules with the capacity to act as templates for the formation of further molecules. DNA and RNA are among them: DNA are autotemplates as well as RNA-templates, and RNA are in turn protein-templates. This is part of the well confirmed hypothesis misnamed *central dogma* of molecular biology, summarized in the heuristic diagrams of Figure 2.8, where the solid arrows represent the "information transfer" occurring in all cells, whereas the dotted arrows represent the "flow of sequence information" occurring in some cells.

We assume then, to begin with,

POSTULATE 2.8 RNA synthesis is the process whereby a DNA molecule

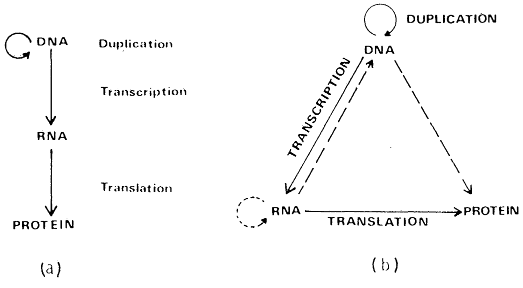

Fig. 2.8. Two versions of the "central dogma". (*a*) The standard version (e.g. Watson, 1976). (*b*) An alternative version (Crick, 1970). For a translation of the metaphorical expression 'information flow' into the nonmetaphorical language of quantum chemistry, wait a few decades.

(template) joins with nucleotides from its environment resulting in the same molecule (template) together with an RNA molecule. I.e. the structure of a DNA molecule contains a function

$$s_R = i_{D_4^*} \times \mathscr{C}_A: D_4^* \times R_4^* \longrightarrow D_4^* \times 2^E,$$

where $i_{D_4^*}$ is the identity function on D_4^* ,and $\mathscr{C}_A$ the composition function $\mathscr{C}_A: R_4^* \to 2^E$, such that

$$s_R(d, r) = \langle d, e \rangle \quad \text{for } d \in D_4^*, r \in R_4^* \; \mathscr{C}_A(r) = e \in 2^E.$$

DNA duplication and RNA synthesis are of course chemical processes, for in both cases a batch of reactants (the set e of precursors "swimming" in the environmental solution) combine into the reaction product. Moreover the entire system is a self-controlled chemosystem, since both processes are controlled by DNA molecules. However, the DNA molecules act not as ordinary chemical controls (e.g. enzymes) but as templates: theirs is template chemistry. (The same holds for the control exerted by RNA molecules in protein synthesis.) This is why the processes summarized by Postulates 2.7 and 2.8 are not represented by ordinary reaction equations, and why we had to introduce the functions ρ (DNA replication) and s_R (RNA synthesis). But this is precisely one of the peculiarities of biochemosystems in contrast to plain chemosystems.

Another peculiarity of biochemosystems is their capacity to synthesize biomolecules and, in particular, proteins. As will be recalled from Definition 2.14, a protein is a compound of amino acids and, more particularly, a member of the set AA^* of strings or sequences containing (protein) amino acids of all kinds. Again, the synthesis of proteins is controlled by RNA molecules acting as templates. More precisely, we introduce

POSTULATE 2.9 Protein synthesis is a process whereby an RNA molecule (template) joins with amino acids from its environment E, to yield the same molecule together with one protein. I.e. the structure of RNA contains the function

$$s_P = i_{R_4^*} \times \mathscr{C}_A: R_4^* \times AA^* \longrightarrow R_4^* \times 2^E,$$

where $\mathscr{C}_A: AA^* \to 2^E$, such that

$$s_P(r, p) = \langle r, e \rangle,$$

where $r \in R_4^*$, $p \in \mathscr{P} \subset AA^*$, $\mathscr{C}_A(p) = e \in 2^E$.

This axiom describes only the overall process: it does not tell us which segments of the RNA molecule correspond to which amino acids in the sequence characterizing the given protein. The fine structure – though by no means the mechanism – of this matching is given by the misnamed *genetic code*. This "code" is nothing but the detailed correspondence between the nucleotides in the RNA template and the amino acids in the protein synthesized on it. Let us describe this correspondence.

Let $R = a \cup g \cup c \cup u$ be the set of ribonucleotides forming the RNA molecules in R^*_4 (recall Postulate 2.5). The latter is the set of strings (or sequences) containing ribonucleotides of each of the four nitrogenous bases, and therefore all the possible triplets of such, e.g. *uca*, *uuc*, and *gcg*, enter into the composition of members of R^*_4. Call R^*_3 the set of $4^3 = 64$ such triplets, called *codons*. See Figure 2.9.

Take next the set AA of 20 kinds of protein amino acids, i.e. the protein building blocks. The full genetic "code" is the function that assigns each codon (triplet of nucleotides in an RNA molecule) a given amino acid in a protein. (Cf. Watson, 1976.)

We reformulate the preceding as a convention and an axiom:

DEFINITION 2.17 Let R^*_3 be the set of 64 triplets of nucleotides in $R = a \cup g \cup c \cup u$ such that, for every $x \in R^*_3$, there exists a segment $y \in R^*_4$ of an RNA molecule for which $x \sqsubset y$ (x is a part of y). Every member of R^*_3 is a *codon*.

POSTULATE 2.10 The codon-amino acid (or RNA-protein) correspondence is the partial function $\pi\colon R^*_3 \to AA$ that

(i) assigns every codon, other than the starting and the terminating codons, one amino acid in a protein. I.e. with the noted exceptions, if $r \in R^*_3$, then $\pi(r) = a \in AA$, where $a \sqsubset p$ and $p \in \mathscr{P}$ is some protein;

(ii) is order preserving: i.e. if $r, r' \in R^*_3$, and r precedes r' in a given codon sequence, then $\pi(r)$ precedes $\pi(r')$.

In the literature a different function f occurs implicitly, namely one assigning each amino acid one codon, i.e. $f\colon AA \to R^*_3$, where $'f(a) = r'$, for

RNA strand *aaugcuuaaaccgggauu*...
Triplets (*aau*)(*gcu*)(*uaa*)(*acc*)(*ggg*)(*auu*)...

Fig. 2.9. The sequence of nucleotides in the RNA molecule, when acting as a template for protein synthesis, is organized into triplets (codons). The kind and the position of each amino acid in the protein are determined by the composition and the position of the corresponding codon.

$a \in AA$ and $r \in R_3^*$, is read '*r codes for a*'. However, it has been found experimentally that different codons can "code for" one and the same amino acid. (I.e. the "code" is degenerate or many-one, hence not a proper code allowing one to break any ciphered molecular message.) In other words, no such function f from AA to R_3^* exists, so that the converse "translation" of protein structure into RNA structures is impossible.

A genuine code is a certain correspondence between two sets of *artificial* signs and, more particularly, *languages* (cf. Birkhoff and Bartee, Ch. 8). The coding and decoding functions of errorless codes are one to one, not many to one like π. Therefore the use of the linguistic concept of code in chemistry is metaphorical. The same holds for the expressions 'the templates instruct (or code for) protein synthesis' and 'the genetic instructions contained in a gene'. That these are analogies is shown by the following facts. First, a genuine information system is one composed of a transmitter, a receiver, and an information channel between them; no such components are apparent in a chemical system. Second, the computations of the quantity of information allegedly locked in a chunk of genetic material (i.e. a segment of a DNA molecule) are phoney – so much so that they occur in no biological law statements and everyone gives his own favorite arbitrary estimate. For these reasons the information-theoretic language employed in molecular biology is a heuristic prop that has now exhausted its heuristic power. Moreover it is a stumbling block on the road to transforming the "central dogma" into a hypothetical-deductive system explaining the synthesis and the duplication of nucleic acids, as well as the synthesis of proteins, exclusively in physical and chemical terms instead of describing them in analogical terms such as 'informational molecule', 'information flow', 'transcription', and 'translation'.

Note finally that, like the previous mappings introduced in this section – namely ρ (DNA replication), s_R (RNA synthesis) and s_P (protein synthesis) – π is not defined by Postulate 2.10, which characterizes a whole class of such functions. However, unlike ρ, s_R and s_P, π is known in detail: indeed it is given by the table that summarizes the so-called genetic code. What is still unknown is the origin of the "code". Nor is it known whether nucleic acids have always been "used" to synthesize proteins.

2.3. *Biochemical System*

A biochemical system may be characterized as a system wherein biomolecules are synthesized or broken down. A ribosome and an insulin synthesis reactor are biochemical systems. On the other hand a cellular membrane is a plain chemosystem because it is not involved in the production or disintegration of biomolecules.

Our explicit characterization is

DEFINITION 2.18 A system σ is a *biochemical system* (or a *biochemosystem*) iff σ is a self-controlled chemical system such that

(i) the composition of σ includes proteins or nucleic acids;

(ii) the environment of σ contains all the precursors of the components of σ and moreover is compatible with the processes of synthesis of proteins or of nucleic acids;

(iii) the components of σ exchange things and energy with the environment (i.e. σ is semi-open) and moreover some of them participate in the reactions happening in σ;

(iv) the structure of σ contains the protein synthesis (or the breakdown), the DNA replication, or the RNA synthesis function.

The reactions in a chemical system can eventually come to a halt because of exhaustion of reactants or as a result of product inhibition. In contrast, a biochemosystem is capable – environment willing – of maintaining its reactions or switching over to alternative reactions by predating on its environment and self-assembling its catalyzers (enzymes), and eventually also its templates. In fact, processes of two kinds are constantly going on and intertwining in a biochemical system: (*a*) the building up or self-assembly of complex molecules from simpler precursors (*anabolism*), and (*b*) the breaking down or dismantling of complex chemicals (*catabolism*). Furthermore these two processes are interdependent: the break down processes require enzymes that had to be synthesized to begin with, and such syntheses are often dependent upon further enzymes occurring as intermediates in breakdown processes. Moreover the anabolic processes consume energy released chiefly by catabolic ones. In short, biochemical systems are characteristically metabolic. We refine this notion by introducing

DEFINITION 2.19 If σ is a biochemical system, then

(i) the *intermediary metabolism* of σ is the set of all the enzymatic reactions involving only components of σ;

(ii) the *metabolism* of σ is the set of all the chemical reactions involving components of σ and the environment of σ.

Certain cell components are metabolizing biochemosystems. However, it is assumed that the precursors of the first organisms, on the Earth and probably elsewhere, were extracellular biochemical systems, and that the first cells emerged by self-assembly from, or the merger of, some such biochemical systems. And it is sometimes conjectured that the immediate precursors of cells may have been systems containing both proteins and nucleic acids. Such systems, though not possessing all the properties of contemporary cells, would have their main emergent properties, namely the abilities to metabolize, self-reproduce, and mutate. (Cf. Küppers, 1975.) However, the problem of the origin of life will be taken up in the next chapter.

2.4. *Concluding Remarks*

In this chapter we have distinguished three kinds of system that are usually conflated: physical, chemical, and biochemical. See Figure 2.10.

Chemical systems are distinguished from plain physical systems by the fact that some of their components are continually engaged in reactions in the course of which some chemicals are consumed while others are produced. Chemical systems are thus paradigms of qualitatively changing things. Not that qualitative change fails to occur in physical systems: the emission and absorption of light are qualitative changes, and so are nuclear fission and fusion as well as changes in the state of aggregation. However, many a physical system can be rendered immune to qualitative changes for a while. In contrast, a chemical system is by definition one whose composition changes relentlessly, so that it eventually becomes

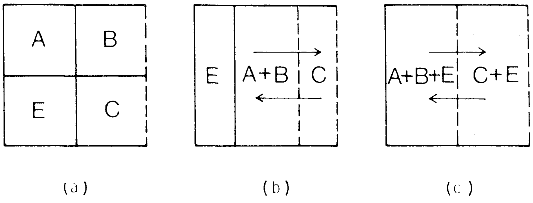

Fig. 2.10. Three kinds of system: (*a*) physical system with four non-reacting components; (*b*) chemical system with one nonreactive component (E); (*c*) biochemical system: all components react, and one of them (E) is an enzyme or proteinic catalyzer. Whereas physical and chemical systems may be almost completely closed (full line) or open only in some respects, biochemical systems must be semiopen (dashed line), for they prey on their environment.

something qualitatively different from what it was in the beginning. That such changes can be explained, at least in principle, with the help of physical theories – though not with them alone – does not turn them into physical processes. We are here concerned with ontological, not epistemological matters: with objective level distinctions not with the understanding of the higher levels with the help of knowledge concerning the lower ones.

Biochemical systems are the seats of even deeper and more sustained qualitative changes. They engage not just in any old chemical reactions but in reactions resulting in the self-assembly or the self-dismantling of huge molecules (often millions of times bigger than the inorganic ones). Moreover some such reactions involve templates, objects that do not occur in ordinary chemical reactions. Finally biochemical systems have a sustained activity thanks to their enzymes, and they can help themselves to environmental morsels. Because of these properties biochemical systems come rather close to biosystems.

The differences among physical, chemical, and biochemical systems are not just differences in complexity: they are momentous qualitative differences, so great in fact that we are justified in speaking of different levels: the physical and chemical levels, and perhaps also the biochemical level. Of course we must not forget that all biochemical systems are chemical systems, which in turn are composed of physical systems: otherwise we won't succeed in explaining biochemistry with the help of chemistry, or chemistry with the help of physics. Nevertheless we must not exaggerate similarities at the expense of differences, particularly if we hope to understand one more qualitative jump, namely the one from biochemical systems to biosystems. Let us take this leap.

CHAPTER 3

LIFE

Life has long been a mystery on which mystery mongers have thrived. It is no longer such: biologists are beginning to understand what makes organisms tick, and physicians to manipulate the control systems responsible for that ticking – which, incidentally, is not like a clock's. This understanding could not be forthcoming as long as organisms were studied either on their own level exclusively (holistic approach) or as physical systems devoid of emergent properties (levelism), and in either case apart from their history. The theory of evolution and molecular biology are to be credited for having transformed the mystery of life into the problem of life: its origin and maintenance, its evolution and extinction.

We have come to understand that many of the peculiarities of organisms have molecular roots. Thus cell division, a typically biological event, is the outcome of a chemical process. Moreover we understand now that other biological properties and processes – such as those of emerging by way of self-assembly of nonliving units, and of being subjected to natural selection – are properties shared by all systems. (Recall Ch. 1, Sec. 3.2.) In other words, we have come to realize that organisms are systems composed of chemical systems, and moreover that they have evolved from lower level things. This suggests the plan of this chapter: we start out with biochemical systems (studied in Ch. 2), endow them with certain emergent properties to obtain biosystems, and examine some peculiarities of biological adaptation and evolution.

The upshot of our study will be a merger of ontological pluralism (or emergentism) with moderate epistemological reductionism. Indeed we shall take the view that ontological monism – whether mechanistic or spiritualistic – is false because it denies the emergence of novel properties and laws as one moves from physical systems through chemosystems to biosystems. On the other hand the program of explaining the higher (more complex and newer) levels by the lower ones – i.e. epistemological reductionism – has proved fertile and is in keeping with contemporary biology. Indeed the latter – particularly molecular biology and evolutionary biology – is explaining life without explaining it away, i.e. without leveling down (let alone up), and is doing it with the help of chemistry, though not in terms of it exclusively.

1. FROM CHEMISM TO LIFE

1.1. *Self-Organization of Biochemical Systems*

According to contemporary biology (*a*) modern organisms descend ultimately from primitive biosystems (protocells), and (*b*) the latter in turn emerged from biochemical systems, which evolved out of biomolecules. (See Oparin (1968), Miller and Orgel (1974), and Oró, Miller, Ponnamperuma and Young (Eds.) (1974).) In turn, all of the biomolecules are carbon compounds, all of which contain also hydrogen and oxygen, and most of them also nitrogen. This is no accident: of all the 100-odd elements, hydrogen, carbon, nitrogen and oxygen constitute the most stable molecules and by far the greatest variety of them. Boron too has the capacity to form large stable molecules, but it is far less common than the other four elements, which exist almost everywhere in the explored part of the universe.

Moreover, the physical conditions necessary for the synthesis of biomolecules – such as plenty of solar energy and humidity, as well as moderate temperatures and pressures – have existed on our planet for about four billion years. Besides, it is reasonable to conjecture that the primitive atmosphere was reducing rather than oxydizing, hence lenient rather than hostile to the self-assembly of biomolecules and systems composed thereof. Under such conditions it is no wonder that biomolecules should have formed and eventually merged to constitute larger systems. In short, ours is "the best of all possible environments for life" (Henderson, 1913, p. 273) – or at least one among a number of environments fit for the origin and maintenance of life. This is not to say that the emergence of life was inevitable: scientists maintain only that it was possible (i.e. lawful rather than miraculous). Moreover, since the conditions for the emergence of life are rather stringent, they are also probably rather exceptional, so that the likelihood that they have occurred elsewhere in exactly the same manner must be vanishingly small. Therefore, although it is very likely that there are extraterrestrial organisms, it is unlikely that they, or at least the more complex among them, much resemble those we know (Jacob, 1977).

Until recently it was assumed to have taken aeons for biochemical systems to form from hydrogen, carbon, oxygen, and nitrogen. And this because it was taken for granted that such self-assemblies could occur only by the simultaneous chance encounters of all the atoms composing a biochemical system. Indeed, such events are so unlikely that they can be ruled out. Although chance is ever present, particularly in chemical dissociations, the chemical reactions of the buildup and substitution kinds are brought about by chemical bonds against the disorganizing random motions of the atoms and molecules in the surroundings. (Surely there is randomness in the very collisions ensuing in chemical compounds, but the latter are unstable, hence short lived, unless the atoms are held together by interatomic bonds. So, chance within the system works against chance in the environment. And even the dissociations caused by random thermal motions may result in reaction products that are in turn reactants forming eventually more stable systems.)

Nowadays we know that chemical and biochemical systems cannot help but self-assemble under the action of bonds of various kinds. Moreover we know that such self-assembly processes are more likely to occur in stages than at one stroke. In particular, the formation of primitive proteins may have proceeded in two stages: amino acid synthesis followed by polymerization. Therefore the first biochemical systems, and even the first organisms, may have formed on our planet and elsewhere as soon as the requisite conditions were met. This explains the short time span between the origin of rocks and the appearance of the first bacteria and blue-green algae.

As soon as biomolecules assembled they could associate with others forming larger molecules or transmolecular systems. About the simplest systems of the latter kind are the colloidal particles. For example, a protein molecule in an aqueous solution attracts a number of water molecules forming a colloidal hydrophilic complex. And in turn a number of such systems can coalesce to form a coacervate: see Figure 3.1. In either case the resulting system is a distinct thing, separate from its liquid medium and with a structure of its own (Oparin, 1968). Presumably nucleic acids can form similar systems. In particular a DNA molecule placed in a suit-

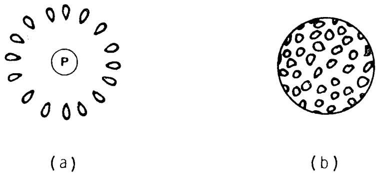

Fig. 3.1. The self-assembly of colloidal particles around a protein molecule (P) in an aqueous solution (*a*), and the coalescence of colloidal particles into a coacervate (*b*).

able solution of nucleotides and nucleic acids could perhaps start synthesizing RNA molecules, which in turn would control the synthesis of proteins as well as of further DNA molecules. Furthermore a protecting double layer of lipid molecules could self-assemble around such a DNA-RNA-protein system. Such a semipermeable membrane would increase the concentration of biomolecules, hence the rate of biochemical reactions, and would keep out disrupting (e.g. dissociating) agents. New reactions would thus be possible, ending up in the formation of new kinds of biopolymers and even of transmolecular systems such as vesicles and organelles of various kinds.

Given biomolecules in a suitable medium, the formation of organelles such as chloroplasts and ribosomes is far from miraculous. Indeed a ribosome, for example, is not an impossibly complicated system: it consists of 58 macromolecules, three of them RNA molecules, and the rest proteins of various kinds. What the ribosome does – its function – is, chiefly, to synthesize proteins from precursors in its environment.

The next step is, of course, the self-assembly of a few such transmolecular systems to form a cell, however primitive – hence inefficient, ergo ill-adapted. The rest is history – evolutionary history driven by mutation and selection. In short, the process of emergence of life may have looked like Figure 3.2.

This diagram condenses what is common to various rival hypotheses concerning the precise self-assembly of primitive cells. (See Florkin (1960), Oparin (1968), Fox and Dose (1972), Miller and Orgel, (1974), Oró, Miller, Ponnamperuma and Young (Eds.) (1974).) There is rapidly accumulating

evidence that most of the buildup processes depicted in Figure 3.2 have been going on on our planet, and at least the first few steps elsewhere as well. In particular, the analysis of Precambrian rocks, of meteorites, and recently of some celestial objects, has been yielding amino acids, fatty acids, and even nucleic acids.

We compress and generalize the above into

POSTULATE 3.1 Let $\Sigma = \langle \Sigma_i \mid 1 \leq i \leq n \rangle$ be a sequence of really (nomologically) possible species of system, such that the systems of kind Σ_i are composed of systems of kind Σ_{i-1}. Then every actual system belongs in the sequence Σ and has self-assembled from systems in the immediately preceding term of the sequence.

1.2. *Definition of a Biosystem*

We have reached the point where we can list the properties of a system we believe to be jointly necessary and sufficient for it to qualify as a living thing. We assume that an organism is a system such that

(i) its *composition* includes proteins (both structural and functional, in particular enzymatic, the latter enabling it to exploit its environment) as well as nucleic acids (which make for its reproducibility and the likeness of its offspring);

(ii) its *environment* includes the precursors of all its components (and thus enables the system to self-assemble most if not all of its biomolecules);

(iii) its *structure* includes the abilities to metabolize, to self-repair, and to reproduce.

We shall spell out this hypothesis into an axiom and a convention. Here is the former:

POSTULATE 3.2 There are systems of a kind B such that, for every member b of B,

(i) b is composed of chemical and biochemical (hence metabolizing) subsystems;

(ii) b incorporates some of the biomolecules it synthesizes (rather than releasing them to its environment);

(iii) the possible activities of b include (*a*) the rearrangement, assembly, and dismantling of components; (*b*) the replacement of nonfunctional components and the removal or neutralization of some chemicals; (*c*) the capture and storing of free energy (in ATP molecules, glycogen, and fat) for future consumption;

(iv) *b* can adjust to some environmental changes;

(v) *b* is a component of some supersystem (organism) or else of some population of systems of the same kind;

(vi) some of the subsystems of *b* are capable of reproducing parts of *b*;

(vii) some of the subsystems of *b* control some of the processes occurring in *b* in such a way that a fairly constant inner environment (*milieu intérieur*) is maintained in the system;

(viii) all of the control systems in *b* are interconnected by signals (diffusion of chemicals, propagating chemical reactions, electrical signals, etc.) and so constitute a signal or information network;

(ix) one of the control systems of *b* (its genetic system or genome) is composed of nucleic acid molecules, is unique to *b*, and controls the development and the reproduction of *b*;

(x) the descendants of *b* are similar to *b* but may possess some new traits of their own (by mutation or gene recombination);

(xi) *b* competes in some respects with other systems of the same species as well as of other species, and cooperates with the same or others in some other respects;

(xii) *b* descends proximately or remotely from biochemical systems devoid of some of the properties listed above, and its nucleic acid molecules keep traces (hence some record) of the ancestry of *b*;

(xiii) *b* lasts, as a member of *B*, for a limited time lapse.

The name of the *B*'s should come as no surprise:

DEFINITION 3.1 The systems *B* referred to by Postulate 3.2 are called *biosystems* or *living things.*

Surely biosystems have many more properties than those we have just listed, but these seem to be necessary and sufficient to distinguish terrestrial biosystems from other things. In particular, clause (ii) exhibits one of the pecularities of biosystems as opposed to nonliving systems. In fact it is possible to assemble in the laboratory systems capable of synthesizing biomolecules that do not go into forming cell components such as organelles and membranes, let alone whole cells. To put it in metaphorical and therefore unscientific terms: a characteristic of metabolism in biosystems is that, far from being either "indifferent" or "self-serving", it "serves" the organism as a whole. (No teleonomy here: those systems that do not metabolize this way do not make the grade: they are either nonliving or sick.) Likewise clause (iii): a nonliving (e.g. biochemical) system need not be self-cleaning and self-repairing but could accumulate reaction-inhibiting chemicals (e.g. toxic substances) that would eventually bring some or even all of its reactions to a halt.

Note that in clause (xi) we have included not only competition, the heart of Darwinism, but also cooperation. Of course in the vast majority of cases cooperation is not deliberate, i.e. it does not consist in solidarity, but it is not less real for that. Without the unwitting cooperation of plants, animals, and other organisms, the terrestrial atmosphere might not be very different from what it was in the beginning, i.e. about five billion years ago: for one thing it might still be reducing rather than oxydizing. Note also a peculiarity of heredity in biosystems (clause (xii)). Like other complex systems, such as stars, mountains, and artifacts, biosystems betray their past. But, unlike nonliving systems, biosystems concentrate their archives in a tiny part of themselves, namely their genome.

Not all of the functions (properties, processes and activities) we attribute to an organism are actually carried out by it throughout its life history. Thus metabolism and cellular division may be temporarily suspended, as is the case with spores and dormant seeds. Some of the properties of biosystems are then dispositions, or potential properties that may actualize under favorable environmental circumstances. (For the notion of potentiality see Vol. 3, Ch. 4.)

We have not included certain properties that are obviously possessed by biosystems – and therefore often listed as definitory – because they are also common to all biochemical systems and even to some physical systems. Among them are (*a*) having a more or less definite boundary separating the system from its environment, and (*b*) being subject to natural selection. That the former property is shared by many a macrophysical nonliving system, is clear. As for the latter property, Postulate 1.6 attributes it to all systems.

Finally note that, according to Definition 3.1, chromosomes are not alive because they do not metabolize, and ribosomes are not alive because they do not replicate. Likewise viri are not alive because they do not function at all outside some host cell – so much so that independent viri are often crystals. (Only the host cell-virus system is alive.) Nor do robots, however sophisticated, qualify as biosystems, if only because they are made of mechanical and electrical components instead of biochemical ones. A couple of properties, no matter how important, do not suffice to characterize a biosystem; the property system consisting of the 13 properties listed in Postulate 3.1 is necessary and sufficient – until further notice.

1.3. *Cell and Organism, Biospecies and Biopopulation*

To begin with let us take a closer look at a feature of biosystems that is of particular philosophical interest, namely their cellular composition. To identify the smallest unit of living matter, as well as that of life, we shall use the notions of biosystem (Definition 3.1) and of system component (Definition 1.2):

DEFINITION 3.2 (i) A *cell* is any biosystem such that none of its components is a biosystem. In obvious symbols,

$$x \in C =_{df} x \in B \;\&\; \forall y\,(y \in \mathscr{C}(x) \Rightarrow y \notin B);$$

(ii) the *cellular composition* of a biosystem is the set of cells that compose it:

$$x \in B \Rightarrow \mathscr{C}_C(x) =_{df} \mathscr{C}(x) \cap C, \quad \text{where} \quad \mathscr{C}(x) = \{y \in \Theta \mid y \sqsubset x\};$$

(iii) an *organism* is a cell or a multicellular biosystem which is not a proper subsystem of a biosystem:

$$x \in O =_{df} x \in C \vee x \in B \;\&\; (\mathscr{C}_C(x) \subset C \;\&\; \neg(\exists y) \quad (y \in B \,\&\, x \prec y)$$

Remark 1 The intersection of *C* and *O* is the set of unicellular organisms. *Remark 2* Useful synonyms for *C* and *O* are *cellular level* and *organismic level* respectively. *Remark 3* According to the above definition, the living part of a coral reef may be regarded as an organism. *Remark 4* A bacterial culture, though a system, is not a biosystem; in fact it is a population. *Remark 5* It has been held that organisms could be construed either as "classes of cells' or as "parts of biological species" (Hull, 1974, p. 48). Both disjuncts are false. Classes, in particular biospecies, are sets, hence concepts, whereas organisms are things and, more particularly, concrete systems. A thing can be a member (∈) of a certain set and a part (⊏) of another thing: it cannot be a part of a set and a member of a thing, and this by definition of the membership and the part-whole relations.

We can now define the concept of a biospecies. We shall construct it with the help of the notion of a natural kind (Vol. 3, Ch. 3, Sec. 3.5) as determined by a bunch of natural laws, and the concept of descent (Definition 1.17):

DEFINITION 3.3 A species is a *biospecies* iff

(i) it is a natural kind (rather than an arbitrary collection);

(ii) all of its members are organisms (present, past, or future);

(iii) it descends from some other natural kind (biotic or prebiotic).

Remark 1 This definition avoids the difficulties that beset some of the hazy notions of a biospecies encountered in the biological and biophilosophical literature. In particular we are not requiring reproductive isolation, for this is irrelevant to organisms that do not reproduce sexually, and it founders in the cases of plant and animal hybrids that fail to be sterile. *Remark 2* We do not confuse a biospecies with a biosystem, as even some eminent biologists have done. (E.g. Dobzhansky, 1970, p. 354: "A species is composed of individuals as an individual is composed of cells, or as a termite or ant colony is composed of fertile and sterile members.") Like any other species, a biospecies is a set, hence a concept. Only, it is not an arbitrary set but one defined by a definite collection of laws. And a biospecies is not an unstructured set but one partially ordered by the relation of descent. But a species is not a concrete system, because (*a*) its members do not all share the same environment, and (*b*) its past and future members are not coupled to its present members. *Remark 3* Because of clause (iii) of Definition 3.3, the organisms that may eventually be synthesized in the laboratory would belong not to biospecies but rather to artificial biospecies.

Finally let us deal with three bioentities that are neither individual organisms nor sets of such:

DEFINITION 3.4 A system is

(i) a *biopopulation* iff it is composed of individuals of the same biospecies;

(ii) a *community* or *ecosystem* iff it is composed of several interacting populations of organisms belonging to different biospecies;

(iii) a *biosphere* iff it is the largest system in which a given biosystem participates.

Remark 1 It is usual to include, in the definitions of biopopulation and ecosystem, the sharing of a territory or habitat, such as a swamp or a tree canopy. This is unnecessary in our case because we have defined those entities as concrete systems: they would not be such unless there were bonds amongst its components, and such bonds are possible only if the individuals concerned are not far apart. *Remark 2* Nor is it necessary to specify the planet in defining the general notion of a biosphere: the definition applies to any planet and it does not hold for the set of ecosystems on all possible planets because such a set is not a concrete system.

1.4. *Biolevel*

We have distinguished, more or less explicitly, six different biotic levels, namely those of cell, living component of an organism, organism, population, ecosystem, and biosphere. We may as well display them for reference purposes:

B_1 = *cell level* = the set of all cells
B_2 = *organ level* = the set of all organs
B_3 = *organismic level* = the set of all organisms
B_4 = *population level* = the set of all populations
B_5 = *ecosystem level* = the set of all ecosystems
B_6 = *biosphere level* = the set of all biospheres.

The family $\beta = \{B_1, B_2, B_3, B_4, B_5, B_6\}$ illustrates the concept of a level structure (Definition 1.8). So, the set β together with the level precedence relation deserves a name of its own:

DEFINITION 3.4 The set β of biotic levels together with the relation $<$ of level precedence, i.e. $\mathscr{B} = \langle \beta, < \rangle$, is the *biolevel structure*.

$\mathscr{B}$ has also been called the *scala naturae* and the *hierarchy* of life. These are misnomers: a ladder proper is supposed to lead somewhere, and a hierarchy proper involves a dominance or subordination relation, while $\mathscr{B}$ does not.

Now, the biotic levels we have included in β are not the only logically possible ones. In particular, one can imagine the existence of subcellular organisms; in fact it has occasionally been claimed that such biosystems exist. We shall assume that whatever is alive or composed of living beings is in β:

POSTULATE 3.3 Every biosystem and every system composed of biosystems belongs in some level of the biolevel structure $\mathscr{B} = \langle \beta, < \rangle$.

This version of the "hierarchical organization" of life is static: it talks about levels and their order but not about their origin. However, most biologists nowadays would claim that biotic levels are so many stages of an evolutionary process: that every biolevel has emerged spontaneously from the preceding (prebiotic or biotic) level. Actually we need no separate axiom to incorporate and refine this assumption, as it is a mere specification of Postulate 3.1:

COROLLARY 3.1 Every concrete system belonging to a given biolevel has self-assembled from things at the preceding level.

In turn, an immediate consequence of this corollary is that every system at a given biolevel is preceded in time by its components or precursors, Hence level precedence and temporal precedence, though not cointensive, are coextensive. The biolevel structure is no longer static: it has become part of an ontology which is not only pluralistic but also evolutionary. Biolevels are not static layers that happen to be piled atop one another. They succeed each other in time (metaphorically speaking) and they do so by virtue of a definite and pervasive mechanism, namely self-assembly. And they are not rungs in a hierarchy leading from lowly atom through middling man to the Supreme Being: levels are but stages in a natural evolutionary process that may have occurred and indeed may be occurring at various places and epochs in the history of the universe, though not twice in the same manner.

1.5. *Concluding Remarks*

We have characterized biosystems as systems composed of chemical and biochemical subsystems. Hence while some of the properties of biosystems can be traced back to their biochemical constituents, others are emergent or peculiar to the former. The most obvious property of this kind is of course that of being alive – a derivative property not a root one. Thus the chloroplasts and genes of a plant cell are essential components of the latter but are not alive. Nor are biopopulations and communities alive. Thus a forest teeming with plants, fungi, animals, and bacteria is not alive.

It follows that the class of biosystems is not included in that of biochemical systems, and that of biopopulations is not included in that of biosystems. What we do assert instead is that, just as biochemical systems compose biosystems, so the latter compose populations. Therefore we reject ontological reductionism, according to which biosystems are just a kind (subset) of biochemical systems, and biopopulations in turn a kind (subset) of biosystems. We assert instead that the components of members of the biopopulational level are members of the biosystem level, which are in turn composed of members of the biochemical level. This emergentist thesis is compatible with the program of explaining the higher in terms of the lower or, more precisely, the system in terms of its components (and the interactions among them). We shall come back to these matters in Sec. 4. (See also Bunge, 1977f.)

2. BIOFUNCTION

2.1 *Health and Death*

Systems, in particular organisms, can cope with their environment with varying degrees of success: recall from Definition 1.14 that the selection pressure exerted by the environment on a population of systems of some kind is a number lying between 0 (total success) and 1 (utter failure). But that concept of degree of adaptation was collective, nonspecific, and phenomenological: it does not carry over to an individual biosystem and it is not physiological. We need a separate concept of degree of adaptation of a given biosystem, not necessarily an organism. Here is one:

DEFINITION 3.5 Let *b* be a biosystem in an environment *e*. Then *b* is *healthy or normal in e* iff *b*, when in *e*, possesses all of the properties (can discharge all of the functions) listed in Postulate 3.1.

Remark 1 This is a physiological concept of health or normality, not a statistical one. It is possible for an entire population of healthy organisms to be wiped out by an environmental catastrophe, such as a severe drought. And it is also possible for most of the individuals of a biopopulation to be sick – a case of statistical normality and physiological abnormality. *Remark 2* Sickness is sometimes regarded as a form of adaptation. This is so in the case of infectious diseases, when the organism synthesizes antibodies that "fight" the invaders. But it is not so in other cases: there is nothing adaptive about arthritis, the obstruction of the bile canal, an infarct, stroke, or stress. Quite the contrary, these are glaring cases of failure to adapt. *Remark 3* Our definition is not limited to whole multicellular organisms: it may apply to cells or organs of a multicellular organism. Nevertheless in such cases it is preferable to restrict oneself to the specific functions discharged by such subsystems. More on this in Sec. 2.2.

The concept of health elucidated by the previous definition is qualitative. It is desirable to have also a quantitative concept of (degree of) health (or sickness) as well as of total health (or health in all respects). One obvious candidate is this: The degree of sickness of a biosystem in a given environment, in a given respect, at a given time, is its relative imbalance (or deviation from the physiological norm) in that respect at that time. Assuming optimistically that such normal values can always be found, we propose

DEFINITION 3.6 Let $F_i\colon B \times E \times T \to \mathbb{R}$ be the ith component of the state function of biosystems of kind B in environments of type E, and $\bar{F}_i$ the corresponding (physiological) normal value of F_i. Further, let $w = \{w_i \in [0,1] \mid 1 \leq i \leq N\}$ be a set of positive reals that add up to unity, and such that w_i measures the weight or relative importance (for the whole biosystem) of the property represented by the function F_i. (Cf. Vol. 3, ch. 2, Sec. 4.2, Definition 2.15 of property weight.) Then

(i) the *degree of sickness* of the biosystem $b \in B$ in the environment $e \in E$, in the ith respect and at time $t \in T$, is

$$s_i(b, e, t) = \left| F_i(b, e, t) - \bar{F}_i \right| / \left| F_i(b, e, t) + \bar{F}_i \right|;$$

(ii) the *degree of health* of the biosystem b in the environment e, in the ith respect and at time t, is the complement of $s_i(b, e, t)$ to unity, i.e.

$$h_i(b, e, t) = 1 - s_i(b, e, t);$$

(iii) the *total degree of sickness* and the *total degree of health* of organism b in e at t are

$$S(b, e, t) = \sum_{i=1}^{N} w_i s_i(b, e, t) \quad \text{and} \quad H(b, e, t) = 1 - S(b, e, t)$$

respectively.

The values of s_i and h_i are real numbers in the unit interval. And each is the same whether $F_i(t)$ equals $n\bar{F}_i$ or $(1/n)\bar{F}_i$, with n an arbitrary integer.

The conceptual interest of the above formula resides in its making sense only within a theoretical model of biosystems of the species of interest. Its methodological interest lies in its reminding us that scientific medicine is just a chapter of biology (including psychology in the case of man).

Finally we come to

DEFINITION 3.7 A thing is *dead* iff, having been a biosystem, it has ceased to perform all of the functions listed in Postulate 3.1.

Remark 1 We could not define death as maximal degree of sickness, or as minimal degree of health, because the concepts of sickness and health refer to living things (Definition 3.6). *Remark 2* Surely not all of the vital functions stop at the same time: death is a process rather than a point event. However, we could not define dying as the gradual cessation of biofunctions, because recovery is not unusual, whereas dying is irreversible. *Remark 3* Because all biosystems emerge from biochemical systems or even from whole cells rather than from scratch (i.e. from physical entities), the process of dying is not the inverse of the birth process. See Figure 3.3 *Remark 4* Life and death are not entities but states of, or processes in, biosystems. Death is the process of breakdown of a biosystem into an aggregate of chemicals. It starts when the biochemical reactions that maintain a steady state – namely the metabolic processes – come to a halt. In particular, no new enzymes necessary for the synthesis of biomolecules are produced and, in general, breakdown processes start to prevail over buildup processes. *Remark 5* That health and sickness, life and death are not entities but states of entities, is obvious from a systems theoretic viewpoint but not from alternative points of view. Indeed, sickness and death have been treated as entities, not only by primitive men but also by some medical and philosophical schools. Having reified and even personified death, it was possible to regard life either as a fight against Death or as the transit towards it. The anxieties elicited by such primitive views (contained in contemporary existentialism) are allayed by the naturalistic doctrine proposed by Epicurus, according to which dying is a process of dismantling of an organism.

2.2. *Function and Value*

Every cell, no matter how simple or primitive it may look at first sight, is composed of a number of biochemical systems of enormous complexity

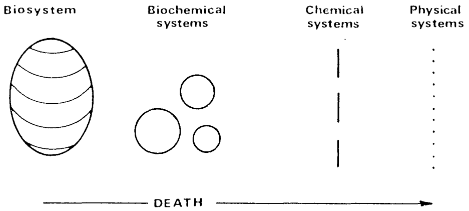

Fig. 3.3. The successive collapses of the state space of a dying biosystem: a gradual loss of properties and of systemicity.

which are linked to one another, and succeed one another, in various ways. If eucaryotic (nucleated), a cell consists of a nucleus and a cytoplasm. The former is composed of DNA and RNA threads, and the latter of subsystems such as ribosomes, mitochondria, chloroplasts (in plants), and cilia – none of which are alive.

Each of the nonliving subsystems of a cell performs certain activities, usually called 'functions', such as storing energy, synthesizing proteins, breaking down excess biomolecules, detecting imbalances, or transmitting signals. Such subsystems of the cell are therefore called 'functional units'. In multicellular organisms (metazoans) this division of labor often carries over to entire cells or even cell groups such as tissues and organs. In either case each subsystem of a biosystem, whether or not the former is alive, discharges certain functions, i.e. does certain things, that are peculiar to it, and others which are done also by subsystems of other kinds. For example, neurons not only generate and transmit signals but also synthesize ATP, nucleic acids, and proteins,

We elucidate these notions by means of the following definition, which employs the notion of a process elucidated in Ch. 1, Sec. 1.7:

DEFINITION 3.8 Let b be an organism, and $a \prec b$ a subsystem of b, of kind $[a]$. Further, call $\pi(a)$ the totality of processes or activities involving a during a certain period. Then

(i) any subset of $\pi(a)$ that includes any of the processes listed in Postulate 3.1 is a *biological function*;

(ii) the *specific biological functions* of a are those performed by a and its likes but not by any other subsystems of b. I.e.

$$\pi_s(a) = \pi(a) - \bigcup_{x \prec b} \pi(x), \quad \text{with} \quad a \neq x \prec b \ \& \ x \notin [a].$$

The biological functions of a subsystem of an organism are valuable or disvaluable to the organism as a whole. For example, the specific functions of the liver are to synthesize certain substances (e.g. albumin and cholesterol) and to store others (e.g. glycogen and iron). No mammal can live without a liver: the latter's value to the organism is maximal, though of course not greater than the values of the heart and the brain. On the other hand a mammal can live without a gall bladder although this organ markets (stores, concentrates, and delivers) the bile produced by the liver, and the bile is useful for digesting fats and other substances. That is, the value of the gall bladder, though positive, is far smaller than that of the liver. Finally, some subsystems of an organism perform disvaluable biological functions: think of tumors.

The above suggests the following measure of the biological value of a subsystem a of an organims b in an environment e: The value of a to b in e equals the degree of health of b in e when equipped with a, minus the degree of health of b in e when deprived of a. More precisely, with the help of Definition 3.6 we lay down

DEFINITION 3.9 Let $H_A\colon B \times E \times T \to \mathbb{R}$ be the health function for organisms of kind B, in environments of type E, when subsystems of kind A are acting in the B's (i.e. when $a \prec b$ and $\pi_s(a) \neq \varnothing$ for $a \in A$ and $b \in B$). Similarly, call $H_{\bar{A}}\colon B \times E \times T \to \mathbb{R}$ the corresponding health function when the A's are not acting in the B's (i.e $\neg(a \prec b)$ or $\pi_s(a) = \varnothing$). Then the *value of A for B in E* is the function

$V\colon A \times B \times E \times T \to \mathbb{R}$ such that, for any $a \in A$, $b \in B$, $e \in E$ and $t \in T$,

$$V(a, b, e, t) = H_A(b, e, t) - H_{\bar{A}}(b, e, t),$$

which is the *value of subsystem a for organism b in environment e at time t.*

Since health ranges between 0 and 1, biological values are comprised between -1 and 1. In particular

a is *maximally valuable* to b in e at t iff $H_A(b, e, t) = 1$ and $H_{\bar{A}}(b, e, t) = 0$;
a is *worthless* to b in e at t iff $H_A(b, e, t) = H_{\bar{A}}(b, e, t)$;
a is *maximally disvaluable* to b in e at t iff $H_A(b, e, t) = 0$ and $H_{\bar{A}}(b, e, t) = 1$.

Thus in humans the heart is maximally valuable, the normal appendix worthless, and a malignant tumor maximally disvaluable. And the values of other systems, such as the reproductive system, the thymus gland and the tonsils, vary with age.

The preceding definition allows one to elucidate another concept, this time of particular interest to surgeons and bioengineers:

DEFINITION 3.10 Two subsystems a and a' of a given biosystem b are *functionally equivalent* iff

(i) a and a' perform the same specific functions, i.e. $\pi_s(a) = \pi_s(a')$, and

(ii) a and a' have the same value during the time interval of interest, i.e. $V(a, b, e, t) = V(a', b, e, t')$ for t and t' in the given interval.

Remark 1 Some biofunctions, such as metabolism and cell division, are common to all organisms. Others are species-specific. For example photosynthesis is peculiar to plants, and the synthesis of enzymes that occurs in the digestion of meat is peculiar to carnivores. The grouping of organisms by biofunction clusters provides just as natural and fundamental a classification as evolutionary taxonomy; only, it is out of fashion. *Remark 2* The more numerous the functions an organism can perform, the better equipped it is to cope with environmental challenges. Multicellular organism that are highly differentiated will therefore be selected by rich and changing environments. Also, because they have spare cells, metazoans are covered against the accidental loss of some cells, so they have better chances of survival than organisms without such spares. (Recall the discussion of reliability in Ch. 1, Sec. 4.1.) These two factors help explain the prosperity of metazoans on our planet. In short, the terrestrial environment has been fit for complex and versatile organisms endowed with a high degree of redundancy. *Remark 3* Alternative definitions of biological value are of course thinkable. One alternative worth looking into is to equate biovalue with efficiency. Another is teleological: Valuable to an organism (or a species) X is whatever contributes to X's attaining its goals. We cannot adopt this alternative because we are not assigning goal-seeking activities to all organisms. Goals will be introduced in the next chapter, with reference to organism endowed with complex nervous systems. *Remark 4* As evolution proceeds, the value of some subsystems increases (preadaptation) and that of others decreases, sometimes to the point of vanishing altogether. In the latter case the subsystem may disappear (as in the loss of the ability to synthesize certain vitamins), or it may be kept functionless for hundreds of thousands of years. Thus it is possible, nay quite likely, that man has a number of fossil (functionless) proteins, genes, entire cells, and even cellular systems – i.e. subsystems that have long ceased to serve any biofunction. But this is very hard to prove. *Remark 5* It is just as likely that certain hereditary pathological conditions were valuable in the past or may yet become valuable. This is the case with sickle-hemoglobin, which is associated with resistance to malaria. Likewise certain congenital malformations, such as flat feet and poor sight, have spared the lives of many men in modern wars. (War selects the unfit.)

2.3. *Biocontrol*

All systems are under environmental control. And biochemical systems are also under internal – in particular enzymatic – control. (Recall Definition 2.17.) Biosystems are then controlled by their environment (in particular by the availability of precursors of biomolecules) and by their biochemical subsystems. In particular, enzymes and nucleic acids exert internal controls. Besides, multicellular organisms have additional control systems, such as the control of growth and size by specific hormones. In short, all organisms are subject to dual controls: internal and environmental, or self and external.

Naturally, the self-control of a biofunction is called *biocontrol.* Most biocontrols are of the feedback type. (See Appendix A, Sec. 1.3.) In such cases, if the output of a subsystem falls below (above) a certain normal value, the control system increases (decreases) the input in such a way that the imbalance is gradually redressed. (The normal output level is sometimes misleadingly called the set of *goal states* or *Sollwerte.* But there is no evidence of goal directed behavior except for certain features of the behavior of animals equipped with an advanced brain: see Ch. 4.)

When all the controls of an organism work properly, the organism attains or maintains a steady state or *homeostasis*: it stays in or near such a state regardless of external perturbations, provided these are bounded. However, homeostasis is usually a global result of frantic molecular and activity. Moreover there are a number of nonhomeostatic states in the life history of every organism, namely all those leading to and from homeostasis – such as the processes of birth and death, of sickness (or injury) and recovery from it. In these cases one speaks of *homeorhesis.*

Biocontrol starts at the molecular level. Thus DNA controls the synthesis of RNA, which in turn controls protein synthesis. (See Ch. 2, Sec. 2.1.) But DNA itself, far from being an unmoved prime mover, is under severe control. In fact, according to the Jacob-Monod hypothesis, genes are turned on or expressed only when such control is lifted. (It is likely that, at least in multicellular organisms, many genes are repressed or inactive most of the time and, like firemen, become activated only during emergencies.) In other words, only when the control is off the gene is free to participate in the synthesis of whatever protein(s) it may. And this is not the whole story: some enzymatic proteins in turn control RNA synthesis. (Furthermore, catalytic cycles formed by RNA molecules and enzymes may well exist: see Eigen (1971).) In short, genetic control is not ultimate and hierarchical. This is a point of philosophical interest in view of the fashionable claim that life is at the mercy of a bunch of selfish and smart genes.

In addition to the enzymatic and genetic controls, which regulate directly the thousands of biochemical reactions going on in the organism, there are highly specialized biocontrol systems, such as those that control acidity, temperature, growth, and motion. These are unicellular or multicellular systems, every one of which can be analyzed into a *sensor* and an *effector* (or *corrector*). The sensor evaluates both the input and the output, and "informs" the effector whether they are adequate. (Actually there is no need for the information concept at this level: all the sensor does is to trigger the effector as soon as it detects an imbalance.)

In a sense every concrete thing can "sense" or detect some other things. Thus an atom can detect light (i.e. react to it) as well as the proximity of other atoms. However, biocontrols are *specific*: some detect gravity (or rather deviations from the vertical); others light intensity; still others light frequency, or acidity differences, or temperature differences, and so on. Furtermore, whereas physical and chemical detectors usually detect absolute values or intensities, all biosensors detect *imbalances*, i.e. differences between actual and normal ("goal") values. This they achieve by being components of negative feedback loops. In short, biocontrols are specific and they correct imbalances.

Furthermore, unlike a bunch of physical detectors, the biocontrols in an organism constitute a network: they interact and, in the healthy organism, they do so synergically, i.e. harmoniously rather than independently from one another. (Such interaction may involve so little energy, and yet may have such important effects, that it is usually called 'informational'. See Appendix A, Sec. 1.4.) For example, the various internal secretion glands in a vertebrate are interconnected by hormones carried by the bloodstream, and the various parts of the nervous system keep in touch ("talk to each other") by synaptic contacts as well as by hormonal "messengers". In short, the control systems in an organism constitute signal (or informational) networks. Actually every organism, however primitive, is equipped with two interconnected signal networks: an internal network constituted by its internal biocontrols, and an interfacial network constituted by biocontrols that sense environmental changes. These two networks are coupled and between them they control all the functions of the organism.

This, then, is one of the peculiarities of organisms: namely that they have multiple control systems grouped into tightly integrated *signal networks*. Another peculiarity is that such networks function well – amazingly well in most cases. 'Well' does not mean either at full blast or else with maximal economy, but instead in whatever manner is most valuable to the organism as a whole. (Recall Definition 3.9 of biovalue.) For example, the rate at which any given protein is synthesized is neither minimal (maximal economy of resources) nor maximal (waste) but somewhere in between – above equilibrium and short of waste. This near optimality is peculiar to biosystems.

Unlike biology, physics and chemistry are dominated by extremal principles such as Hamilton's, i.e. basic law statements according to which, of all the conceivable processes of a given kind, only those are actualized that either minimize or maximize a certain magnitude, e.g. the action. (Cf. Appendix B, Sec. 1.4.) These principles "operate" of course for the physical components of a biosystem, but these components intertwine in such a manner that certain properties of value to the organism as a whole are near-optimized rather than either minimized or maximized. I.e. such near optima are not determined locally by each separate system but result from the interaction among the various subsystems of the organism. In fact since the various components of the control network of the whole organism are interdependent, the near optimization of certain local variables will hamper that of others. So, what would be best for each subsystem is unattainable. But the next best is attainable, and this is a compromise among a number of optima. This compromise may be called *overall* (or organismic) *near optimality* – not full optimality because no organism is perfect. (A perfect biospecies would not be subject to evolution.) Only the biological organization of *successful* species *tends* to optimality.

An organism may be said to possess an efficient biocontrol network if it is capable of redressing whatever imbalances may occur – i.e. if it can detect and correct them. If not, the organism becomes sick and may die. More precisely, every malfunction of a specific biocontrol system is a specific sickness. (The converse is false. For example infectious diseases, if overcome, are so by the proper functioning of the immune response system.) And if several biocontrol systems malfunction, or do not function synergically, a nonspecific (generic) sickness supervenes. Natural death is probably the final state in a process of generic (nonspecific) sickness.

Biocontrol has given rise to the belief that organisms are goal-seeking: that they act in everything so as to ensure their own preservation or at least that of their species. First the theory of evolution through natural selection, and in recent times the theory of control, should have corrected that illusion. In the first place self-control is a property of all biochemical systems – by virtue of their enzymatic activity – whether or not they are alive. And if system integrity were defined as equilibrium (steady state), then every biochemical system would be seen to behave *as if* it reached for its own preservation. Secondly, biocontrol is not always efficient: it falls short of optimality when the organism becomes sick and it fails utterly at death. Thirdly, biocontrol can fail, even in healthy organisms, when certain imbalances grow beyond bounds during catastrophes such as floods and droughts. (After all, the great majority of terrestrial biospecies have become extinct.) Fourthly, biocontrol is occasionally defective. For example, only a small part of the RNA synthesized in the cell nucleus migrates to the surrounding cytoplasm to control protein synthesis: most of it is broken down into nucleotides without ever being "used". Another example: many genes are never "expressed" or activated. Fifthly, genetic control is not so strict as to prevent mutations, most of which are deleterious. In any case, we need not invoke goal-directedness to explain why biocontrol is normally beneficial for the organism as a whole: the organisms not endowed with efficient control networks succumb before reproducing, and that's all.

2.4. *Development*

The history of any system can be represented as the trajectory of its representative point in a suitable state space for the system. (Cf. Ch. 1, Sec. 2.2.) In particular, the *life history* of an organism can be represented as a line in its state space. The part of the life history comprised between the beginning (birth) and the attainment of the adult state of the organism is called its *development*. (See Bonner (1974).) The development process of an organism has three main strands, each of which is taken care of by a bunch of components of the state function representing its possible states. These strands or aspects of development are:

(i) *growth*, or multiplication of cells of certain kinds (at uneven rates for different subsystems of the organism);

(ii) *morphogenesis*, or formation of new subsystems;

(iii) *differentiation*, or specialization of cells.

All three aspects of development proceed under a triple control: enzymatic, genetic, and environmental. The environment supplies or withholds the wherewithall, the enzymes make the transformation of environmental precursors possible, and the genes guide the entire process – provided their controls permit them to do so, as we saw in the previous subsection. (Some molecular biologists tend to play down the control effected by the environment. However, the latter can be dramatic, as illustrated by the sporulation of moulds that occurs in a poor environment.) One way of characterizing the salient features of the development process is by means of

DEFINITION 3.11 If *b* is a biosystem, then

(i) *b grows* iff (*a*) some DNA molecules in *b* replicate, and (*b*) the rates of RNA and protein syntheses in *b* are greater than the corresponding breakdown rates;

(ii) *b* is involved in *morphogenesis* iff some processes in *b* consist in the formation of new subcellular systems (*intracellular morphogenesis*), or new cells (*cellular morphogenesis*), or new organs (*organogenesis*);

(iii) *b differentiates* iff *b* is a multicellular organism such that (*a*) the number of specific functions of *b* increases as the number of cells increases, and (*b*) different specific functions are performed by different cells or multicellular systems.

Of these three aspects of development, morphogenesis has always seemed the most mysterious and the one most clearly indicative of design and purpose. To begin with, the very word 'morphogenesis' suggests a process whereby the formless (e.g. an egg) acquires a definite form (shape or spatial pattern). While this is so at the physical and chemical levels, as in the cases of the generation of waves in a homogeneous fluid, or the growth of crystals in solutions, it is not so at the biolevel: here morphogenetic processes are those where new forms emerge out of old. (For examples and models of self-organization processes at various levels, see Glansdorff and Prigogine (1971), Gierer and Meinhardt (1972), Glass (1973), Tyson (1976), and Nicolis and Prigogine (1977).) Particularly in embryology every developmental phase is structured rather than amorphous. Moreover, shape change is not the primary or driving feature of development but an outcome of a profound process such as the diffusion of the products of an enzymatic reaction, or the multiplication of cells under the control of morphogens – enzymes, hormones, and genes. (Classical morphology was restricted to describing the net outcome of such processes: it neither attempted nor could explain them by hypothesizing biochemical and cellular mechanisms. Likewise the pretentious work of

Thom (1972), with its total disregard for morphogens, physical constraints, natural selection, chance, and history, does not go beyond classical morphology except for the addition of a mathematics of dubious utility.)

Morphogenesis may be regarded as a particular case of self-assembly of molecules, organelles, or cells, as the case may be. Like other self-assembly processes, the morphogenetic ones are guided by both internal forces and environmental resources and circumstances. The formation of an organelle, a cell, or an organ is controlled by genes and other morphogens in conjunction with the *milieu intérieur* and the environment. The DNA and RNA molecules, the hormones and other morphogens control the chemical reactions and the diffusion proceses, as well as the assembly and dismantling of the various units, but nothing gets done unless the environment supplies the materials and the energy.

A self-organization process can start spontaneously in an initially homogeneous system of reactants and morphogens. Thus a local chance fluctuation in their relative concentration can diffuse throughout the medium, ending up in a differentiated system (Turing, 1952). However, reaction-diffusion processes are not the only morphogenetic mechanisms, nor are they typically biological. Alternative mechanisms are: (*a*) sorting processes (grouping of functionally similar units, as in the case of polyribosomes), (*b*) cooperative interactions among molecules or cells of different kinds, (*c*) packing, folding, and other mechanical effects of accretion and external pressure; (*d*) enzymatic syntheses of morphogens proceeding until a new entity is formed – and inhibited thereafter.

Let us take a quick look at processes of the first kind, i.e. sorting processes (Steinberg, 1963; Mostow (Ed.), 1975). Let C be a set of cells of two kinds, A and B. Assume that all these cells are motile and that like cells adhere to one another more strongly than do unlike cells. Moreover, suppose that the cells of type B adhere to one another less strongly than those of type A. In sum, assume that the adhesion works (or energies) compare like this:

$$W_{\mathrm{A}} > W_{\mathrm{B}} \geq W_{\mathrm{AB}},$$

where W_{A} measures the adhesion of cells of kind A, W_{B} that of cells B, and W_{AB} that of unlike cells. One can imagine, and indeed prove rigorously, that the cells clump together and sort out all by themselves. In particular, if $W_{\mathrm{AB}} = 0$, the sorting will be complete: two separate tissues will ensue. See Figure 3.4.

Although the details of such self-assembly processes are far from being

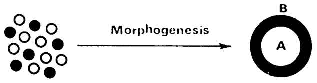

Fig. 3.4. The formation of an onion-shaped organ constituted by two concentric spheres composed of cells of different kinds, A and B, according to Steinberg (1963).

known, there is no excuse for regarding them as unknowable. Morphogenetic processes look mysterious only if one adopts either a vitalistic view or a primitive version of mechanism – one according to which matter is a mere aggregate of inert particles. But biology has outgrown both extremes: it has no use for supramaterial entities or forces, and it has learned that molecules, particularly carbon compounds, can stick together in numerous ways, forming systems of great complexity and often also of great beauty.

One outcome of morphogenesis in multicellular organisms is differentiation. The degree of differentiation of a system may be taken to equal the total number of specific functions performed by its various subystems. Now, for a complex system to keep together, its various subsystems must be well coordinated. In other words, while systemicity in general requires the existence of bonds among the system components, *organic systemicity* requires that these bonds be well coordinated, so that nearly every system component be valuable to the system as a whole. In particular, not only the right reactants must be present under favorable circumstances to their reactions, but the latter must proceed at the proper pace and in the proper sequence; and no component must block the operation of the other components – unless such blocking be of value to the organism as a whole. All this is compressed into the well worn platitude that "The greater the differentiation of an organism, the greater its coordination and integration". (Needless to say, it is not the case that coordination is a goal of development, but rather that the organisms that fail to achieve efficient coordination perish.)

2.5. *Reproduction and Heredity*

One of the properties of organisms is that they are capable of reproducing. (Sexually reproducing organisms do not reproduce unless they mate, but most of their cells divide. And neurons do not normally divide but other cells, linked to them, do.) Moreover organisms reproduce "true to type" i.e. their offspring belong to the same species. (Speciation takes many generations because it is a result of cumulative mutations and successive selections.)

The root of reproduction is the chemical process of DNA replication. (See Ch. 2, Sec. 2.1.) This explains the invariant aspect of heredity, particularly in asexually reproducing organisms. Sexually reproducing organisms are far more variable because of the recombination (nearly random shuffling) of parental genes. In either case the genetic system, or genome – which is composed of DNA molecules – is "in charge" of heredity. Organisms are not pulled by goals but pushed by the genetic memory of the past – pardon the metaphor.
